INTRODUCTION TO PLANTING

Garden Planning

Jeff Cox

The best and most satisfying gardens are the result of careful planning and sound design. Whether you want to design a flower garden, plant a shrub border to screen an outdoor patio, or add plantings of vegetables, fruits, and herbs to your yard, there are some basic principles that will help you make decisions as you plan.

You don't have to be an artist to create an attractive and useful environment around your home. Landscaping is a form of personal expression, an extension of the care you put into arranging the inside of your house. There is no "right" landscape; what works for your neighbor may not suit your needs or look good on your site.

Having a beautiful and unique property depends on five basic steps: gathering ideas, creating a design, taking a close look at your site, installing plants and structures, and maintaining the landscape. Attractive landscaping will help you enjoy your home and increase its value as well.

Gathering Ideas

Start the design process by looking around for ideas. Great landscaping ideas are all around you. Look at homes in your community and take note of landscapes that catch your eye. See whether a garden club in your area sponsors tours of local gardens; these "open gardens" are a great way to get a close view of plants and design ideas that are appropriate for your area. Public parks and botanical gardens can also give you planting ideas. Check out the wide variety of gardening books available; they're packed with photographs and tips about other people's success stories.

When you look at a landscape, try to visualize it as a series of garden "rooms." Like a room in a house, each part of the landscape has walls, a floor, and a ceiling. The walls could be

Continued →

a hedge, a row of trees, a fence, or a trellis. The floor might be turf, mulch, groundcover, crushed stone, or wooden decking. The sky or an arbor may serve as the ceiling.

Breaking a landscape down into rooms makes it easier to identify the elements you need to add or change. For example, if you want to separate the vegetable garden from the rest of your yard, you need some sort of wall. If you don't want to see the garden, you could plant a hedge or install a solid wood fence. If you are enclosing the garden to protect it from animals, you might try a woven wire fence planted with attractive vines. These rooms need doorways, too—don't forget to think about gates or openings in the walls.

When you view a landscape as a combination of these solid elements, the whole process of planning a design is much more manageable. If you see a landscape that you particularly like, try to figure out what makes it special. Is there an attractive fence that makes a nice backdrop for the plants? Is there a beautiful tree or shrub you would just love to have for your own property? Has your neighbor come up with a clever way to screen the front yard from the street? You may not want to copy any of these ideas exactly, but they will give you some idea of what is possible for your own home. The unlimited combinations of these elements make it easy to create a landscape that is unique to your property. And that's what landscaping is all about: making the best of your site.

CREATING A DESIGN

Creating a design starts with a wish list, based on the ideas you've gathered from books and neighboring properties. This list should include design ideas, garden structures, and specific plants. This isn't the time to be realistic—go ahead and put down anything that you'd like to see in your yard.

The next step is figuring out what you really need in the landscape. If you have children, a play area may be the most important use of the yard. If you do a lot of entertaining, a shady arbor might be just the place for parties. For a large family, parking may be a major consideration. Besides play areas, entertaining, and parking, think about privacy, security, noise reduction, pets, flowers, and food production.

LIST YOUR LANDSCAPE NEEDS

Once you've started thinking about your yard and what you want it to do, it's time to start a garden notebook. You'll find that keeping all your records in one place is invaluable as you make plans and review the progress of your garden. A good garden notebook doesn't need to be anything fancy—a loose-leaf notebook with a pocket or two to hold pencils and notes will do fine. Don't worry if it gets cluttered and messy as time goes on; you can still get what you need from it as long as you can read it and find things.

Inventory Your Site

You may think you know everything about your yard, but once you start really looking at it, you may be surprised at how many details you've forgotten. Here's a list of important facts and features you'll want to keep in mind as you make your design. As you read about them, use a page in your garden notebook to make notes about them. When you're finished, you'll have a much clearer idea of where you could put a garden or gardens in your yard.

The Vital Statistics

Before you draw up your garden plan and goals, collect some facts about your property. Doing this will help you organize your priorities and make realistic plans. You'll need to know about:

- Hardiness zone and local weather conditions
- Soil condition
- Drainage, including both wet and dry sites around your yard
- Exposure, such as areas with full sun, partial shade, or full shade
- Property dimensions, including a breakdown of the space available for gardens, recreation areas, pet runs, and other areas
- Existing insect and disease problems
- Areas to avoid, such as septic tank fields and underground utility cables or waterlines
- Locations of essential features, such as a water source, tool shed, or compost pile
- Established plants and their condition, as well as possible effects on new plants, such as shade or competition for nutrients
- How much time you have to spend on your yard and garden .

Know Your Microclimates

Knowing about the microclimates on your property—places that are warmer or cooler than the rest—can be valuable when it comes to siting all your plantings. Planting a vegetable garden in a frost pocket, where frost settles late in spring and early in fall, can shorten your harvest season tremendously, for example. A sheltered, south-facing site, on the other hand, can be quite a pleasant place to sit on a cool winter day. Such sites will also encourage spring flowers to bloom earlier than in cooler parts of your yard. To verify your hunches about warmer or cooler pockets that would affect your plans, take temperature readings at different times of day throughout the year in various locations in the garden.

Use the "Landscape-Needs Checklist"to help you start thinking about what features you'd like to have in your yard. As you review the list, make sure you look at your yard from every perspective: Look out at the yard from inside the house, including the upstairs windows; look at it from the street, from down the street, from the front door, from the sides, from the back door, from the back boundary line; look back at the house from the yard. Taking a fresh look at your yard will help you identify features you'd like to hide or views you'd like to improve—such as the view out your kitchen window, for example. Date your list; you might want to add or change things later.

Then compare your wish list and landscape-needs list. Some things will probably appear on both lists. The rose hedge on your wish list, for example, may match your need to keep romping pets out of the vegetable garden. Other wants and needs may be totally incompatible. If your yard is a popular place for neighborhood football or volleyball games, a delicate rock garden might be out of the question. Discuss the lists with your family, and decide which elements are acceptable to everyone. Also, don't forget to consider maintenance needs. A lovely perennial border can quickly deteriorate into a tangled mess if you don't have time to take care of it.

Sizing Up Your Site

Now that you've looked at what features and plantings you'd like to have on your property, it's time to take stock of what conditions you have to work with. Taking a careful look at your site—its soil, climate, and exposure—will make it easier to decide where to locate your vegetable garden, plantings of flowers or fruit, trees, hedges, or other plantings you'd like to add.

See "Inventory Your Site" to help you get a better idea of what you have to work with. Take note of wet, shady, and rocky spots, and try to take advantage of them. A wet spot may not be desirable in a play area, but it could be a good place for a group of moisture-loving plants. Also, think of the landscape as it changes through the seasons. Evergreens and berried shrubs, along with a bench in a sunny spot, can make your yard a pleasant winter retreat. A little careful planning can give the landscape four-season appeal. Don't forget details like specimen plants, interesting rocks, or sculpture to give the garden character.

HOW TO MAKE A GARDEN MAP

You don't need professional skills to draw a map of your garden. Using lined graph paper, any gardener can make a usable garden map.

Your first step should be to measure the boundary lines of your property, using a flexible measuring tape that's 25 feet or longer. It's easiest to do this with a helper to hold one end of the tape. If you work alone, stick a pencil through the loop at the end of the tape and push it into the ground to secure it. If you have a survey of your property, you can skip this step. Just use the dimensions on your survey or make a photocopy of the survey to use as a base map.

You'll also want to take measurements of the size of your house and note its location with regard to boundary lines. Make sure to note the size and location of existing garden beds and plantings as well.

Next, sit down with your list of measurements and your graph paper. Choose a scale, such as one square on paper equals 1 foot of actual space. If you have a large property, you may need to tape a few sheets of paper together to work on that scale. Or you can choose a different scale, such as 1 inch on paper equals 5 feet of actual space.

Draw your boundaries, and then fill in the location of existing buildings and plantings. Make as accurate a plan as possible, and include all your garden's features—paths, trees, buildings, fences, and walkways. Double-check your counting to be sure you've drawn things accurately. With this base map, you'll have a template to use when sketching in your plans and dreams for the ideal yard and garden.

Rather than drawing your plans directly on your base map, however, it's best to draw on overlays. Use sheets of thin tracing paper as overlays to sketch in ideas and see how they fit while you work on the design. That way, you can use your master plan again and again until you decide on the best arrangement of pathways, flower beds, and other features. Then transfer the final design to your master plan.

Plan for Practicality

Whether you design your home landscape yourself or leave it to a professional, make sure that the finished plan fits your needs. Don't add a deck just because all your neighbors have them in their backyards if what you really want is a dooryard herb garden. And while you don't want to copy your neighbors exactly, try to keep the general theme of the area in your design. A woodland garden in the Southwest would look as out of place as a cactus garden in New England. By using plants that are best adapted to your area, your landscape will have the appropriate regional look, and your plants will be healthier, too.

There are some basic practical considerations to keep in mind while you're designing your garden. A variety of people need to have access to your property. Oil or gas delivery people need to get to the tank or inlet. Meter readers need to get to the meters. Be sure to accommodate their needs when you plan. An element as simple as a short stepping-stone path through a flower bed to a meter enables the reader to get in and out without damaging your plantings.

Electric, telephone, and cable television service people may trim trees that grow near their lines. It pays to design plantings that they will be able to work around.

Don't forget to consider your own everyday needs, either. Have you planned your paths so you will be able to get your

Continued ➔

Landscape-Needs Checklist

Here's a list of ways you can use plants and gardens to enhance your landscape, along with features you might want to add to your yard. In your garden notebook, jot down all that apply in your situation, but use this list only as a starting point. To unlock all the potential your yard has to offer, try to think about what activities you would like to have space for and what you would like it to do for you.

- Screen a patio or deck from the neighbors.
- Hide a bare foundation, or transform a dull or ugly foundation planting.
- Add a vegetable garden.
- Add interest along the front of the yard.
- Create a welcoming entrance to the house.
- Create a sitting area under shade trees.
- Add a colorful planting along the driveway,
- Make the front entrance to the house more appealing.
- Create a quiet sitting area outdoors.
- Make an area for composting or tool storage.
- Beautify a lamppost or mailbox.
- Create a boundary around the property.
- Hide an unattractive view or element (like a utility pole, laundry line, or chain-link fence).
- Make an attractive view into the yard from a prominent window indoors.
- Fill a bare spot.
- Create a place to walk to in the yard.
- Beautify a garage or outbuilding.
- Surround a bench, trellis, or arbor.
- Give a new home a more finished look.

Plan before you plant. One way to reduce maintenance in the long run is to make a plan before you buy foundation plants and then choose among the many low-growing and dwarf cultivars of trees and shrubs that mature at the size you would like. Providing plants with the room they need to develop properly allows them to display their natural beauty, and you won't need to shear them into cubes or cones in an attempt to keep them in bounds. If the planting looks too sparse at first, fill in spaces with annuals, perennials, or bulbs until the shrubs develop.

INFORMAL DESIGN. *Even a rectangular lot can have an informal design. Parts of the garden—terraces, lawn areas, groundcover beds, flower gardens, or plantings of shrubs and trees—all have free-form shapes that flow together in a unified, informal design.*

FORMAL DESIGN. *Because they can be unfussy and simple, formal designs are often very effective on a small lot. Rectangular beds filled with herbs and edged with dwarf shrubs, straight walks, and symmetrical design are all characteristic of a formal garden.*

mower and garden cart where you need to go? Is it easy to take out the garbage? What about someone delivering bulk garden supplies like mulch—is there a place for that?

And of course, don't plan, and certainly don't dig, before finding out where underground utilities run. Not only do you want to avoid injuring them or yourself, but you may not even be allowed to build or plant permanent features over them.

Understanding Design

Your site will determine some of your design choices. For example, the style of your home may influence the feel of the design you'd like to have. If you have a brick house, the landscape might include brick paths and clipped evergreen hedges. A house with natural wood siding lends itself to wood-chip paths and rail fencing. You'll also need to plan access areas, such as paths, steps, and ramps.

There are two general types of garden design styles—formal and informal. Formal gardens exhibit classical symmetry. Flower beds, terraces, pools, and other features are generally rectangular (or sometimes round), and walks are straight.

Formal gardens are not necessarily grand; gardens designed in this manner can be unfussy and simple.

Informal gardens feature curved, free-form flower beds that sweep along the land's features. Lawns, terraces, walkways, and other features are also irregularly shaped, with one gentle arc leading to another. Natural-looking woodland wildflower gardens and free-form island beds of perennials are both examples of informal style. If the lay of your land is irregular, it will lend itself to an informal design.

BASIC DESIGN PRINCIPLES

Regardless of style, all well-designed gardens make use of three essential principles—balance, proportion, and repetition—to blend the various parts of the garden into a harmonious whole.

Balance. When elements on two sides of a central point are similar in size or visual weight, they are balanced. Balanced design gives the viewer a peaceful, restful feeling; unbalanced, lopsided design is unsettling. Balance doesn't necessarily mean symmetry; you don't need mirror-image plantings to accomplish it. Several good-sized clumps of a plant can balance one large one, for example. Symmetrical balance is a hallmark of formal gardens; and asymmetrical balance, of informal gardens.

Proportion. Garden features (plants, flower beds, terraces, and so forth) are in proportion when their scale is in good relationship to their surroundings. For example, a large clump of 9-foot-tall giant reed planted in a bed with low-growing, 2- to 3-foot perennials creates a picture that is out of proportion. Similarly, a huge shed would be out of proportion in a small yard.

Repetition. Repeating an element—color, texture, shape, or even building materials like landscape timbers—throughout a garden adds unity and harmony to a design, so the parts of the garden fit together more closely. For example, repeating the color red at intervals in a flower bed leads the eye through the design and creates a feeling of wholeness and rhythm. You can repeat the same plant, or use different species with similarly colored blooms, to achieve the same effect.

Plants and Design

The color, height, form, and texture of plants play a vital role in any garden. All plants change from season to season and year to year. They may grow taller than planned, spread too vigorously, or not bloom when expected. Balancing and working with these changes is what makes gardening an art. Even the most carefully designed gardens are never static; their owners adjust and develop the design over time.

USING COLOR

In a garden, color can be used in many different ways. One gardener may prefer bright reds and yellows; another, soft pinks, blues, and lavenders. Color can influence the mood of a garden. Hot colors—vibrant reds, oranges, and yellows—are cheerful and bright. Cool colors—greens, blues, and purples—are more serene.

Color can influence perceived perspective. Hot or warm colors appear to bring an object or scene closer. Cool colors tend to recede and push the object farther away, so they're a good choice for making a small garden seem larger. Use them in large clumps to catch the eye, and remember that they can be easily overwhelmed by warm colors.

Use balance, proportion, and repetition to design your color scheme. Strive for balanced distribution of color. A large planting of one color can overwhelm a design. Repeating a color at intervals can unify the design. Use clumps of a single plant or several different species with the same flower color.

BALANCING HEIGHT AND FORM

Plant height and plant form should be balanced and in proportion. In a planting in front of a fence or other backdrop, plant the tallest plants in the back, the shortest in front. If the planting bed's shape is free-form, put the tallest plants at the widest parts of the border. In island beds, which can be viewed from all sides, plant the tallest plants in the center, with shorter plants around the edges.

Form refers to a plant's shape—round, vertical, creeping, or weeping, for example. It's used to describe the entire plant or just the flowers. For example, delphiniums are vertical plants with spike-shaped bloom stalks; marigolds are mound-shaped with round blooms. Intersperse different plant forms throughout a design for balance and interest. Form can be used like color, although it's more subtle. Repeating a form at intervals strengthens unity and harmony. You needn't repeat the same plant to achieve this effect; several plants with similar forms will do.

INCORPORATING TEXTURES

Plant leaves can look coarse, crinkled, glossy, fuzzy, or smooth. Flowers can be feathery and delicate or waxy and bold. Using plants with a variety of textures—and repeating interesting textures at intervals—adds interest and appeal. Like form, texture is a subtle characteristic.

Garden Size

Several factors play a role in determining the best size for the individual gardens in your design. Available space may be the main consideration, but keep in mind what landscape purpose the garden is to serve. For example, if you need a shrub border to screen an unattractive view or create a private patio space, determine the size by walking around your yard and studying where the largest plants need to be planted to accomplish your purpose. Smaller shrubs and perennials that connect these larger plants into a continuous border can be filled in later, as time and budget permit. The beauty of having an overall plan is that nothing is planted haphazardly and you'll be able to work gradually toward your goal.

Continued ➔

For a flower garden that blooms all season, you will need enough space to accommodate a variety of plants that will provide an extended bloom period. About 125 square feet will give you enough room to amass flowers for a succession of color. For a formal garden, a 5-foot x 25-foot rectangle, two 5-foot x 12½-foot beds, or a 12-foot-diameter circle all provide about 125 square feet. In an informal garden, make the shapes free-form, or plan several related beds divided by paths. In general, don't plan gardens that are less than 4 or 5 feet wide if you want a lush effect. Don't plan them any wider if you want to be able to tend the plants without stepping into the bed, or else plan on an access path on either side.

CONSIDER TIME AND MONEY

These last considerations are critical: How much time and money do you want to spend? You can plan for features that reduce maintenance, but any garden will require basic care—especially in the early stages. Consider how much time you want to devote to such tasks as weeding, staking, watering, and pruning. Look for tough, low-maintenance plants if you want to keep these chores to a minimum.

Plants and supplies also cost money; decide on your budget before you start to dig. If you're not realistic about what size garden you can control, it will end up controlling you. Once you have a plan, you can plant each area as time and budget permit. Plan your garden so you'll have time to enjoy it.

Installation

Once you actually have a plan, the next step is to carry it out. The first consideration in installation is often the cost. If you can't or don't want to do everything at once, consider carrying the plan out over several years. It's usually best to start with structures, such as fences and buildings. Next, add the trees and hedges. Eventually, add smaller shrubs, flowers, and groundcovers. This approach makes it fairly easy to install the landscape on your own.

If you do want to carry out the plan all at once, it may be best to hire a professional; this is especially true if the plan includes grading and drainage changes or irrigation and lighting systems. For your protection, get three bids for large projects, and make sure you have signed contracts before work begins. Also, don't forget to check local regulations and get necessary permits before starting.

MAINTAINING THE LANDSCAPE

After you have spent all this time developing and installing your landscape, you'll certainly want to take good care of it. In new landscapes, watering is probably the most important task. Regular watering for the first year or two helps plants to settle in. After that, water your plants less frequently to encourage strong root systems. Pruning, applying mulch and fertilizer, and controlling insects and diseases are all routine maintenance tasks that keep your landscape looking its best.

Edible Landscaping

While many gardeners would like to grow their own fresh produce, not all have time or space for a separate food garden. Edible landscapes do double duty—they produce food and make our yards attractive at the same time. An edible landscape is also convenient. Slogging out to the vegetable garden on a rainy evening after work is a chore. Picking a few ripe tomatoes on your way in from the car or gathering a handful of fragrant herbs from a small garden beside the back door is a pleasure.

For New Gardeners

If this is your first garden, stick with easy, surefire plants such as tomatoes, leaf lettuce, zucchini, marigolds, and impatiens. Talk to experienced gardeners in your area for their suggestions on the best varieties for your conditions.

If you live in the South, look for varieties that are able to withstand the heat. Or, if you garden in the North and have a short growing season, choose varieties that will withstand the cold and mature quickly. Many seed catalogs indicate adaptability to climate in their variety descriptions.

And don't be discouraged if you have a few losses. If you continue to care for your soil and plants organically, your garden will become healthier, more productive, and more beautiful with each passing year.

The concept of edible landscaping is not new. Ancient Egyptian pleasure gardens included fish ponds, flowers, grape arbors, fruit trees, and places to sit and enjoy the serenity. But by the Renaissance, gardeners began to exclude edible plants from their formal ornamental gardens. They planted separate herb gardens, vegetable gardens, and orchards. Edible landscaping concepts came to the fore in the 1980s. Gardeners recognized that many edible plants are also beautiful, and they reintroduced them to the general landscape.

MAKING THE TRANSITION

Only those who move into newly built homes have the luxury of designing the landscape from scratch. Most likely, your yard already has many permanent plantings. While you won't want to redesign and uproot your whole yard overnight, there are many ways to gradually transform your existing plantings into an edible landscape. Keep in mind that an edible landscape is one in which *most*, but not necessarily all, of the plantings are food-producing plants.

Start by including some edibles with your annual flowers. Remember, you don't have to plant vegetables in rows—they'll grow just as well interplanted among ornamentals and herbs. Use the same design rules you would with flowers alone. Try

accenting a flower bed with deep green rosettes of corn salad, small mounds of 'Spicy Globe' basil, or crinkly red leaf lettuce.

Plant perennial herbs and vegetables in your existing ornamental borders—make room by relocating or replacing existing plants. For example, lavender and rosemary have upright forms with thin leaves and will add four-season interest to a border. Artichokes are perennial in Zones 9 and 10; their silvery, spiky foliage makes an interesting foil for other plants.

If you need to remove an existing tree or shrub that has died or outgrown its site, consider a fruit or nut tree as a replacement. A nut tree (pecan, hickory, English walnut, hazelnut—whatever is suitable for your climate) can replace a large shade tree. A full-sized fruit tree might be a good replacement for a medium-sized tree. Many of the spring-flowering pears, cherries, and crab apples used in landscaping are sterile hybrids that do not produce fruit. Their fruiting cousins are equally attractive in bloom and do produce fruit.

There are several other special ways to incorporate edibles into your existing landscape:

- Convert areas of lawn into new garden beds and include edibles in the design.
- Replace grass with food-producing groundcovers in some areas. Alpine strawberries produce fruit all summer and tolerate light shade.
- Make use of existing walls and fences, or add new ones. Train dwarf fruit trees against them, or use them to support raspberries, blackberries, or vegetables.
- Plant a fruiting hedge. Shrub roses such as rugosa roses (*Rosa rugosa*) make a lovely and intruder-resistant barrier.
- Build an arbor or trellis. Grapes are traditional, but hardy kiwi would also be a good choice for a large arbor. Vegetables like cucumbers, melons, and beans work well, too, but some need special support for the fruit.
- Add containers to your landscape. Many dwarf fruit trees are now available and can be grown in large tubs. Dwarf citrus will grow even in northern climates if the trees are moved to a cool, sunny, indoor location during the winter. Strawberry jars are good for strawberries or herbs.

SELECTING PLANTS

When you become an edible-landscaper, you'll find that bringing vegetables and fruit trees out of hiding and into the total landscape makes your gardening even more rewarding.

There are food-producing plants to satisfy every need in your landscape. Fruit and nut trees come in a wide range of sizes and shapes, provide shade, and may provide spring blooms and/or fall color. Berry-producing shrubs, such as blueberries and wild plums, also provide flowers and fall color. Some blueberries even have attractive red branches in the winter. The flowers of certain annual and perennial flowers, such as nasturtiums and chives, are edible. Many herbs and vegetables have interesting foliage and some have showy flowers or brightly colored fruit. Fruiting vines such as grapes, melons, and climbing beans will cover fences and trellises. Some edibles, such as creeping thyme and alpine strawberries, make good groundcovers.

Your personal tastes and how much space you have available will determine what you plant. Consider these factors as you select plants:

- What foods do you like and use most? You're defeating the purpose of an edible landscape if you plant crops you won't eat.
- How big is each plant and how much will it produce? Fresh homegrown sweet corn is a treat without comparison, but those large cornstalks yield only two or three ears apiece.
- Do you have a location suitable for growing edibles? Many fruit and vegetable crops will thrive only if they have direct sun for at least six hours daily. Your choices will be limited if you have a shady yard.
- What fresh foods can you buy locally, and which are expensive or difficult to find? You may decide to plant raspberry canes and forego zucchini plants. Good raspberries are next to impossible to buy at the grocery store, while zucchini in season is cheap (or available free from friends).

A GALLERY OF EDIBLES

Almost all food-producing plants have ornamental value. The following listings are only a small sampling of the many excellent edible landscape plants.

Trees In warm climates, citrus (orange, lemon, lime, grapefruit) are versatile trees. They are large enough to provide good shade, cooling the house or an area of the garden during the heat of the day. They retain their shiny deep green leaves through the winter, and they have fruit in various stages of development and ripeness on their branches year-round. When in flower, their fragrance perfumes the air. The flowers of the orange tree are extremely sweet and can be used to flavor honey, sugar, and tea, or as a beautiful garnish.

In the East, if your flowering dogwood (*Cornus florida*) trees are in decline, replace them with Korean dogwood (*Cornus kousa*). It blooms in June (later than the flowering dogwood), the flowers are longer-lasting, and it has brilliant fall foliage. The edible fruit resembles a pale strawberry. It is tartly sweet, with a pearlike, mealy texture, and is favored by birds and wildlife. Figs make interesting foundation plants, but they need a sheltered location and winter protection in the North. Dwarf fruit trees work well in small areas.

Shrubs. A blueberry bush makes a good foundation plant but must have acid soil to thrive. Bush cherries, wild plums,

Continued ➔

gooseberries, currants, hazelnuts, and highbush cranberries (*Viburnum trilobum*) make good hedges. Tightly planted raspberries or blackberries create a living fence. Some shrub-type roses, such as rugosa roses, produce large, bright orange or red, edible rose hips with 60 times the vitamin C of an orange. The hips can be used to make tea, jam, or jelly.

Ornamentals with Edible Parts. Leaves of amaranth (especially 'Love Lies Bleeding', 'Red Stripe Leaf', and 'Early Splendor'), leaves and flowers of anise hyssop (*Agastache foeniculum*), young leaves of balloon flower (*Platycodon grandiflorus*), seeds of love, mist (*Nigella damascena*), and leaves and flowers of nasturtium and violets are edible.

Budget-Stretching Ideas

There are many ways to stretch your gardening dollar. Here are a few to consider:

- Renting can be much less expensive than buying tools or equipment you may need, especially large power equipment such as shredders and tractors that you may need only occasionally. Renting also may make the difference between being able to do a job or having to hire someone to do it for you.
- For a soil-enriching boost of almost-free fertilizer and organic matter, plant a green manure crop like annual ryegrass, soybeans, or buckwheat and till it under before planting.
- Making a nursery bed is a great way to save money on plants. If your design calls for lots of groundcovers or hostas, for example, buy only a plant or two. Then systematically propagate them for a year or more by division, cuttings, or layering, depending on the species, until you have a small nursery of plants to move to your garden. A nursery bed is perfect for young seedlings, too. Keeping the young plants together ensures they get the care they need, since they're easier to water and weed en masse. Transplant to the garden when the plants are large enough to thrive on their own.

  To make a nursery bed, prepare the soil and add plenty of compost or leaf mold; a raised bed is ideal. Shade if the bed is in hot sun.
- Make shady and sunny nursery beds. Don't make the beds too small—you'll be propagating your plant and growing them on, so you'll need more space than seems likely at first.
- Don't be afraid to invest in top-quality cultivars if you can divide or propagate them.
- Look for special packages from nurseries—group offers of daffodils, hostas, and other popular perennials. You can save money with these packages, but be aware of the trade-offs: If you buy a group of unnamed plants, don't expect cultivar quality—put them on a slope or distant area that needs color rather than in a nearby bed or border. If you buy a "named, our choice" special, you won't sacrifice quality—you just won't know exactly what you're getting.
- Make compost. It saves money on purchased mulch and soil amendments, makes great fertilizer, and recycles valuable nutrients.
- Ask your local utility company who does their tree work, and call. Many will dump wood chips on your property for free mulch.
- Spend your money on the best—not necessarily the most expensive—materials possible; they will last longer and be a better investment.
- Start with smaller plants. Small plants are easier to plant and are less expensive.
- Order plants with a friend or group to take advantage of volume discounts.
- Plan before you shop, and buy only what you need. Impulse shopping is costly.
- Include some edibles in your design. You'll harvest tasty food and save money. Many edible plants are ornamental, too.
- Recycle what you have, use found materials, and make the best use of existing plants and features.
- Trade plants with neighbors. Almost everybody has too much of something, and these "extra" plants are often fast-growing—take up just what you need for quick color.
- Buy from reputable nurseries. You'll find healthier plants, often for little more than those found at bargain-basement sales. Reputable nurseries will often replace plants for free if they don't thrive.

Showy Edibles. The following edibles have colorful and attractive flowers: amaranth (green, purple, red), artichoke (lavender), beans (red, purple, white), cardoon (lavender), chives (lavender, white), dill (yellow-green), eggplant (lavender), garlic (white), Jerusalem artichoke (yellow), nasturtium (orange, red, yellow), okra (white, yellow), rosemary (pale blue), salsify (blue), and sugar peas (purple, white).

The foliage of edibles also comes in many interesting colors and forms. Various cultivars of artichoke, cabbage, cardoon, kale, lavender, leeks, marjoram, onion, rosemary, and sage feature shades of gray and blue. Beets, purple basil, red cabbage, red chard, pink cress, purple ornamental kale, red lettuces, and purple mustard feature pink and red shades. Carrots, endive, white ornamental kale, variegated lemon balm, nasturtiums, and thyme feature light green, yellow, and white. Asparagus has attractive green fernlike foliage.

Vines Peas are lovely trained on a fence, and they can be followed by cucumbers or squash as the season progresses. Hardy kiwi is a vigorous climber. 'Scarlet Runner' beans have bright red-orange flowers and are pretty planted with white flowering cultivars of beans. Indeterminate tomatoes can be trained on a trellis or arbor; let the side shoots grow in for maximum coverage.

Groundcovers Alpine strawberries produce tasty fruit. Many herbs are also low-growing and vigorous and can be used as groundcovers as well.

Fragrant Edibles Certain fragrances may be attractive to some people and annoying to others. The most fragrant edibles include basil, chamomile, chives, fennel, mint, oregano, parsley, sage, strawberry, thyme, and tomato. Creeping varieties of thyme and oregano are low-growing and work well planted between stepping stones, where they may be lightly stepped on, releasing their fragrance.

Getting Started

Vicki Mattern

Gardening organically is really quite simple. Push a seed into the soil, give it sun and water, add compost, and keep down the weeds. The seed knows what to do. It will sprout, soak up nutrients, develop a stem and leaves, and before you know it, reward you with flowers, fruits, and seeds.

Your role is to nurture it along using techniques adapted straight from nature. There's nothing difficult or artificial; there are no expensive chemicals to buy. Follow this simple advice and experience the joy of growing food and flowers the healthful way—without toxic pesticides and fertilizers.

Site It Right

When choosing a new garden site or expanding an existing one, take a close look at the surrounding landscape—especially at any nearby trees. Estimate how big those trees will be in 5 to 10 years, then plan your garden so that it won't be shaded when the trees get larger.

If you are able to garden year-round, be sure to consider where the sunlight will hit your garden in winter, too. If possible, site your garden on the south side of a building to take full advantage of the winter sun.

No matter where you live, try to orient vegetable garden beds to run from north to south. That way, taller crops won't shade shorter ones however you plant them.

Raise Your Beds

The loose soil of a well-prepared raised bed allows plant roots to spread out and take in the maximum amount of nutrients and water. Raised beds also warm up faster in spring and drain better than flat beds. And because you don't walk on them (you work them from the sides), the soil never becomes compacted.

To keep plants within easy reach, make the beds no wider than *double your arm length* (about 4 to 5 feet). The length of the beds depends on the size of your garden and the lay of your land. Shorter beds can save time when weeding or harvesting, but the paths around lots of short beds can take up valuable garden space if you have a small garden. Many gardeners find 15- to 20-foot-long beds to be about the right size for convenience and efficient use of space.

If you have a structure (such as a fence or building) on one side of your garden, put a narrow bed along it rather than a path. Maneuvering a wheelbarrow down a path next to a fence or building can be difficult.

Plan Perfect Paths

When creating your garden plan, consider the width of paths you'll need to accommodate your equipment. If you plan to use a wheelbarrow, tiller, or cart, you'll need at least a few main paths that are 18 to 24 inches wide. Smaller, secondary paths can be narrower—12 to 18 inches wide.

To keep the weeds out of those paths, mulch them with a thick layer of clean straw, hay, or wood chips. Or simply make them wide enough for a lawn mower and grow grass on them. Mow the paths regularly and use the clippings to mulch the beds.

Keep the Compost Close

Compost is a must for any organic garden! It contains all of the primary nutrients, trace minerals, and beneficial organisms that plants need to grow and thrive. It also discourages plant diseases and neutralizes the chemistry of the soil. If your soil is too acidic or too alkaline, you can help put it back into balance by adding compost.

Plan to locate your compost pile or bins as close as possible to the garden. You'll be more inclined to use the compost, and you'll save time and effort because you won't need to do as much hauling. And when summers are dry, you can water the compost at the same time you water your garden.

Planning and Shopping Smart

Fern Marshall Bradley

How can you improve your garden while doing less work? Plan in advance. Many of us never seem to find the time for it, but making a garden plan can actually save time, labor, and expense during the gardening season. Perhaps the following ideas from successful gardeners and designers on how to plan, make garden maps, and keep records can inspire you to really get organized ahead of time.

Once you've laid your garden plans, you'll be ready for one of the most exciting, yet most frustrating, aspects of gardening—the shopping. If you know exactly what plants or seeds you want, shopping is easy. But more often than not, you have to make decisions balancing what's best for the garden with what's best for the wallet. In this section, garden professionals share hints and insights that will help you be a smarter garden shopper whether you're shopping by mail order or at your local nursery or garden center.

Group Landscape Plants

If you have difficult soil, such as sand or clay, you've no doubt worked pretty hard to make it palatable to your shrubs and trees. "It makes sense then," says Kris Medic Thomas, a landscape manager and aborist for the city of Columbus, Ohio, "to plant other trees, shrubs, perennials, and annuals in that area, too. But there's more to it than just making use of well-prepared soil." Trees, shrubs, and other plants have a better chance of survival if they share space. They are protected from mower damage, and they create microclimates for each other. For example, they shade each other's roots, lower soil temperature, and break the force of harsh winds.

Planning for the Big Picture

Planning can be extra-important for gardening the organic way. Having excellent-quality soil and using preventive techniques to keep pests from getting too pesky means thinking and doing before you plant. You'll find lots of helpful tips on improving your soil in "Balancing the Soil," beginning on page 046.

But planning is a mix of the practical and the creative. We'll begin here with some of the big principles that you might want to mull over as you dream up your master garden plan.

DESIGN MANY GARDENS IN ONE

Don't be afraid to break free of traditional yard designs as you plan. Go beyond the typical rectangular plot for vegetables and fruit, flowers and shrubs around the foundation, and isolated shade trees dotting the lawn. The award-winning garden design of Kansas gardeners William and Brenda Reid mixes and blends different types of edibles and ornamentals throughout the landscape. Their corner lot produces high yields of fruits, nuts, and vegetables, has imaginative play areas for the children, provides birds and wildlife with year-round habitat and food, and is beautiful from any aspect. William Reid says, "Brenda did most of the initial design work. Essentially, she started with the perimeters and worked herself inward, always leaving pathways and walks where they naturally fell."

Here are some of the Reids' unusual design ideas:

- A border of perennial wildflowers mixed with dwarf apples, dwarf pears, raspberries, and pecans surrounds the property.
- Apples and pears espaliered against a wall form a backdrop for perennials. Other fruit trees and native pecan trees are scattered throughout the yard.
- Many plants in the landscape attract birds, including Buffalo currants, gooseberries, a pawpaw tree, persimmons, mulberries, elderberries, and an edible viburnum.
- Beans grow up and over a bean tunnel to create a special play area for children.
- Asparagus is planted in several places in the yard as a backdrop to other plantings.

PICK PLANTING SITES WITH PRECISION

The key to a successful planting is matching the plants to the site. This is especially true for plants that you are giving a more or less permanent home, like perennials, shrubs, and trees.

If you put a plant in a site that doesn't suit its growing needs, chances are it will suffer from pest problems or just not perform well. "People tend to put perennials where they want to see them, not where they will grow best," explains Dick Lighty, Ph.D., the director of Mount Cuba Center for the Study of Piedmont Flora in Delaware. "I often see people putting sun-loving plants in shade. Or if they put them in sun, as they should, they forget about whether the plants need water at the roots or not." You'll do your garden a favor if you research the needs of the plants you like. Be firm in weeding out plants that are simply not right for the site.

Cole Burrell, a Minnesota garden designer, explains that while you can't change your basic climate or the exposure of a site, you can improve soil conditions before planting to suit the plants you want to grow. "In my own garden, I brought in a lot of compost and manure to improve the soil in one spot where I have lots of perennials," says Burrell. "As the garden moves out to the front, the soil gets sandy and dry." For poorer conditions like those, Burrell selects perennials that can tolerate dry soil, including rough gayfeather (*Liatris aspera*), dotted blazing-star (*Liatris punctata*), wild bergamot (*Monarda fistulosa*), and prairie coral bells (*Heuchera richardsonii*).

GO NATIVE BUT NOT WILD

There's no such thing as a *no-maintenance* landscape, but the wise use of native plants can help create a *low-maintenance* one. "Natives often have the advantage of being disease- and insect-resistant. Some are widely adaptable or tolerant of difficult landscape conditions," says Dick Bir, a North Carolina State University extension specialist. One example of a wide-ranging native tree that can be a wonderful addition to the home landscape is sourwood (*Oxydendrum arboreum*). Hardy to Zone 5, sourwood is native to the eastern and southeastern United States, has excellent form, flowers in late summer, and displays brilliant autumn color.

Bir also notes that there are as many poor-choice native plants as there are good ones. Natives, like other plants, may need fertilizing, watering, and weeding to become established. They may have occasional pest problems and require some pruning.

"And going native," Bir points out, "doesn't mean taking plants from the wild. Even when removing common plants in plentiful supply, you may unknowingly be disturbing other species that might not grow there again for a century. You also don't know what problems, such as poison ivy roots, you might bring back to your property."

Give a Child a Garden

Gardening is a great way to teach children about nature, and it provides lots of fun activities for them as well. If you'd like to include children in your garden plans, here are a few things you may want to think about:

Take the children into the garden while you work. Explain your activities, and share your feelings about gardening. Ask them questions, and encourage them to ask questions of you.

Give children simple, fun projects. Children love activity. They'll enjoy cutting pictures from seed catalogs and pasting them on a garden plan, or jumping on a bag to thresh seeds inside. Provide children with their own gardening decisions, with your guidance.

Show children the miracles of gardening. The more spectacular something is, the more it holds children's interest and encourages their willingness to learn. Help them build a vine teepee or grow giant sunflowers or huge pumpkins with their name engraved on the side. Give them tall, colorful, fast-growing, scented, fuzzy, or edible plants to grow.

Provide experiences first, and talk later. Experiences are often more memorable than words. Have children feel the soil, smell flowers, taste an herb, pull a carrot from the ground, or listen to leaves rustling. Talk to them about their discoveries after they've had the chance to explore.

Garden plot. The child-size garden should create a private world where they can play. Let them make their own.

BE YOUR OWN DESIGNER

Are you puzzled by the prospect of how to design an attractive and interesting bed of ornamentals? If you feel intimidated by the complexities of design, relax. Nancy DuBrule, the owner of Natureworks, an organic garden center in Connecticut, suggests that beginners work from four easy principles, which she explains here in everyday terms:

1. **Put plants with opposite texture, shape, and form next to each other.** "Contrasts show each other off better," says DuBrule. For example, think of the contrast between a clump of grassy-leaved Siberian iris (*Iris sibirica*) and the full form of a large-blossomed clump of peonies.
2. **Pay attention to which plants retain good foliage throughout the season, and use them.** "If you build an interesting framework of foliage, you don't notice the plants that get scraggly after they bloom," says DuBrule. She suggests that gardeners include some plants such as artemisias, meadow rues (*Thalictrum* spp.), and sages for their foliage rather than their blooms.
3. **Plan a focal point for each month.** "It can be striking in color or outrageous in shape and form. You want it to catch the eye and hold attention," DuBrule explains. For example, a bold mass of an ornamental grass such as feather reed grass (*Calamagrostis acutiflora* 'Stricta') turns a striking orange-brown in the fall.
4. **Allow adequate space for each plant.** "Leave a minimum of 1½ square feet for each plant. Some, such as daylilies, require much more," says DuBrule. "If the garden looks too sparse while you're waiting for the perennials to fill in, plant annuals between them. But even then, be careful. Annuals can grow pretty large, too."

Practical Planning Pointers

Once you've set general goals for your yard and garden, focus on specific sites. Planning for the vegetable garden, where you're worried about ease of harvest and crop rotation, is different from planning for other areas, where your biggest concern may be keeping maintenance low. Here, several of our specialists offer tips on dealing with specific planning considerations.

FANCY-UP A FRONT GARDEN WITH FLOWERS

Urban gardeners often have only a small patch of land between the sidewalk and the front of the house. Usually, a little lawn and a foundation planting fill the space, but Sarah Williams, an experienced urban gardener from Vermont, suggests that gardeners try a mixed ornamental planting instead. She offers several points to keep in mind when designing a small front garden:

Limit colors. "Too many colors in one spot are visually confusing," says Williams. "Stick to two or three—for instance, white, a range of blues, and a range of pinks—and be sure the major house color and any trim colors are repeated and complemented by the flowers in the front."

Continued →

Keep plants in proportion. "You don't want to have to remove something because it has gotten too big or is giving too much shade," Williams explains.

Plan for continuous blooms throughout the season. You can have a gorgeous floral display from the first bulbs to the last chrysanthemums. Williams says, "A mixture of annuals, biennials, and perennials gives the largest visual variety and longest bloom time. Leaving spots for annuals varies the look every year and keeps the garden exciting."

Let low-maintenance be your watchword. Front gardens are highly visible, and you don't want them to end up as an embarrassment. "Bark mulch is a lifesaver," declares Williams. "It keeps weeding chores to a minimum, and its dark color contrasts nicely with the flowers."

REDUCE RENOVATION WOES

One daunting feature of an "inherited" yard can be an overgrown ornamental garden. If you face the task of renovating such a garden, you may appreciate these tips from Nancy DuBrule, the owner of Natureworks, an organic garden center in Connecticut. "First of all, find the plants that resist being moved," she suggests. "Design around them if possible." According to DuBrule, plants in this category include balloon flower (*Platycodon grandiflorus*), blue false indigo (*Baptisia australis*), false lupines (*Thermopsis* spp.), gas plant (*Dictamnus albus*), lupines (*Lupinus* spp. and hybrids), and peonies (*Paeonia* spp.).

Other plants will need dividing. DuBrule suggests that people lift and split plants such as daylilies, ornamental grasses, and irises. Before you replant the area, replenish the soil by adding organic matter and fertilizers. You may choose to select new plants or to replant some of the ones you lifted. "You can move them around to fit your new design. They're tough enough to take a transplant without being set back," DuBrule explains.

If the garden contains invasive plants, such as bee balm (*Monarda didyma*), coreopsis (*Coreopsis* spp.), feverfew (*Chrysanthemum parthenium*), and evening primroses (*Oenothera* spp.), now is the time to lift them, states DuBrule. You may want to keep some pieces, but think carefully before replanting or you may, in turn, pass along garden headaches to the next owner.

DEALING WITH DRAINAGE DILEMMAS

What can you do with wet spots on your property? "The first approach, and probably the most practical, is to choose plants that can take it, such as Japanese iris [*Iris ensata*], spotted Joe-Pye weed [*Eupatorium maculatum*], and perennial Hibiscus species," says Nancy DuBrule, the owner of Natureworks, an organic garden center in Connecticut. "The second approach is to raise the soil level." DuBrule likes to bring in topsoil when creating a raised area for a planting. "You can enclose the area with stone or wood, but you certainly don't have to," she adds. The most expensive and time-consuming approach is to correct the drainage by installing drainage tile.

DuBrule urges gardeners to be honest with themselves about the drainage characteristics of a site. In a poorly drained area, planting species that can't tolerate wet feet will just lead to headaches—and probably dead plants. So put up your umbrella, and take a long, slow walk around your yard next time it rains. Note where water settles in your garden beds or on the lawn. Make notes on your landscape plan, and follow through to deal with those drainage problems as you put your garden plan into effect.

THINK AHEAD TO SAVE LABOR LATER

Some simple advance planning can save precious time and energy during the rush and heat of the growing season. Oregon farming consultant Lynn Coody offers these examples of ways to plan for labor saving:

Assemble necessary supplies during the winter. You'll have more time for the catalog shopping that's needed to find many organic soil amendments and pest control supplies that aren't stocked in garden centers. It can be hard to order these materials in garden-size rather than farm-size quantities, so Coody seeks out other gardeners who are interested in placing a joint order and dividing up the materials.

Group crops by water requirements. This allows you to regulate watering needs more easily later in the season. For example, deep-rooted crops like lima beans and pumpkins need less water than shallow-rooted crops like cauliflower, lettuce, and spinach.

Divide the garden into weeding areas. Coody divides her garden into Areas 1, 2, and 3. "As soon as I plant, I begin to weed," she explains. "I thoroughly weed Area 1 first, letting the weeds grow in Areas 2 and 3. I move into Area 2 next, and finally, Area 3." Coody likes this approach because she never faces the overwhelming task of having to save her entire garden from the crush of overgrown weeds.

MADE IN THE SHADE

The shade cast by a vine-covered trellis may be just the twist that gardeners in hot-summer regions need to help their plants survive the heat. "If more people would use trellises and vines to shade some of their perennials and some of their vegetables,

they'd get much longer show or yield from them," says Jim Wilson, a cohost of public television's *The Victory Garden*. Wilson suggests planning for a fence on the western side of your vegetable garden or perennial beds, to block the sun from midafternoon on. "When Jane [his wife] and I were growing herbs at our farm, we had some of them backed up against the afternoon shade of trees, and they always held up two to three weeks longer than the ones in the baking sun," he says. Some shade also helps to extend the spring harvest of leafy vegetables such as lettuce.

GROW GRASS IN THE PATHS

Grass in the vegetable garden may not be a bad idea—if it's in the pathways. Janet Bachmann and partner Jim Lukens, who co-own a small organic farm in Arkansas, have discovered that keeping vegetable garden paths planted in permanent sod not only reduces maintenance but also benefits their crops. They grow vegetables in permanent beds, 4 x 50 feet. Three-foot-wide sod pathways composed of perennial ryegrass (*Lolium perenne*) and white clover (*Trifolium repens*) separate the beds. Bachmann explains the advantages of the system: "The sod provides a continuous supply of high-quality mulch material for the growing beds. When we mow, the lawn mower throws the clippings onto the beds, saving us a step. We can also concentrate our fertilizers this way; we don't spread them on the sod pathways, which don't need them. The sod allows us to walk in the garden after a rain. We don't have to worry about compacting our soils."

Bachmann and Lukens designed their beds and paths so that their tractor, which has a 7-foot span from wheel to wheel, travels on the sod when they till their beds. You may want to design your paths so that you can mow them in two passes with your lawn mower.

Getting the Plans on Paper

Does trying to draw a map of your yard or garden plot leave you tearing up endless sheets of paper—or tearing out your hair? If so, read the following sections for advice from the experts on hassle-free map making.

PLAY WITH POST-IT PLANNING

Those sticky squares of paper commonly known as Post-it notes are perfect for the trial-and-error process of planning the layout of your vegetable garden beds. North Carolina gardener and garden writer Bob Heitman stumbled across the idea for Post-it planning two seasons ago. "I was doing my second most favorite thing, armchair gardening, when I thought of it," Heitman remembers. "I started playing with the Post-its and found that using them was a quite pleasant and orderly way of planning my garden."

To try planning with Post-its, you'll need a smooth, hard surface to work on. Heltman made his own lap-size garden board out of a piece of tempered Masonite fiberboard. (You could also use a large erasable memo board. Decide the scale of your garden, such as 1 inch equals 1 foot. If your beds are 3 feet wide, you can use 3 X 5-inch Post-its. If they're 4 feet wide, you can snip an inch off of the 3 x 5-inch Post-its. Heitman also notes that you don't need a ruler with Post-it planning. "You can use the Post-it itself to measure spacing within and along a bed."

Try drawing on an erasable memo board when you're brainstorming garden plans or designs for flower beds and borders. You can quickly sketch in plant groupings and alter their size and shape by simply wiping them off and redrawing. Once you're satisfied with the general outlines of the plan or design, use it as a guide for creating a more detailed, formal drawing on paper.

Write each crop name on a Post-it, and go to work. You can lift and restick each crop as many times as you like until you hit the arrangement you think is best. If you succession-crop, just layer Post-its one on top of another. For example, if you plan to follow an early crop of lettuce with beans, you can use two Post-its on that plot to show the succession.

Once you have the final layout of your garden, you can draw it up on a more permanent map (Post-its do tend to lose their stickiness over time), or you can encase the Post-it board in plastic wrap to keep the Post-its intact. This will also protect them from getting dirty or wet if you take the board out to the garden with you.

MAKE MULTIPLE MAPS

Once you've drawn a general map of your property or the layout of your vegetable garden, save redrawing time by making photocopies. John Dromgoole, the host of PBS television's "The New Garden," makes 20 copies of his garden map each year and puts them in a notebook. "I try so many new things every year and do so much succession cropping that I need an efficient way to keep track of everything. The maps let me do this," says Dromgoole. He uses one map to plan out the first plantings of the year. As the season progresses, he records the placement and dates of following crops on separate copies. "I put notes on them, too," says Dromgoole. "For instance, I tried out a new kind of drip irrigation system last year. I really liked it in the beginning of the year, but by the end of the season, it developed leaks. I noted all the leaky spots on my maps."

Keeping Good Records

Keeping written notes on your garden is part of the ongoing process of making your plans a reality. Records help you know which of your new methods worked and which flopped. They help you decide which plants are best suited to your site. In the following tips, our veteran gardeners explain what they keep track of and the record-keeping styles that work best for them.

MARK THAT CALENDAR

If you're the gardener who's forever procrastinating about starting a record-keeping system, calendar record keeping may be just right for you. Stewart Hoyt, who operates a Community Supported Agriculture (CSA) operation in Vermont, says, "I've never been really good with record keeping. But now that we're doing a CSA, we have to keep track of things. So I've developed a simple system that I can stick to." Hoyt uses a calendar with "huge" daily spaces. When he comes in from the gardens each day, he notes everything he did that day along with the number of hours he spent on it. So post a calendar by the tool rack or just inside the back door, with a pencil on a string attached to it for maximum convenience. Take 3 minutes to note essentials. A calendar is a good place to record:

- Type and quantity of seed sown or number of transplants planted (including cultivar names)
- Rainfall or watering
- Areas weeded
- Pest control techniques used
- Harvest times and quantities

Then at the end of the season, sit down with the calendar and summarize the performance of your crops.

GET THE PICTURE

"Photographs are as useful as written records," says John Dromgoole, the host of PBS television's "The New Garden." "I can capture the whole garden in a few shots. I take pictures every few weeks during the growing season." Photographs refresh your memory and can answer questions about when and where things were planted if succession and intercropping plans get complicated.

KEEP THOSE RECORDS ON FILE

A handy way to keep track of crop performance in the vegetable garden is to make notes on file cards. New Hampshire organic farmer Rick Estes says, "File cards are the best record-keeping tool I've found." It's easy to separate cards into categories with dividers. Each year, you can drop in new notes just where you want them. Estes says, "I use the cards for keeping track of numbers and dates, how many of what crop I've seeded, and when." Estes also finds the cards effective for quick review and improvement of his techniques from year to year. "For example, the notes on my cards for tomatoes the year before last said 'leggy' next to the transplant date," he explains. "So I delayed seeding by a week, and last year's tomatoes weren't leggy."

IN-FIELD RECORD KEEPING

Thanks to plastic and indelible ink, you can keep year-to-year records right in your garden. Ken Ryan, an organic farmer and farm manager from New England, sticks an 8-inch plastic tag at the head of every bed as he plants it, noting the cultivar and planting date with a laundry marker. Rather than remove these tags at the end of the season or when a crop is finished, he leaves them in place. "I have years of tags at the head of every bed," says Ryan. "I have to touch up the writing every so often because it fades, but I keep up with that." Ryan likes this system because it helps him maintain good rotations if he has to deviate from his yearly plan.

Try To Remember

Try to keep a year's worth of garden records in your head, and your memory may fail you. Write it down! Be sure that you:

List crop rotations. Changing the placement of crops within your garden each year is one way to outwit pests and fungi that attack certain plant families. Using a map or chart to record where you planted each crop last year will give you a visual reference for planning this year's crop placement. This will help ensure that you don't plant crops from the same family in the same spot year after year, making them more vulnerable to diseases and insects.

Maintain soil records. Keeping track of timing, type, and amount of fertilizer applications is important in avoiding mineral imbalances. Lack of nutrients can limit plant growth, and excesses of certain nutrients can also have detrimental effects.

Keep a weather diary. Environmental disorders, such as water stress, sometimes cause symptoms that look very much like symptoms caused by insects or diseases. If you have data on weather conditions to refer to, it will help you make a better judgment about the underlying cause of the symptoms you see.

Compare cultivar records. Include jottings of how well your plants resisted heat and pests and also how well they were received on the dining room table! Perhaps you'll find some favorite cultivars or decide to choose new ones.

Seasonal Care

Sally Jean Cunningham

Wouldn't you like to be a little bird peeking over the fence at the way other people garden? Then you could see their tricks and techniques for planting, watering, and all the other gardening chores! I certainly have plenty of quirks, shortcuts, and odd habits that are the real way I get things accomplished in my garden. Some of my methods aren't much like the directions I've read in gardening books, especially the books where the gardeners look so well-dressed and clean! I also know that lots of us garden with limited budgets and would rather make or find something than buy it. So I'll share an honest peek with you at how I care for my garden from winter on through the whole busy year—plus I'll add a lot of tips I've learned from some other "cleaned-up" gardeners that may make things easier for you.

Gardening through the Year

Deciding when the gardening year starts is a bit like deciding which came first, the chicken or the egg. Perhaps it starts when you plant seeds and plants in the spring. But perhaps it starts in the fall, since many fall activities, such as preparing compost piles and tilling the soil, are really the groundwork for next season's garden.

I'm one of those gardeners who can't get the garden out of my thoughts, even when the soil is buried under 2 feet of snow (which happens quite often here in the shadow of Lake Erie!). For me, the gardening year starts in January with indoor tasks like ordering seeds and cleaning tools, and "ends" (at least briefly) in late fall when I harvest the last of the carrots and greens.

FIVE SEASONS OF GARDENING

I divide the gardening year into five seasons: winter, early spring, late spring, summer, and fall. When those seasons start and end varies according to where you live and according to the weather. For me, late spring can be mid-May, but in a cold year, it's closer to mid-June! And for a gardener in North Carolina, late spring may be late April. You'll need to decide for yourself when these seasons fall on your calendar.

In this section, you'll find a to-do list for each season that summarizes the garden tasks for that time of the year.

As you browse through this section, keep in mind that you can't always garden "according to plan." We gardeners are often at the mercy of the weather. For example, on the day when the soil is just right for tilling, you may not be able to borrow a tiller, and rain will be forecast for the rest of the week. In cases like this, you won't be able to garden according to your perfect plan, but perhaps you can figure out a strategy that's good enough to get you through—like hiring the teenager next door to help dig part of the garden by hand so you accomplish some planting before the downpour.

Remember, gardening is and always should be fun, so don't let my to-do lists increase your stress level. Heaven knows, I don't always have my garden in tip-top shape, but I still get a good harvest each year—of produce and of satisfaction.

Gardening in Winter

Winter is the time for make-it-yourself garden projects and tasks that you'll be too busy to accomplish once the weather turns nice. It's also the season for reading gardening books like this one and for dreaming over all those tempting catalogs while you make your seed and plant lists.

SHOPPING FROM CATALOGS

Run to the mailbox and grab your pen! The arrival of garden catalogs in January creates great bursts of excitement at Wonderland Farm. But I've learned to be careful about catalog fever, because it's easy to overspend. So here are some tips for smart catalog shopping.

Read between the lines. Catalogs are sales tools, so naturally they only mention a plant's strong points. Look for what's not said. For example, if a tomato is billed as a "great keeper," but its flavor isn't mentioned, it may be pretty bland!

Compare prices. Even if you buy your seeds and plants locally, use catalogs to check typical price ranges, and watch for early- and late-season bargains on supplies.

Use regional sources. Companies that raise their plants and seeds in a climate similar to yours are more likely to sell varieties and species suited for your garden.

Order early. To be sure you get the choices you want, place your order before winter ends. Reputable companies will wait to ship your plants at an appropriate time for planting.

MAKING GARDEN EQUIPMENT

Make-it-yourself projects appeal to me because they save money, they let me turn trash and recyclables into useful items, and they're fun! You probably have your own special make-it-yourself items for the garden. Tomato cages and plant stakes are some of my favorites.

Step-by-Step Tomato Cages

I like sturdy tomato cages at least 4 feet tall. I haven't found commercial cages that really satisfy me, so I make my own out of wire fencing. I use fencing made from 14- or 16-gauge wire that has 4- by 6-inch openings. The fencing is available in 30-foot rolls, which is enough to make six or seven cages. Here's how I fashion the cages.

Step 1. Unroll the wire fencing on the floor, and use wire cutters to cut a 4-foot section of fence for each cage you want to make. Cut through the horizontal fence wires just beside one of the vertical wires.

Continued →

Step 2. Line up the midpoint of the section of fence with an 8-foot-long wooden stake. Use a staple gun to fasten the wire to the stake. The pointed end of the stake should extend 18 inches below the edge of the fence.

Step 3. Bend the edges of the fencing together to form a cylinder. Wrap the cut ends of the horizontal wires around the vertical wire. Wear gloves to protect your hands from the sharp points of the wire.

These cages will support any type of tomato, even vigorous beefsteak varieties. The cages last six years or longer, depending on how heavy the fencing is and whether you store the cages inside during the winter.

John's Cheap Stakes

My friends and I like to make our own garden stakes and markers. For example, Master Gardener John Holnbeck recycles wooden shingles into inexpensive row markers by breaking them lengthwise into pieces about 1½ inches wide and 12 inches long. He then cuts strips from white plastic bleach bottles; each strip is about 3 inches long and ¾ inch wide. He staples the strips to the stakes and uses a waterproof pen to write on the strips. They are really "cheap stakes."

I make row markers out of chopsticks that I save from my monthly excursion to my favorite Chinese restaurant. I dip the chopsticks in paint or mark them with crayons to make color-coded markers. Or you can write on the wide end with a waterproof pen.

You can also fashion plant labels by cutting up yogurt containers, detergent bottles, and plastic orange-juice containers.

TUNING UP YOUR TOOLS

I don't have enough time to take good care of my tools during the active garden season, so I work hard to clean and sharpen them well each winter.

When you bring your dull and dirty tools inside for clean-up day, first spread out newspapers or a sheet—it saves you from having to clean your floor when you're through with the tools! Using a dry steel brush, brush any dry soil off the tool blades. Then set to work with soap and water and steel wool. Next, dry the tools, and apply linseed or tung oil to the wooden handles.

The final step is sharpening. I use a #10 bastard file to sharpen my garden tools. To sharpen the edge of a hoe, shovel, or trowel, push the file hard across the blade, using the full length of the file on each pass. Be sure to sharpen the beveled side of the blade.

Gardening in Early Spring

If you live in the southern United States, you may not yearn for the change from winter and early spring to late spring. But for northern gardeners, early spring is a distinct and sometimes frustratingly long time of year. It's finally warm enough to work outside, but the soil's still too wet to dig, and there's too much danger of frost to plant most of your crops. But I manage to find plenty of early-spring fix-up projects to satisfy my need to get outside.

BUILDING TRELLISES

Early spring is a good time to set up trellises for crops you want to grow vertically, like pole beans, peas, and gourds. I often use teepees for beans, and chicken-wire trellises for peas.

My friend Mary Giambra, a Master Gardener from Marilla, New York, designed a sturdy structure from PVC pipe that has several possible uses, including an arching trellis. You can also add sections to make a series of arches in order to build the framework for a hoop house. To make these arches, you'll need 36 feet of PVC pipe, six T-joints, and eight elbow joints.

Step-by-Step PVC Arches

To make a trellis out of PVC arches, prepare by using a hacksaw to cut eight 2½-foot pieces, seven 2-foot pieces and four 6-inch pieces of PVC pipe.

Step 1. Make two arches, connecting the lengths of pipe.

Step 2. Connect the arches by inserting three 2-foot sections of pipe as crosspieces in the open fittings in the T-joints.

Step 3. Sink the feet of the arches into the soil of your garden or raised beds, inserting about 1 foot of pipe into the soil. The PVC is too slippery for some plants to cling to, so cover the trellis with pea netting, or weave rough twine in a zigzag pattern back and forth between the two arches.

UNMULCHING

Pulling mulch off your beds on sunny spring days helps warm and dry the soil. You can re-mulch after planting (you'll have to hoe lightly to kill surface weeds before you plant). In areas with poor drainage or heavy clay, it's important to cover unmulched areas with a solid cover like plastic or a tarp when it rains to keep the soil from becoming saturated.

I don't unmulch the perennial clusters or the beds where I plan to plant hot-weather vegetables like peppers, pumpkins, and basil. The soil will warm naturally under the mulch by the time air temperatures are suitable for planting these crops, so unmulching will just lead to weed problems.

When you unmulch, leave some mulch in place at the ends or sides of beds to shelter spiders, ground beetles, and other good bugs that overwinter under mulch.

COLD-WEATHER WEEDING

On days when your first thought is "It's too cold for gardening," try some weeding. It's good exercise, and it will help free your garden of any tough weeds later. Pull weeds whenever the ground is unfrozen but damp. The weeds usually pull out quite easily. As long as they haven't gone to seed, put the pulled weeds in a stockpile for composting.

One special warning about early weeding: Don't pull out the companion plants you'll be looking for later! Your garden beds may include many weed, wildflower, and volunteer seedlings from last season's annuals and herbs. Learn to recognize the useful plants in their infancy.

GROOMING PERENNIALS

To help your perennials bloom longer in summer, take time to care for them in spring. If you left seedheads in place for the birds to feed on or for winter interest, cut them back now. Remove old leaves or plant debris, too. Remember, go lightly: Birds, beneficials, and other wild things like it wild!

When you work in your perennial beds, keep in mind that some perennials don't start to regrow until late spring. Don't dig them up in your impatience to fill the vacancy! Butterfly weed (*Asclepias tuberosa*), balloon flowers (*Platycodon* spp.), and butterfly bushes (*Buddleia* spp.) are slow starters. It's too easy to destroy the crowns of these plants by digging before the new foliage starts to emerge.

USING SIMPLE COLD FRAMES

Cold frames are great for extending the growing season in spring and fall. They can help you start some crops early, harden off your trays of seedlings and transplants before planting day, and carry lots of crops into the late fall. If you don't plan to build or buy a permanent cold frame, try setting up a temporary cold frame. One method is to buy bales of straw, set them up in a rectangle, and place window glass or clear plastic across the top to form a tiny greenhouse. I rigged a protected area for trays of seedlings by suspending old storm-door glass panes across the path between two raised beds. Even an old storm window propped against your house can provide short-term protection and give you a small jump on the season.

STARTING VEGETABLES FROM SEED

Many home gardeners get great satisfaction from starting their own seeds under lights. On the other hand, lots of people try it and end up frustrated, with poor results after a lot of fuss. My advice: Only start seeds indoors if you plan to set up indoor lights. (Windowsills just don't provide enough light, at least in the Northeast.)

I'm lucky to live near some great nurseries that produce high-quality transplants, so most years, I don't take time to start seeds indoors. When I do, I concentrate on the easiest seeds for indoor starting, the Cabbage Family and Squash Family crops. You can also start tomatoes, peppers, and eggplant from seeds, but they require some extra care. If you enjoy the process and have the setup, great!

Gardening in Late Spring

Although the dates you call "late spring" may vary from year to year, you know when it's arrived: Late spring is the time you can actually work the soil and do some serious gardening!

WORKING THE SOIL

To tell when your soil is ready to be worked without damaging its structure, squeeze some in your hand. If the soil crumbles, it's ready for digging. If it cakes or forms a patty, it's too wet, and you'll have to wait.

Whether you work your soil with a rotary tiller or by hand, don't overdo it. Till or fluff the soil no deeper than 7 inches about two weeks before your estimated planting day. Your purpose is simply to break the soil crust, kill the surface weed seedlings, and expose weed seeds and grubs to the birds. Then on planting day, work the surface again, no deeper than 2 inches, to kill off any new weed seedlings.

TRANSPLANTING TIPS

Now's the time to set out transplants for many crops, whether you've grown them yourself or bought them at a garden center. Remember these guidelines for successful transplanting.

- Harden off your transplants for one to two weeks before planting by putting them outside during the day. At night, bring them inside, or keep them inside a cold frame.
- Transplant on an overcast, cool day—not the first hot, sunny day you have.
- Keep transplants out of the wind while you're transplanting.
- Moisten seedlings thoroughly before you plant, and water well afterward.
- Pull or cut circling or matted roots apart before you plant.
- If frost, heavy wind, or hard rain threatens, protect newly planted transplants by covering them with baskets, tin cans, milk cartons, or sheets draped over short stakes.

PREVENTING PEST PROBLEMS

Now is the time to start stopping pests—before they hurt your plants. In a companion garden, your most important pest-prevention tactic is in the planting. But there are some other techniques you can try in late spring that may prevent problems later on.

Continued →

Using Row Covers

Floating row covers are sheets of lightweight synthetic fabric that let air and water through but keep pests out. When you drape row covers over your crops, you'll prevent problems with common pests like flea beetles, imported cabbageworms, cabbage loopers, and squash bugs.

Several brands of floating row covers are available at garden centers and from mail-order garden suppliers. I recommend that you buy row cover fabric in 5- or 6-foot widths so that you can cover your beds and still have excess fabric to bury at the edges. Choose one of the heavier-grade fabrics that doesn't tear easily, because your row covers can't have holes for those little pests to sneak through.

I sometimes keep crops like broccoli and cabbage covered from transplanting to harvest. I also cover vine crops like squash to keep out squash bugs. If you do this, remember to allow for pollination, or there will be no squash or pumpkins! Just remove the row covers when you see the plants in full flower.

Stopping Slugs

I don't know of any companion plant that repels slugs, but I wish I did. Slugs can be a real problem, especially when there's a wet spring. They eat a wide variety of garden crops, especially lettuce, spinach, and Cabbage Family crops.

You can fight back by handpicking and killing the slugs. It's not a fun job, but it really helps. Slugs gather under the boards that I use as garden pathways. During the day, I flip the boards over and offer the slugs as a meal for the birds. I also sink shallow dishes into the soil and fill the dishes with yeasty beer or a solution of water and yeast. The beer and yeast attract the slugs. When the slimy critters crawl into the dishes to drink, they drown.

Welcoming the Helpers

In a companion garden, spring is the season to put out the welcome mat for garden helpers. Here's a list of reminders about how to attract beneficial insects, birds, and other beneficial animals to your yard.

- Stick a tall bird perch or two in the garden, where birds can land, rest, and look around. A perch can be just a tall stake with a small crosspiece attached.
- Set up birdbaths with lots of pebbles in them.
- Allow some dandelions to bloom to provide early nectar for lady beetles, then pull the plants before they go to seed.
- To supply nectar early, sink pots of annuals into the soil, and remove them for use elsewhere when your garden has other flowers to offer.
- Make toad houses from inverted clay pots with chipped holes for doorways. Or simply pile up some rocks to provide a cool hiding spot.

Gardening in Summer

It seems to me that we spend weeks yearning for summer, but when summer gets here it's too hot to enjoy being outdoors! When summer heats up, I garden in the early morning and in the evening to beat the heat.

WATERING

Even the best mulchers have to water sometimes. We don't want to use more water than necessary, but we don't want to wait until our plants have wilted to tell us they're thirsty. Here are some quick rules of thumb to help you decide when and how to water.

How often? Water when the soil feels dry to your finger about 2 inches down.

How much? Water vegetables and most flowers until the soil is damp at least 4 to 5 inches down.

What time of day? Watering in the morning is best. I avoid evening watering because it promotes fungal growth and creates perfect conditions for slugs. I avoid midday watering because the water evaporates fast, and it's not efficient. However, if the plants are stressed, *water them!* Sometimes you can't fit in watering in the morning, so it's better to water when you can than not to water at all.

We've all heard that our gardens should get 1 inch of water per week, and believe me, that's more water than you'd think. For example, it takes about 120 gallons of water to supply one inch of water for a 10- by 20-foot garden. Just one full-size tomato or pumpkin plant needs 2 to 3 gallons of water a week.

Fixing Hoses on Short Notice

If someone accidentally runs over your hose with the lawn mower, or if your hose just springs a leak, it's wise to know how to repair it fast. You can repair your hose with a simple repair kit, available at your hardware store or garden center. (It's guaranteed that hoses always rip on holidays, when the stores are closed, so I keep a basket of hose repair supplies, complete with sharp knife and all the ends and connectors I may ever need.)

Step-by-Step Hose Repair

Here's my technique for fixing failing hoses:

Step 1. Use a sharp knife to cut out the leaky or damaged section of hose. Be sure to cut straight across the hose. If the weather's cold, bring the hose inside. It's hard to cut through a cold, brittle hose.

Step 2. Insert the repair coupling into the opening at the end of the intact hose and push it firmly into place. Repair couplings can be made of either metal or plastic; both types work well. Again, it's easier to do this when the hose is warm.

Step 3. Use a screwdriver to tighten the clamp in place next to the coupling. Discard the damaged section of hose.

PATROLLING FOR PESTS

In your companion garden, you should have very few serious pest problems, but it's still well worth it to inspect your plants for signs of trouble.

Walk through your garden and inspect each plant up close. Look on the undersides of leaves, at the growing tips, and down near the base of the stem—all likely spots for pests to hide and disease symptoms to show.

You may spot signs of disease here and there in your garden, but don't panic. A few discolored leaves don't mean a crop will be ruined. But if you find a plant that's seriously diseased, pull it up and throw it away—you wouldn't get a worthwhile harvest from it, and it would only spread the disease throughout more of your garden.

FERTILIZING

Adding fertilizer as a *side dressing* or *top dressing* isn't essential, but at times it can really help your crop. This simply means putting a little organic fertilizer on or into the soil near the plant roots. I side-dress most crops when the plants have just begun to produce fruit, tubers, or whatever I'm planning to harvest.

I use compost or alfalfa meal for side-dressing crops. I spread the material in a circle beneath the outer canopy of leaves for plants like broccoli, brussels sprouts, and tomatoes. For corn, I sprinkle the fertilizer all along a row of plants. For crops like onions that I plant in blocks, I sprinkle the fertilizer as evenly as I can around the plants.

One alternative to side dressing is to spray plants with a solution of fish emulsion or seaweed extract. These products are rich in a wide range of nutrients. They may cost more than other fertilizers, but for a small garden it may be well worth your investment. Apply the spray diluted according to the directions on the package.

I don't bother fertilizing peas, beans, most root crops, or greens like lettuce and spinach, because it doesn't seem to increase their yields.

PLANTING FOR FALL

After all the work of preparing fertile garden beds, I certainly don't want to let them sit empty. So as soon as I finish harvesting a crop, I plant something else in its place. This creates a whole new set of crops to harvest in the fall.

There are some real advantages to fall gardening. For one thing, I'm not as busy as I am in the summer, so it's easier to find time to care for the garden. There are many fewer pests to contend with. It's also a second chance for success with crops that didn't do well the first time around.

HARVESTING

You've probably been harvesting since late spring, but a lot more harvesting happens quickly at the end of summer. If you're lucky, you have friends and family to help gather, store, prepare, freeze, or can your treasures. The gardener's job is to keep the harvest going.

Remember to keep things picked: Letting fruits stay on the vine can signal the crop to stop producing.

It's okay to let a few herb, broccoli, lettuce, and spinach plants go to seed, because some of them provide just the right nectar at the right time to keep our beneficial insect friends around the garden.

Gardening in Fall

In the fall, we clean up the vegetable garden and cover the soil for the winter. It's also the time to set up safe havens for beneficial insects, birds, and helpful wildlife.

HELPING BENEFICIALS AND BIRDS

Many beneficial insects overwinter right in the garden. Cover crops and mulch protect these overwintering beneficials. Leave the water dishes in your garden filled right up until freezing weather so beneficials have a source of water. Leaving boards, stones, or cardboard in place also protects ground beetles over the winter.

Birds require water and food, either to survive in your local area or during migration, so learn about bird feeding, and keep feeders filled through the winter. In the garden, leaving the seedheads of perennials, cover crops, and weeds in place will attract many birds.

GARDEN CLEANUP

Garden cleanup is a bit different than usual in a companion garden. You won't just make a clean sweep, because your garden neighborhoods will finish at different times. And you'll treat each bed differently, depending on which crop family and plant friends will move into the bed next spring. In some beds, you'll sow a cover crop as soon as you finish harvesting. In others you'll continue to harvest right through fall, so after clearing out the crop, you'll work the soil and then cover it with organic mulch, plastic, or a tarp. In beds where you want optimum nutrition next season you'll sheet compost by spreading a layer of manure or other high-nitrogen organic matter over the soil surface.

As you clean up, watch for annual weeds, like ragweed, lamb's-quarters, and pigweed, that have gone to seed around your garden. Snip off the stems, gather the seedhead, and discard them with your household trash.

Where Cleanup Counts

Some kinds of garden cleanup are vital. If any sections of your garden suffered insect or disease problems, the damaged plants must be pulled, roots and all, in the fall. I always remove the remains of cucumbers, melons, squash, pumpkins, and all Cabbage Family crops from my garden. I burn the remains but if burning isn't allowed where you live, dispose of them in your trash.

Continued →

It's also important to harvest potatoes and tomatoes thoroughly, and if you compost the plant remains, make sure they're in an active compost pile. Late blight, a serious fungal disease, and several other disease organisms can overwinter in garden debris and reappear in volunteer plants that sprout from unharvested fruits and tubers. So it is especially important to resist the temptation to take advantage of those "freebies." Instead, destroy them.

OVERWINTERING GARDEN FAVORITES

I don't get fancy with hoop houses and cold frames, but there are a couple of simple tricks that extend my harvest of carrots and greens until Christmas.

Carrots get sweeter and sweeter as the temperature drops, so cover them with a thick straw mulch, and you can harvest a snack any time you happen to be skiing by!

Lettuce, spinach, and most greens—including Chinese cabbage and Swiss chard—will tolerate several frosts. Keep them going by placing straw bales around the plants and covering the bales with a discarded storm window or a piece of heavyweight, clear plastic. You can also use the hoops that held up your row covers to support clear plastic to make a mini-greenhouse. (In warm spells, be sure to lift up the sides to avoid "cooking" the plants.)

SUMMING UP THE GARDEN YEAR

If you ever write in a garden journal, fall is the most important time for making notes. Record the names of what you grew, what looked great, what had problems, what was too close or too far apart, and which companions worked best.

Whatever the season, remember that the less factual but more personal notes are also very important to include in your garden journal. After all, gardening is a passion for many of us—but still a hobby and not a job! So add comments on what you did and didn't enjoy doing and what was pleasing or frustrating during the season. (My notes always include "mulch more and weed less!") You may want to try drawing sketches of your garden in your journal or taping some photos of your garden to the pages. The more fun your journal is, the more likely you'll use it in all seasons.

Gardener's To-Do List

Vicki Mattern

January

Zone 3

- For an early taste of spring, grow some sprouts. Mung bean, radish, and buckwheat sprouts grow well in vented jars. Just put the seeds inside, cover them with water overnight, drain, then rinse twice a day.
- Explore seed catalogs, then send in your orders.
- Start snapdragon and pansy seedlings.

Zone 4

- Check the viability of old seeds by sprouting a few of each kind in damp paper towels enclosed in plastic bags.
- Set up your seed-starting system.
- Start a flat of hardy perennials or alpine strawberries.
- Rearrange houseplants so that all get their share of bright light. Later in the month, give them a light feeding.

Zone 5

- Gather your seed-starting equipment, then start seeds of pansies, snapdragons, and hardy perennials.
- Toward the end of the month, start onion seeds.
- Order seeds of cabbage, broccoli, cauliflower, parsley, and peas.
- Dig up a frozen chunk of chives and force them into early growth indoors.
- When the snow cover is thin, check shrubs and perennials. If the roots have heaved up too close to the surface, press them back into place.
- Late this month, begin pruning apples.
- If rabbits are ravaging fruit trees and shrubs, lure them to a distant spot with corn or hay.

Zone 6

- Start hardy flowers under lights.
- In midmonth, start cabbage and onion seeds indoors.
- Order seeds for other cool-weather crops, such as broccoli, cauliflower, spinach, celery, lettuce, and peas.
- Get your coldframe ready. Mound a 4-inch layer of leaves or soil around the outside to help it hold heat.
- Check winter mulches and replenish those that have thinned.
- Wrap wire mesh around tree trunks that have been damaged by rodents.

Zone 7

- Start seeds of cabbage, onions, and hardy herbs under bright lights early this month.
- Clean out your coldframe.
- Collect plastic jugs to use as cloches.
- Late this month, mow winter cover crops.
- Direct-seed sweet peas.
- Indoors, start seeds of perennials, such as columbine and balloon flower.

- Begin dividing daylilies.
- Prune crape myrtles.
- Set out junipers, hollies, and other evergreens.

Zone 8

- Harden-off cool-weather transplants (cabbage, broccoli, etc.) that you've started indoors.
- Start lettuce indoors. When seedlings have several leaves, set them out under plastic milk jug cloches.
- Sow peas outdoors late this month.
- Set seed potatoes in a bright spot to encourage sprouting.
- Take advantage of your last chance to dig and divide crowded daylilies and daffodils.
- Dig and transplant dormant phlox, thrift, and hosta.
- Trim old leaves from liriope, but don't disturb the crowns.

Zone 9

- Sow beets, carrots, lettuce, peas, and spinach in the garden.
- Indoors, start seeds of tomatoes, peppers, and eggplants.
- Direct-seed alyssum, California poppies, nasturtium, and cornflowers.
- Prune geraniums to stimulate bushy new growth.
- Plant new persimmons, loquats, and figs.
- In the West, plant young pistachios in well-drained soil, then stake them securely.

Zone 10

- Set out transplants of onions, potatoes, cabbage, and broccoli.
- Water transplants often to keep them growing strong.
- Plant dahlias, caladiums, gladiolus, and tropical tubers, such as amaryllis and crinums.
- Set out bedding plants such as pansies, dianthus, and petunias.
- Plant young plumerias in containers.
- Trim back poinsettias and other tropicals after they finish blooming.
- Taste citrus fruits regularly so that you can harvest them at their peak of flavor.

February

Zone 3

- Garden indoors! Grow some leaf lettuce, chives, and cress beneath lights.
- Move geraniums that have been stored indoors for winter into brighter light. Slowly coax them back to life with dribbles of water and weak fertilizer.
- Late in the month, sow onion, celery, pansy, snapdragon, and viola seeds indoors.

Zone 4

- Sow seeds of onions and chives indoors under lights.
- Late in the month, start some seeds indoors of early cabbage, broccoli, cauliflower, and celery, as well as of pansies, daisies, and other hardy flowers.
- Prepare your coldframe for use next month.
- Check peonies and other perennials for signs of heaving. Press them back into place with your foot if their roots show aboveground.
- Lightly trim damaged wood from mature apple trees, but postpone heavy pruning for a few more weeks.

Zone 5

- Kick off the growing season: Start celery, onions, leeks, and hardy herbs indoors beneath lights. Toward month's end, start early cabbage.
- Outdoors, cover compost with black plastic to help it thaw.
- Start cold-hardy flowers, such as snapdragons, stocks, pansies, and lobelias, indoors beneath grow lights.
- Between snows, direct-seed poppies and larkspur outdoors.
- Order new disease-resistant apple trees such as 'Enterprise', 'Freedom', and 'Goldrush'.

Zone 6

- Indoors beneath lights, start cabbage, cauliflower, celery, and broccoli.
- Outdoors, work the soil as soon as it has dried, preparing beds for peas, potatoes, and other early crops.
- Check stored dahlias and pot up those that have begun to sprout.
- Prune back clematis vines, and sow Shirley poppies outdoors wherever you want them to bloom.
- Start seeds of slow-growing petunias indoors beneath lights.
- Root geranium cuttings.
- Late this month, cut back ornamental grasses.
- Prune apple trees and rake the orchard floor to interrupt the life cycles of insect pests.

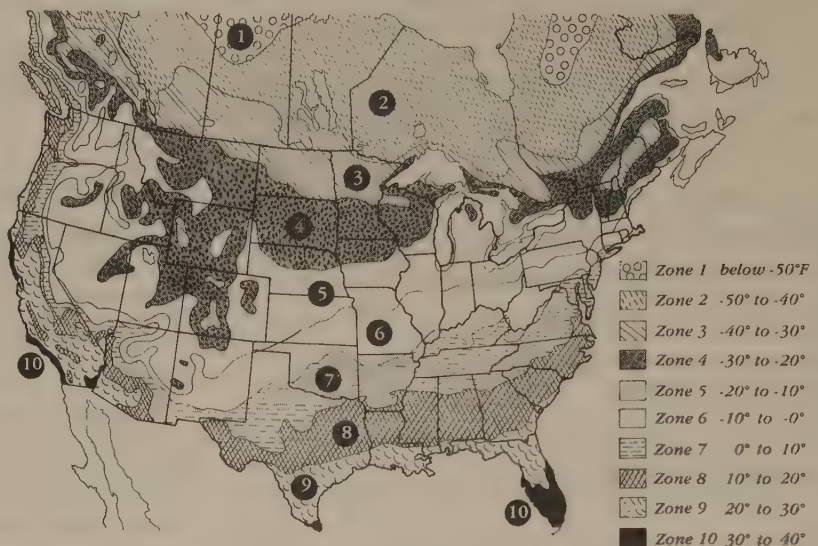
What's Your Zone?

Claire Kowalchik and William H. Hylton

The U.S. Department of Agriculture's plant hardiness zones are determined by the average annual frost-free days and minimum winter temperatures, and they're accurate in a general way. They are not specifically accurate, however. If you live on a high hill and face north, you may actually be in the next colder zone, while someone a few miles away in a sheltered, south-facing part of a valley floor could be in the next warmer zone.

Besides such local variations, there are national variations. Zone 6, for example, is as diverse as Maine and Nevada. Eastern Zone 6 is subject to lots of rain, and plants that like it moist will do well there. But the same plants may not do well at all in Nevada, where the land is thousands of feet above sea level and dry as dust.

Use the zones as a general measure of plant hardiness, rather than as a climate guide. You know your local climate, rainfall patterns, and environmental conditions better than any map.



Average Minimum Temperatures for Each Zone

Zone 7

- Start slow-growing lettuce and early tomatoes indoors under lights.
- Set seed potatoes in a warm place to encourage sprouting.
- Harden-off cabbage seedlings outdoors in a coldframe; toward month's end, plant them in the garden beneath cloches.
- Outdoors, sow peas and parsley near the end of the month.
- Mow winter cover crops and turn them under if the soil is dry enough to cultivate.
- Spread compost over beds that you will plant next month.
- Late in the month, prune hybrid tea roses hard, but give shrub roses only a light trim.
- Weed strawberries and blanket them with a row cover to encourage early bloom.

Zone 8

- Harvest asparagus spears all month!
- Plant potatoes and mulch them well. Pop onion sets or plants into fertile, well-drained beds.
- Late this month, direct-seed lettuce, endive, and other leafy greens in the garden, and prepare a bed for carrots.
- Start tomatoes and peppers indoors; as soon as the seeds sprout, move the flats or pots beneath bright lights.
- Weed and clean the garden beds where your pansies and other hardy spring flowers will soon bloom.
- Set out new roses, and heavily prune established hybrid tea roses.
- Expand your selection of small fruits! Plant figs, blackberries, blueberries, and strawberries. Also fertilize established fruits.

Zone 9

- Finish planting cabbage, celery, peas, and broccoli early this month.
- By midmonth, direct-seed beets, carrots, and leaf lettuce.
- Mulch potato plants.
- Thin leafy greens and water them regularly. Late this month, begin planting beans, cucumbers, and early sweet corn. Also sow annual herbs, such as dill, fennel, and basil.
- Indoors, be sure to keep tomato, pepper, and eggplant seedlings beneath bright lights.

Zone 10

- Sow bachelor's buttons, nasturtiums, and California poppies outdoors.
- Cut back ornamental grasses to the point where you see new growth.
- Plant muscadine grapes and figs. Mulch them well to keep the roots evenly moist.
- Control pest caterpillars on vegetables with *Bacillus thuringiensis* (BT).

March

Zone 3

- Start cabbage, celery, brussels sprouts, broccoli, parsley, onions, and leeks indoors under lights.
- Start hardy flowers, including snapdragons and pansies, right away.
- Late this month, start petunia seeds indoors; sow poppies and sweet peas outdoors in the garden (shovel snow first, if you must!).
- Toward month's end, get a jump start on salad season by sprouting spinach and lettuce indoors.

Zone 4

- Start cabbage, broccoli, cauliflower, parsley, and celery beneath lights.
- Trim the tops of onion and leek seedlings to an inch or so high, to keep them stocky.
- Late in the month, start seeds of head lettuce, eggplant, tomatoes, and peppers indoors.
- Sprout snapdragons, pansies, and dianthus indoors, then move the seedlings to a coldframe late this month.
- Begin to prune apples and pears.
- As snow disappears, begin covering strawberries with row covers to encourage early blooming.

Zone 5

- Put seed potatoes in a warm, bright windowsill to encourage them to sprout.
- Start tomato and pepper seeds indoors.
- Plant new asparagus and rhubarb beds; fertilize established ones with a blanket of compost.
- Prepare planting beds for cool-weather crops as soon as the soil is dry enough to work.
- At month's end, move broccoli, cabbage, and cauliflower transplants outdoors to a coldframe. If a hard freeze threatens, cover the frame with an old blanket.
- Sow sweet peas, poppies, and wildflowers directly into the garden late in the month.
- Finish pruning apples and grapes, and plant new fruit trees and bushes.

Zone 6

- Start tomato, pepper, eggplant, and basil seedlings indoors under lights.
- Move broccoli, cabbage, and cauliflower seedlings to a coldframe.
- Take a soil sample and have it tested; make the necessary adjustments, using compost and organic fertilizers.
- Start planting potatoes, peas, spinach, beets, carrots, and radishes late this month.
- Plant nasturtiums, alyssum, and other half-hardy annuals indoors.
- Take cuttings from geraniums and root them in small pots indoors.
- Finish pruning fruit trees, then follow up with a dormant-oil spray.

Zone 7

- Plant peas, potatoes, and parsley right away.
- Begin a new compost pile—using leftover leaves and kitchen scraps—if you don't already have a batch going.
- After the last hard frost, transplant cabbage, broccoli, and onions to the garden. Indoors, start seeds of tomatoes, peppers, eggplant, and basil.
- Sow carrots, chard, spinach, radishes, beets, and dill in the garden.
- Start harvesting asparagus!
- Pull winter weeds from flowerbeds, then direct-seed cosmos, rudbeckias, and nasturtiums.
- Plant roses, lilies, and all types of hardy ground cover plants.
- Fertilize strawberries with compost when the first blossoms show.

Zone 8

- Mulch potatoes with straw as soon as the fat sprouts emerge from the soil.
- Thin leafy salad greens to keep them growing fast.
- Make a second sowing of carrots, beets, chard, and dill early this month.
- After midmonth, sow cucumbers, bush beans, and early sweet corn.
- Fill in empty spaces in flowerbeds with direct-seeded cosmos, nasturtiums, and lavatera.

Continued ➔

- Set out gerbera daisies and other hardy perennials, such as roses, lilies, hardy groundcover plants, and woodland shrubs.
- Apply compost or other organic fertilizers to fruit trees and shrubs.

Zone 9

- Make your last sowings of carrots, beets, and heat-tolerant leaf lettuce, then start planting warm-weather crops.
- Start eggplant seedlings and sweet potato slips indoors.
- For quick color, sow cosmos and nasturtium seeds right where you want them to grow.
- Sow sunflowers and tithonia where their height will mesh with your garden design.
- Transplant salvias, marigolds, zinnias, celosia, gomphrena, and other annuals to flowerbeds and borders.

Zone 10

- Set out tomato and pepper transplants; plant basil, squash, corn, beans, cucumbers, and melons.
- Set out caladium corms in shady spots, or mix them with coleus in containers.
- Before slugs, snails, and pill bugs dig into your strawberries and leafy greens, defeat the pests with beer traps.
- Plant kiwi vines and avocado trees, and water new plants every few days to keep the roots from drying out.

April

Zone 3

- When weather permits, set out new asparagus and rhubarb plants.
- As soon as the soil is warm and dry enough to cultivate, begin planting onions, peas, spinach, carrots, lettuce, beets, chard, and radishes.
- Late in the month, start tomatoes, peppers, and eggplants indoors.
- Direct-seed poppies, alyssum, bachelor's buttons, cosmos, and calendulas anytime (they don't mind chilly soil).
- Remove winter coverings from peonies, then top-dress them with compost.
- Set out new strawberries.

Zone 4

- Harden-off cabbage, broccoli, and cauliflower seedlings for a week before setting them out in the garden beneath cloches.
- Sow spinach, lettuce, and radishes, then cover them with plastic tunnels to get them growing in a hurry.
- Start tomatoes, peppers, and basil indoors.
- Late this month, plant potatoes and peas.
- Set out snapdragons, dianthus, and pansies.
- Divide daylilies, phlox, and other clumping perennials.
- Fertilize raspberries with compost and renew mulches beneath blueberries.

Zone 5

- Harden-off cabbage, then set out plants beneath cloches.
- Plant potatoes, peas, and spinach, followed by carrots, lettuce, and other greens.
- Start basil, tomato, and pepper seedlings.
- Plant new beds of asparagus and rhubarb.
- Set out new shrubs and trees.
- Fertilize established fruits with a thin layer of compost.

Zone 6

- Plant peas, potatoes, spinach, lettuce, and other leafy greens.
- Set out kohlrabi and broccoli under cloches.
- Between rainy spells, prepare beds for bush beans, sweet corn, and other summer vegetables.
- Weed flowerbeds, and remove protection from roses and other perennials.
- Dig up, divide, and transplant crowded daylilies, phlox, and hostas.
- Overseed sparse areas in lawns.
- Set out new fruit trees and shrubs, and fertilize established berries.

Zone 7

- Sow more carrots and lettuce early this month, and mulch potatoes with 6 inches of straw.
- Set out a few early-ripening tomato cultivars beneath cloches.
- At midmonth, sow sweet corn, cucumbers, summer squash, and bush beans, as well as herbs.
- Set out annual flowers, and plant roses, dahlias, lilies, and glads.
- Fill the backs of sunny flowerbeds with tall sunflowers or tithonia.
- Propagate ground covers and hostas in shady areas.
- Set out blackberries and strawberries, and be sure to provide plenty of water.

Zone 8

- Check the brassica patch for cabbageworms; if you spot any, handpick them or apply *Bacillus thuringiensis* (BT).
- Set out tomatoes, peppers, and eggplant, and sow sweet corn, squash, cucumbers, and beans.
- Start sweet potato slips to transplant next month.
- Replace faded lettuce with okra, peanuts, field peas, or lima beans.
- Plant annual vines to shade heat-sensitive plants from summer sun.
- Top-dress roses with compost.
- Sow easy-growing annuals such as celosia, zinnias, and sunflowers.
- Late this month, thin peaches and plums to 6 inches apart.

Zone 9

- Replace spent spring crops with okra, asparagus beans, Malabar spinach, cherry tomatoes, and sunflowers.
- Cage tomatoes, peppers, and eggplant.
- Side-dress rows of garlic, shallots, and onions with compost.
- Late in the month, sow cantaloupe, pumpkins, and squash.
- Sow hot-weather flowers such as celosias, sunflowers, portulaca, and zinnias.
- Set out bedding plants, such as asters, coreopsis, impatiens, and salvia.
- Apply mulches!
- Harvest strawberries before slugs and snails beat you to it!

Zone 10

- Pull up bolted brassicas and leafy greens, and compost them.
- Try underplanting okra with sweet potatoes.
- Keep harvesting tomatoes, cucumbers, melons, and squash to encourage continued production.
- As parsley, coriander, and dill go to seed, replace them with plants of lemongrass, Cuban oregano, and Vietnamese coriander.
- Plant allamanda and other flowering vines as shade screens for decks, patios, and windows.
- Water and remulch beds frequently.

May

Zone 3

- Plant peas and potatoes.
- Harden-off cabbage-family seedlings and set them out at midmonth.
- Direct-seed lettuce, spinach, and root crops.
- Plant asparagus, rhubarb, and celery.
- Fill flowerbeds with pansies, cosmos, and petunias.
- Set out new berry plants.

Zone 4

- Plant peas and potatoes, and direct-seed parsley and kohlrabi.
- Get busy sowing lettuce, carrots, beets, and radishes.
- Start pumpkins indoors for planting next month.
- At month's end, sow beans, sweet corn, muskmelons, cucumbers, and squash; set out tomato plants under cloches.
- Plant new perennial flowers and sow seeds of cool-weather annuals such as nasturtiums and cosmos.
- Mulch fruit trees with compost.

Zone 5

- Plant peas and potatoes right away, followed by beets, lettuce, radishes, and spinach.
- Sow carrots and early cukes around midmonth.
- Toward month's end, plant corn, beans, muskmelons, squash, watermelon, basil, tomatoes, and peppers.
- Fertilize broccoli now to keep it growing fast.
- Thin leafy greens.
- Plant sunflowers and other colorful summer annuals.
- Plant roses and perennials by midmonth.

Zone 6

- Harden-off tomato and pepper seedlings for transplanting in midmonth.
- Sow basil, sweet corn, beans, cucumbers, squash, and melons.
- Plant leaf lettuce in the partial shade of taller plants.
- Thin leafy greens and use them in salads.
- Mulch potatoes.
- Top-dress roses with compost.
- Sow sunflowers, zinnias, marigolds, and other summer annuals.
- Wait for the fading foliage of spring-blooming bulbs to turn brown before you remove it.

Continued →

Zone 7

- Set out the last of your tomatoes, peppers, eggplants, and sweet potato slips.
- Be sure to harvest leafy greens often because they soon will bolt.
- Plant sweet corn, beans, melons, gourds, okra, and field peas.
- Keep mulching potatoes.
- Have *Bacillus thuringiensis* (BT) ready to apply at the first sign of caterpillar pests.
- Plant summer-blooming bulbs, such as cannas, glads, and tuberous begonias.

Zone 8

- If you expect a dry summer, install drip irrigation lines.
- Mulch everything!
- Stop watering onions, garlic, and shallots when the foliage begins to turn yellow.
- Set out sweet potato slips on a cloudy day.
- Plant okra, eggplant, peanuts, cherry tomatoes, field peas, and limas.
- Reseed sparse patches of lawn.
- Dig up and divide irises, daylilies, and Oriental poppies after they finish blooming.
- Thin fruits after the first "extras" fall from trees. Water all fruit trees and bushes during dry spells.

Zone 9

- Harvest remaining cool-season crops.
- Thin early sowings of corn and beans.
- Plant okra, melons, black-eyed peas, and jicama.
- Mulch beds if you haven't already done so.
- Begin pinching the tips of chrysanthemums and impatiens to encourage bushy growth.
- Fertilize late-blooming crape myrtles.
- Keep flowers, lawns, and roses well watered.
- When fruits begin to bloom, give them a booster feeding of fish emulsion.

Zone 10

- Plant only heat-loving edibles and ornamentals now, and water them often.
- Protect developing tomatoes and peppers from blistering and cracking by providing some shade.
- Keep tomatoes and peppers evenly moist.
- Remove faded flowers from annuals and perennials.
- Be sure fruit and nut trees receive enough water to prevent excessive fruit drop.

June

Zone 3

- Thin leafy greens and eat your thinnings.
- Harden-off and then set out melon and squash plants.
- Plant beans, cucumbers, and sweet corn.
- Get tomatoes and peppers into the ground by midmonth.
- Start brussels sprouts, cabbage, Asian cabbage, endive, and kale for fall.
- Brighten up beds with colorful warm-weather annuals such as marigolds, celosia, and impatiens.

Zone 4

- Plant the rest of your tomatoes, and set out peppers, eggplant, and basil.
- Sow more beans, sweet corn, leaf lettuce, and cucumbers.
- Midmonth, start seeds of cauliflower, broccoli, and brussels sprouts for the fall garden.
- Sow winter squash directly in the garden for a fall harvest.
- Near month's end, sow cilantro for the salsa you will make later this summer.
- Mulch blueberries and raspberries.
- Dress up drab corners with marigolds, zinnias, and other easy-care summer flowers.

Zone 5

- Mulch your potatoes.
- Trellis peas, and stake or cage your tomatoes.
- Make second plantings of bush beans and sweet corn.
- Sow pumpkin seeds for a Halloween harvest of jack-o-lanterns.
- Plant dahlias and gladioli bulbs, then stake them right away so that you don't damage the roots later.
- Midmonth, thin apples and peaches to 6 inches apart so the trees won't carry more fruits than the limbs can handle.
- Start seeds of brussels sprouts, broccoli, and cabbage for the fall garden.

Zone 6

- Stake or cage your tomatoes, mulch them, and remove any leaves that show signs of early blight.
- Set out sweet potato slips.

- Make second sowings of squash, cucumbers, sweet corn, and bush beans.
- When spring lettuce bolts, replace it with field peas, okra, or more tomatoes.
- When your peas are finished, replace them with pole beans, cucumbers, or asparagus beans.
- Pinch back chrysanthemums to make them bushy.
- Prune spring-flowering shrubs after they finish blooming.

Zone 7

- You still have time to plant heat-loving field peas, luffas, and asparagus beans.
- Start seeds (or root cuttings) of early-maturing tomatoes for a fall crop.
- Cut and dry bunches of thyme, oregano, and mint.
- Snake a drip irrigation line through your tomato patch before the plants begin to sprawl.
- Pull up cold-loving pansies when they succumb to the heat, and replace them with annual vinca, zinnias, or celosia.
- Water all of the fruit trees and bushes that you planted this spring.

Zone 8

- Harvest, weed, and mulch!
- Replace spring peas, lettuce, and potatoes with field peas, limas, or a summer cover crop of soybeans.
- Hand-pick Colorado potato beetles and other pests.
- Plant chrysanthemums, balsam, celosia, begonias, salvia, dusty miller, geraniums, vinca, and verbena.
- Harvest blackberries and blueberries.
- Mulch figs and muscadine grapes.

Zone 9

- Replace peas with beans, substitute Swiss chard for spinach, and put in taro after harvesting early potatoes.
- Start another generation of zinnias, sunflowers, and marigolds for late-summer bloom.
- Pinch back chrysanthemums.
- Water plants in the morning so they don't become susceptible to fungus and insect infestation.
- Solarize pests and diseases in vacant beds by wetting the soil, then covering it with clear plastic for about a month.

Zone 10

- On that rare cool day, create a new bed for fall greens. Cultivate the soil, add organic matter, wet the bed down, then cover it with clear plastic for at least a month to kill weed seeds and nematodes.
- Prune cassia trees, poinciana, bougainvillea, and jasmine after they bloom.
- Prune litchi, mangoes, and other tropical fruits after the harvest this month.

July

Zone 3

- Continue to direct-sow bush beans, carrots, turnips, and beets.
- Start your first fall runs of lettuce, spinach, and other greens in the shade of taller crops.
- Mulch your potatoes!
- Gather and dry basil, mint, and other herbs before they flower.

Zone 4

- Set out seedlings of broccoli, brussels sprouts, cabbage, and cauliflower for fall harvest.
- Direct-sow some bush beans.
- Sow leafy greens such as mustard, Chinese cabbage, turnips, and lettuce, placing them where they'll get some afternoon shade.
- Plant fall spinach late this month.
- Sneak some potatoes into empty spots to harvest as "new" this fall.
- Deadhead annual flowers to keep them neat.
- Trim and repot gangly houseplants.

Zone 5

- Hurry and plant more bush beans, cucumbers, carrots, and summer squash.
- By midmonth, set out seedlings of cabbage-family members for fall harvest.
- Sow fall lettuce, oriental greens, daikons, and snap, show, or shell peas.
- Gather and dry herbs and everlasting flowers.
- Mulch your potatoes again.
- Set out asters and mums and sow some fast-growing annual flowers in the vacant spaces of flowerbeds.

Zone 6

- Direct-sow carrots, beets, and chard.
- Stretch the season with midmonth plantings of cucumbers, bush beans, and squash.

Continued ➔

- By month's end, set out broccoli, cabbage, brussels sprouts, and cauliflower.
- Sow snap, snow, or shell peas.
- Plant any sprouted potatoes from your kitchen for a late crop of tender, new spuds.
- Water all fruits as needed through the harvest.
- Prune out old wood from raspberry and blackberry patches.

Zone 7

- Early in the month, sow a little more sweet corn and set out new tomato plants.
- Plant pumpkins and winter squash in a shady spot, but where the vines can soon run into the sunlight.
- During the second half of the month, start seedlings of broccoli, cabbage, cauliflower, and brussels sprouts indoors.
- Prepare beds for fall crops by sowing them now with a cover crop of fast-growing field peas or other legumes.
- Harvest blueberries and mulch strawberries heavily to protect them from heat and drought.

Zone 8

- You still have time to plant field peas, okra, limas, watermelon, and asparagus beans.
- Now's the time to solarize sick soil. Water empty beds, then cover them with clear plastic for at least a month.
- In the warmest parts of the zone, start tomato and pepper seedlings indoors.
- Set out chrysanthemums and pinch them back.
- Sow zinnias and sunflowers where you need late-summer color.

Zone 9

- Start tomato, pepper, and eggplant seedlings indoors for planting in fall.
- Outdoors, use old sheets or shade cloth to protect peppers and tomatoes from sunburn.
- Set out more sweet potato slips.
- In lower elevations, continue to plant corn, squash, beans, and field peas.
- In desert areas, prune back tomatoes by two-thirds.
- In humid regions, set out tropical vines and shrubs during rainy spells.
- Solarize empty beds that are infested with root-knot nematodes, or where diseases have been a problem.

Zone 10

- Direct-seed pole beans and limas, cantaloupes, collards, sweet corn, okra, southern peas, and watermelon.
- Indoors, start seeds of eggplant, peppers, and tomatoes now for the fall garden. Choose heat-tolerant cultivars, such as 'Heatwave'.
- Inspect passion fruit vines daily for caterpillars. When necessary, spray with *Bacillus thuringiensis* (BT), a natural caterpillar killer.
- Add everything you can to the compost pile. You'll need lots of humus to mix into the soil in fall.

August

Zone 3

- Finish planting your lettuce and spinach.
- At midmonth, pick off all tomato flowers so the plants' energy can be devoted to ripening fruits.
- Be ready to cover your tomatoes, peppers, and beans to protect against the first frost.
- Harvest everlasting flowers after a period of warm, dry weather.
- Renew mulches around roses, but stop feeding them.
- Prune out the oldest raspberry canes after harvest.
- Set out new strawberry plants.

Zone 4

- Water the garden as needed to keep everything growing fast.
- Make a last sowing of spinach and cold-hardy lettuce.
- Dig compost into beds before setting out Chinese cabbage and fall brassicas.
- Root cuttings of perennials and herbs to grow indoors this winter.
- Dig and divide irises and daylilies.
- Sow Iceland poppies and set out pansies for fall color.
- Protect grapes and late-bearing tree fruits from birds.

Zone 5

- Sow spinach, turnips, and cold-hardy lettuce for fall.
- Water the garden if it doesn't receive at least 1 inch of rain per week.
- If you want to create a new garden bed or rejuvenate an old one for next year, cultivate the space well and sow a cover crop of oats, rye, or ryegrass.

- Sow hardy biennial flowers, such as sweet William and forget-me-nots.
- Trim ragged tops of perennials that have finished blooming.
- Prune out old raspberry canes.
- Top-dress strawberries with compost.

Zone 6

- Plant a rainbow of lettuces, multihued radishes, and colorful kales for your fall salad garden.
- Plant plenty of spinach!
- Harvest potatoes, bulb onions, beans, and squash.
- Thin fall salad greens.
- Late this month, set out pansies for fall and spring.
- Sow Shirley poppies, larkspur, snapdragons, and sweet William.
- Collect seeds of favorite annual flowers.
- Water strawberries and transplant robust new runners.

Zone 7

- Early this month, start seeds indoors for the fall garden, including broccoli, cauliflower, cabbage, Chinese cabbage, and scallions.
- Sow carrots, beets, kale, and chard in the partial shade of taller plants.
- Make your last sowings of squash and cucumbers.
- Plant fall peas by midmonth, and set out brassica seedlings for fall harvest.
- When Labor Day is near, direct-seed kohlrabi, kale, and collards.
- Keep watering fall-bearing raspberries and everbearing strawberries; replenish their mulch as needed.

Zone 8

- Start some basil, cucumbers, and squash indoors and set the plants out a week after they sprout.
- Direct-seed bush beans, pumpkins, and sweet corn by midmonth, followed by peas and dill.
- Start carrots in a bed of loose soil.
- Prune back okra by one-third to encourage side shoots to bear.
- Start celery, broccoli, cabbage, and brussels sprouts indoors, then set out the seedlings when they have six leaves.
- Rake the orchard floor clean to interrupt the life cycles of pests.

Zone 9

- Sow watermelon early in the month, along with limas, southern peas, and sweet corn.
- After midmonth, begin setting out your tomato and pepper transplants.
- Direct-seed cucumbers, squash, and bush beans in partial shade.
- Plant basil and dill.
- Renew fading flowerbeds by filling them with fast-growing marigolds, zinnias, and annual vinca.
- Harvest tree fruits and use spoiled fruits as bait to lure green fruit beetles into narrow-necked jar or bottle traps.

Zone 10

- Set out tomato and pepper transplants after midmonth, then cover them with shade cloth to shield them from the summer sun.
- Start seeds of hardy perennials indoors, including pansies, gaillardia, and daisies.
- Direct-sow foxglove, larkspur, cosmos, and hollyhocks.
- Pinch chrysanthemums to encourage new blossoms.

September

Zone 3

- Before the nights get too cold, pick all of your mature green tomatoes and store them indoors to ripen off the vine.
- Harvest squash, beans, and other tender vegetables.
- Cook up big batches of tomato sauce for freezing or canning.
- On freezing nights, cover lettuce, cauliflower, broccoli, and carrots to stretch the season.
- Wait 'til after frost to harvest and savor kale.
- Plant tulips, daffodils, and other spring-flowering bulbs.
- Clean and repair tools before storing them for winter.

Zone 4

- Extend the season! Plant salad greens, such as spinach, winter lettuce, and kale, in a coldframe.
- Before the first freeze, harvest tender vegetables, such as tomatoes, peppers, and melons.
- Can or freeze the last harvests of sweet corn, tomatoes, and beans.
- Prepare to cover broccoli, cabbage, and cauliflower.
- Toward month's end, dig up potatoes, onions, turnips, and carrots.

Continued →

- Gather leaves and pine needles to use for winter mulching.
- Plant spring bulbs.

Zone 5

- Plant a fall salad garden of winter lettuce, spinach, and mâche in a coldframe or plastic tunnel.
- Remove the bottom leaves from brussels sprouts plants to direct energy to the sprouts.
- Harvest winter squash, pumpkins, tomatoes, and peppers before frost.
- Pick apples, pears, and other late fruits, then freeze or can them to enjoy this winter.
- Prune herbs and geraniums, pot them up, then set them on sunny windowsills indoors.
- Plant pansies and spring-flowering bulbs.
- Don't cut back ornamental grasses; enjoy their feathery foliage throughout winter.

Zone 6

- Save seed from your best plants of heirloom beans, tomatoes, squash, and melons.
- Gather up and compost all of your spent garden plants.
- Harvest broccoli, cabbage, cauliflower, and kohlrabi if they're ready; if not, prepare to cover them on freezing nights.
- Harvest apples, then rake the orchard floor to disrupt the life cycles of pests.
- Weed blueberries and raspberries, then mulch them with chopped leaves.
- Plant pansies, spring-flowering bulbs, and hardy perennials such as daylilies.
- Sow a fall cover crop in vacant vegetable beds.
- Clean and repair tools before storing them for winter.

Zone 7

- Continue planting spinach, lettuce, radishes, arugula, oriental greens, kale, and collards.
- Dig up sweet potatoes and peanuts while the weather is still warm; cure them before storing.
- Late this month, plant next year's garlic crop.
- Divide multiplier onions.
- Set out new strawberry plants.
- Start pansies, snapdragons, and sweet William from seed.
- Reseed and fertilize thin areas of fescue lawns.

Zone 8

- Set out brussels sprouts, kale, broccoli, cauliflower, and cabbage transplants; check them daily for leaf-eating pests.
- Direct-seed carrots, beets, lettuce, parsley, spinach, turnips, leeks, and kohlrabi; shade the beds until seeds germinate.
- Late in the month, sow sweet William, pansies, bachelor's buttons, poppies, and snapdragons.
- Plant trees and shrubs, then water them well weekly.
- Work compost into beds; replenish mulches.

Zone 9

- If scorching temperatures have eased up, set out tomato transplants by midmonth.
- Direct-seed snap beans, sweet corn, squash, and cucumbers.
- Late this month, start seeds of broccoli, kale, and cauliflower indoors.
- Toward month's end, sow peas, beets, and carrots in the garden.
- Direct-seed cold-hardy herbs such as parsley, chives, and sage.
- Have *Bacillus thuringiensis* (BT) ready to use if leaf-eating caterpillars show up on brassicas.

Zone 10

- Plant okra early this month.
- Set out transplants of tomatoes, peppers, and onions.
- Direct-seed cucumbers, melons, and squash, as well as herbs.
- Replenish mulches and soil amendments, such as compost.
- Prune poinsettias for holiday bloom.

October

Zone 3

- Clean up the garden and compost the residue.
- Finish harvesting cauliflower, cabbage, broccoli, beets, and turnips.
- Cover hardy crops, such as spinach, parsley, and kale, to keep them growing another month.
- Shred leaves, then use them for mulch.
- After the first hard freeze, cover perennials with a winter mulch of leaves, pine needles, or straw.
- Wrap the bases of fruit trees with chicken wire to protect against winter rodents.

Zone 4

- Time to harvest brussels sprouts, kale, parsley, and other hardy crops, or to prolong the harvest by covering them on cold winter nights.
- Store carrots in the garden all winter by removing the tops, then covering the bed with a foot of mulch.
- Brush white paint on young tree trunks to protect them from sunscald.
- Rake up fallen leaves, then mow or shred them. Wait until the ground freezes to use them as mulch over peonies, lilies, and other perennials.
- Scout your local garden center for bargain bulbs, then get them into the ground before month's end.

Zone 5

- Plant annual rye or winter wheat in vacant beds to prevent weeds and provide "green manure" for next season.
- Mulch carrots heavily to keep them from freezing.
- Cover salad greens with plastic on frosty nights.
- Harvest kale and brussels sprouts.
- Prune roses, rake up all their old mulch, then replace it by piling fresh straw or chopped leaves up to the lowest buds.
- Rake the orchard floor clean to interrupt the life cycles of pests and diseases.

Zone 6

- Gather up and compost all your withered garden plants.
- Harvest broccoli, cauliflower, cabbage, and kohlrabi as soon as they're ready, or be prepared to cover them on cold nights.
- Dig up sweet potatoes and harvest pumpkins and winter squash before the first hard freeze.
- Weed blueberries and raspberries, then mulch them with shredded leaves.
- Dig up and store tender bulbs and tubers, such as cannas, begonias, and caladiums, before the first frost.
- Cut back chrysanthemums and asters after the flowers fade, but wait until spring to move them.
- Plant spring-blooming bulbs.
- Set out new strawberries.

Zone 7

- Thin any spinach that you won't overwinter, and eat the thinnings.
- Cover broccoli and cauliflower on frosty nights.
- Plant garlic and multiplier onions. Set out evérgreen shrubs.
- Sow seeds of poppies, larkspur, blue flax, hollyhock, bachelor's buttons, and sweet rocket.
- Plant spring-flowering bulbs.
- Set out new strawberries. Stockpile leaves and pine needles.

Zone 8

- Sow more spinach and parsley, and thin leafy greens.
- Dig up sweet potatoes and peanuts, and cure them before storing.
- Keep the roots of tomato plants constantly moist; ripening fruits are less likely to crack after heavy rains.
- Plant bunching onions, regular onions, and leeks, and prepare a fertile spot for garlic.
- Replace summer flowers with hardy annuals.
- Lift and store caladiums.
- Go wild by direct-seeding wildflowers, such as gilia, black-eyed Susan, poppies, candytuft, cone flowers, and coreopsis.

Zone 9

- Direct-seed Chinese cabbage, spinach, lettuce, and radishes.
- Set out seedlings of the cabbage-family crops you started last month, and check them daily for pests.
- Harvest sweet potatoes, cure them, then store them.
- Color-up fall flowerbeds with alyssum, calendula, dianthus, snapdragons, and ornamental kale.

Zone 10

- Thin and water fall greens and root crops.
- Fill empty spaces in the garden with Chinese cabbage, beets, cauliflower, collards, broccoli, kale, turnips, and spinach.
- Set out new strawberry plants.
- Lightly fertilize citrus trees with compost or other organic fertilizer, and water them if rainfall has been low.

November

Zone 3

- Clean up the garden and compost the remains.
- Cover empty beds with a blanket of compost.
- Dig up carrots and parsnips before the ground freezes hard.
- Cover fall-planted pansies and snapdragons with evergreen boughs.
- Trim broken branches from trees.
- Rake the orchard floor, then add a fresh layer of mulch beneath young fruit trees and grapes.

Continued ➔

- Put chicken wire collars around the bases of fruit trees to protect them from rodents this winter.

Zone 4

- Compost spent plants.
- Dig up root crops before the ground freezes.
- After the ground freezes, cover perennials with mulch.
- Pot up some spring bulbs to force into winter bloom.
- Apply dormant-oil spray to apple and other fruit trees on a mild day.
- Paint the lower trunks of young trees to prevent winter sunscald.

Zone 5

- Harvest carrots, brussels sprouts, and cabbage and store them in a cool basement or unheated garage.
- Clean up the asparagus bed.
- If the weather cooperates, prepare a few beds now for early planting next spring, then cover them with mulch.
- Pop spring-blooming bulbs into beds if you haven't done so already.
- Mulch around pansies and other hardy flowers, but don't smother anything that's still green.
- Mow fallen leaves, then use them to mulch strawberries and blueberries.

Zone 6

- Harvest cold-weather-sweetened carrots, brussels sprouts, cabbage, and kale.
- Continue to thin lettuce and spinach.
- Hoard a mountain of leaves, then use them to cover beds for early-spring planting.
- There's still time to divide daisies and to direct-seed Shirley poppies, bachelor's buttons, and larkspur.
- Set out evergreen shrubs and trees.
- Weed strawberries and mulch bramble fruits with chopped leaves.
- Apply dormant-oil spray to fruit trees on a mild day.

Zone 7

- Start digging up winter carrots as soon as they are big enough.
- Harvest bunching onions, then plant more in a new site.
- Plant garlic.
- Gather blankets for covering lettuce and other half-hardy crops during the first hard freezes.
- Edge bulb beds with overwintering pansies for a nice look next spring.
- Trim back faded mums late in the month. Thin larkspur and poppy seedlings, and move bachelor's buttons.
- Harvest pecans.
- Use fresh pine needles to mulch strawberries and brambles.

Zone 8

- Harvest beans, tomatoes, peppers, and other tender crops before the first frost.
- Begin to harvest fall cabbage, broccoli, and brussels sprouts after cold weather arrives.
- Plant garlic, and dig and divide multiplier onions.
- Sow winter cover crops.
- Gather and bag leaves to use as mulch throughout the rest of the year.
- Lift caladium corms and store them in damp sand or vermiculite.
- Set out pansies, dianthus, snapdragons, and ornamental kale.
- Use fresh pine needles to mulch azaleas.
- Trim damaged branches from trees.

Zone 9

- Harvest squash, cucumbers, and your first fall tomatoes.
- Start planting your winter garden: Set out seedlings of cabbage, celery, and broccoli.
- Direct-seed peas, beets, carrots, lettuce, Chinese cabbage, spinach, and chard.
- Renew the herb garden with fresh plants.
- Dress up flowerbeds with some new starts of alyssum, calendula, and dianthus.
- Direct-seed bachelor's buttons, cosmos, and hollyhocks.

Zone 10

- Plant more cool-weather greens, such as lettuce, spinach, and Chinese cabbage.
- Late this month, prune back a few peppers and eggplants—they'll bear an early crop next spring.
- Harvest sweet potatoes.
- Fill empty patio pots with petunias.
- Plant tropical bulbs, such as freesias and sparaxis.
- Keep citrus fruits well watered and check often for bird damage.
- Spray *Bacillus thuringiensis* (BT) on brassicas as soon as you spot leaf-eating caterpillars.

December

Zone 3

- Pot up a few more bulbs to force into bloom for early spring, and move those that already have sprouted into bright light.
- Check stored vegetables for signs of spoilage.
- Wrap the bases of fruit trees with wire mesh to protect them from hungry rodents.

Zone 4

- After the soil freezes, mulch over the crowns of perennials to keep them from heaving out of the ground during winter thaws.
- Pot up some spring bulbs to force into bloom; keep them cold (but not freezing) until they sprout.
- If whiteflies and mealybugs are attacking your houseplants, set the plants in the shower and wash your troubles down the drain.
- Inspect stored fruits, bulbs, and corms for signs of spoilage.
- Check the bases of tree trunks for mouse marks; encircle the trunks with wire mesh to prevent further damage.

Zone 5

- If you've run out of straw to cover carrots, parsnips, and salsify in the garden, dig up these root crops and store them in a cool basement.
- Harvest brussels sprouts and cabbage plants, roots and all; they'll keep for weeks that way if stored in a cool basement or root cellar.
- Cover parsley with milk jug cloches, then surround the covers with insulating leaf mulch.
- Protect overwintering spinach with row covers.
- Wrap chicken wire cages around young fruit trees to protect them from deer.
- Before the ground freezes, dig planting holes for any trees you intend to plant in late winter.

Zone 6

- Cover perennial flowers, as well as pansies and snapdragons, with evergreen boughs to protect them from ice and harsh winds.
- Harvest brussels sprouts and cabbage.
- Mulch empty vegetable beds with chopped leaves.
- To enjoy spinach throughout winter, cover the plants now with a plastic tunnel.
- Rake up all fallen apples and apple leaves to stop the spread of scab and other orchard diseases.
- On a mild day, apply dormant-oil spray to smother scale and other sap suckers.

Zone 7

- Harvest brussels sprouts, kale, cabbage, and collards.
- Mulch Jerusalem artichokes, carrots, parsnips, and other crops that will spend winter underground.
- Spread mulch over beds where early spring crops will grow.
- Turn compost one last time, then cover it with a tarp to prevent nutrients from leaching away during winter rains.
- Dig, divide, and replant crowded bulbs. Continue setting out hardy annual and perennial seedlings, then cover them with cloches.
- On a mild day, apply dormant-oil spray to smother scale and aphids.

Zone 8

- Harvest frost-sweetened spinach, kale, and collards.
- Pile compost and leaf mulch on vacant garden beds.
- Near the end of the month, start seeds of cabbage and hardy lettuces indoors.
- Plant spring-blooming bulbs.
- Direct-seed sweet peas, larkspur, Shirley poppies, and bachelor's buttons.
- Continue planting pansies, dianthus, and snapdragons.
- Prune roses, then replace their old mulch with oat straw to discourage black spot.

Zone 9

- Plant cool-season vegetables, such as lettuce and cabbage-family crops. Be patient—they grow slowly during winter's short days.
- Around month's end, start seeds of tomatoes, peppers, and eggplant indoors.
- Direct-seed poppies, bachelor's buttons, nigella, cosmos, and larkspur in well-drained beds.
- Apply a fresh layer of clean mulch to berries and grapes.

Zone 10

- Plant all sorts of greens, beets, carrots, and peas.
- Around month's end, start seeds of tomatoes, peppers, and eggplant indoors.
- Pop bedding plants, such as pansies, dianthus, and snapdragons, into both containers and empty spots in beds.
- Plant ornamental shrubs and trees.
- Enjoy your homegrown citrus fruits.

SOIL

Digging In: Creating Good Homes for Plants

Barbara Pleasant

Getting to Know Your Soil

The plants in your garden depend on the soil for their survival, because it's where they get the water and nutrients they need. You can keep plants alive in lousy soil, but why spend all your time pumping them with water and fertilizer when healthy soil can take care of a lot of that work for you?

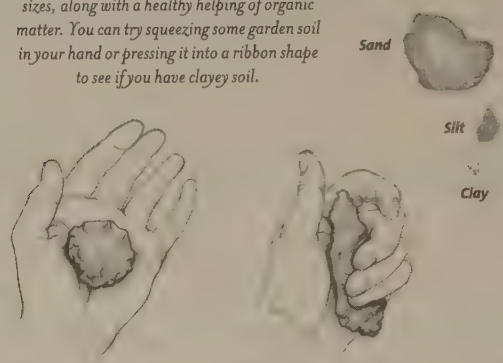
TAKE A TEST

Whether you are new to gardening or have been at it for years, a soil test from a laboratory gives you priceless insight into your soil. Numerous factors determine a soil's basic characteristics—from the kind of rock from which it was formed, to rainfall and temperature patterns, to how the previous owner cared for it. Bulldozers move soil around when houses are built, so it's possible that your yard includes several different types of soil. If so, you may need more than one soil test.

For a reliable test, obtain a soil test bag or box through your local cooperative extension office, or contact the soil lab of the agricultural college in your state or province. The bag or box comes with instructions for collecting a sample, which is a simple matter of digging a 4-inch-deep hole and collecting a handful-size sample. When you fill out the information form to mail in with the sample, be sure to specify that you want organic gardening recommendations. The test results will include an analysis of your soil's available nutrients, organic matter content, and pH—all of which will change as you improve your soil.

THE QUESTION OF TEXTURE

One soil characteristic that will change very slowly, and never be radically altered, is your soil's texture. Texture is determined mostly by the size of the soil particles. Sand particles are large, so sandy soil has a light, loose texture, whereas clay particles are very small, so clay soil is comparatively heavy and tight. Intermediate-size particles, such as silt or bits of organic matter, modify extremes in these two soil types. If you are lucky, your soil is either "sandy loam" or "clay loam"—meaning it's basically sand or clay with lots of silt and organic matter. Most gardeners are not so lucky and face the task of improving their soil's texture by adding organic matter. More important, understanding your soil's texture helps you tailor your gardening practices to bring out the best in your soil's hidden talents.



Good soil is a mix of mineral particles of various sizes, along with a healthy helping of organic matter. You can try squeezing some garden soil in your hand or pressing it into a ribbon shape to see if you have clayey soil.

The Scoop on Sand

Very sandy soil drains fast, which is generally good. At the same time, fast drainage means that dissolved nutrients may drain away before plant roots have a chance to absorb them. Sand particles are also slippery, so nutrients don't bind to them. Because sand particles are large, the spaces between them also are quite roomy. For this reason, sandy soil does not need to be cultivated often since its air-holding capacity is already excellent. It does need to be continually enriched with organic matter, which will enhance its ability to hold onto nutrients from fertilizer. If you garden in sand, heavy mulching is so practical and useful that it should become a fundamental method in your soil-care practices.

Working with Clay

Tiny clay particles pack so tightly that they trap water and stay wet, so plant roots may find it difficult to push their way through the soil, and then be dissatisfied with constant wetness. On the plus side, clay soils hold nutrients well, so rich forms of organic matter added to clay soil may nurture plants for a long time. Clay soil responds well to cultivation—which introduces much-needed air—as long as you dig or till it only when it is lightly moist to dry. If you add in compost or other soil amendments each time you replant in clay soil, over time you will see a steady lightening of your soil's texture. Avoid walking on clay soil, which compacts it by squeezing out air.

Sweet and Sour Soil

In some regions, the chemical composition of the soil makes the water in the spaces between the particles acidic—think vinegar or lemon juice. In other regions, the soil is alkaline, also called sweet or basic. The measure of the acidity or alkalinity is called

What about Manure?

For thousands of years, gardeners have used animal manure to enrich their soil with organic matter, nitrogen, and other plant nutrients. Yet modern farming methods give gardeners good reason to think twice before using manure, which may contain undesirable chemicals, weed seeds, and potentially dangerous bacteria such as *E. coli*. If you can get manure from organically raised animals, and compost it completely, manure can be a valuable soil amendment. A less risky option is to limit your use of manure to organic fertilizers (many of which contain poultry manure) that have been processed to rid them of potential contaminants.

the pH. Distilled water, with a pH of 7, is neutral. Acidic soils have a pH less than 7, while alkaline soils are above 7.

Soil pH is important because it determines what nutrients are available to plants. Some nutrients are tied up in unavailable forms at certain pH levels, while others may be overabundant to the point of toxicity. Most plants thrive in soil with a pH between 6 and 7.5. A few, such as blueberries and azaleas, require a more acidic soil.

An inexpensive home pH test kit will give you a general idea of your soil's pH, but a soil test is more precise and reliable.

- If your soil is acidic, you can nudge it toward neutral by mixing in ground-up limestone, simply called lime. Lime is available as a powder, or in easy-to-use pellet form. Adding lime does not give instant results, so it's important to mix it in and allow rain to move it through soil crevices before planting seeds or plants.
- Alkaline soils are harder to modify, and the first step is to add acidic soil amendments such as leaf mold or peat moss. In addition, you can add elemental sulfur as a powder or granules, which will further lower the pH.

Whether your soil is acidic or alkaline, adding organic matter regularly will help bring the pH closer to the neutral mark.

Making Plant-Friendly Soil

Armed with knowledge of your soil texture and pH, you can choose wisely among the methods and materials available for improving it. When you continue the soil-improvement process season after season, it often gives amazing results. Keep in mind that it took thousands of years to form the soil, and it can take several years to transform dead dirt into dream soil. You'll begin to see some improvement right away, and your plants will reflect their satisfaction by showing steady, sturdy growth.

Regardless of your soil's type, the main way to make it better is to increase its organic matter content. Organic matter is made up of decaying plant and animal materials, such as leaves, roots, dead insects, animal droppings, and just about anything else that was once alive and is now dead. There are four main ways to increase your soil's organic matter content: digging in soil amendments, growing green manures, using organic mulches, and recycling garden and kitchen wastes into soil-building compost. The projects in this chapter provide fun and practical ways to explore each of these options, so you can tailor your choices to suit your personal tastes.

UNDERSTANDING ORGANIC MATTER

Most natural decomposition takes place at the soil's surface, so topsoil contains more organic matter than deeper subsoil. The organic matter content of unimproved topsoil usually hovers around 3 percent, while loamy garden soil contains three times as much. Organic matter feeds a host of soil-dwelling organisms, both large and small—earthworms, insects, fungi, bacteria, and the like. The activities of these organisms enhance the soil both physically and chemically. Earthworms, for example, make tunnels that loosen the soil and improve aeration. Their excretions, called castings, are rich in readily available plant nutrients. Enzymes, acids, and other chemicals result from the biological activities of smaller soil microorganisms. These chemicals become nutrients that are used by plants.

Earthworms and other soil-borne life-forms need oxygen to do their work, so a second function of organic matter is to help hold air in the soil. When you improve soil by adding organic matter, you are creating a better home for plants as well as the organisms that form the foundation of a healthy soil community.

THE SCOOP ON SOIL AMENDMENTS

A soil amendment is a material that you mix into the soil to instantly raise its organic matter content. You can buy soil amendments in bags at garden centers, or you can buy them by the truckload. Sometimes you can scare up a local supply that's free for the taking, such as decomposed peanut shells, cocoa bean hulls, or ground, composted corncobs. Six of the most widely available soil amendments—and how to use them—are described in the "Six Inexpensive Soil Amendments" chart.

It's convenient to buy bagged soil amendments, especially if you're in a hurry to create a new garden bed. But what exactly is in those bags of compost, humus, or soil conditioner? You may need to buy a few sample bags to find out, because what one company calls compost may be remarkably similar to what another calls humus. Here is what you are likely to find inside.

Continued →

Make a Micronutrient Spray

Not all plant fertilizers come in bags, bottles, or jars. Compost is loaded with micronutrients, so it's the perfect starter material for a nutritious foliar-feed spray. Use your compost to make this nutrient-rich tonic.

1. Place 1 gallon of finished, crumbly compost in the bottom of a 5-gallon bucket. Fill the bucket to within 3 inches of the brim with lukewarm water. Stir to combine the compost and water, and cover the bucket with a piece of cloth.
2. Let the compost steep for up to a week, stirring occasionally.
3. Strain out the solids through a piece of window screening. Allow the mixture to settle, and strain again through a double thickness of cheesecloth. Add a few drops of dishwashing liquid to help the mixture stick to plant leaves, and apply it using a clean pump spray bottle.

- Composted yard waste is made mostly from leaves, which are gathered in the fall and piled into huge heaps, which are turned and watered until they decompose into a soft, fluffy, dark brown to black compost. These products are an excellent choice, because the material still has a little way to go before it is completely decomposed. Purchasing them also supports the recycling of materials that might otherwise end up in landfills.
- Humus can be just about anything, but it often includes blackened chunks of nearly decomposed wood and bark—waste gathered from lumber mills that is mixed with a little soil and then composted. Chunky soil amendments often persist longer in tight clay soil, but they do not give the fast results you are likely to see with finer materials.
- Soil conditioner is a catchall term used on the labels of a range of products. They often are topsoil gathered from floodplains, where the soil is naturally high in organic matter, mixed with other types of compost.

The best advice: Experiment with various products, avoid those that smell rotten or sour, and choose products with light, fluffy textures over those that are heavy and dense.

Once you have a soil amendment, the next step is simple. Spread it over the site you want to improve, and dig it in with a spade or digging fork, lifting and turning until the amendment and the soil are nicely mixed. If you make a habit of digging in organic soil amendments each time you replant a bed or row, your soil will be well on its way to becoming a fertile, fluffy, well-drained medium that is sure to please your plants.

Keep in mind that soil amendments are not the same as fertilizers. Organic fertilizers do add organic matter to the soil as they decompose, but their primary purpose is to provide nutrients.

Health Food for Plants

Organic fertilizers contain such a huge range of ingredients that it's difficult to make generalizations as to what you will find in the package. Like synthetic fertilizers, organic fertilizers include three hyphenated numbers on the label, for example 6-4-4, which is called the fertilizer analysis.

- The first number stands for nitrogen, the main nutrient plants need to make new growth.
- The second number stands for phosphorus, an essential nutrient for vigorous root and bloom development.
- The third number stands for potassium, which supports good overall plant functioning.

Animal by-products are a good natural source of nitrogen, so organic fertilizers with a high first number tend to be based on processed manure from poultry, bats, or even crickets. Fish-based fertilizers also are often rich in nitrogen, as are fertilizers that contain ground cotton or alfalfa seeds. To boost their phosphorus and potassium content, dry organic fertilizers often include pulverized rocks, such as rock phosphate or greensand, a sedimentary, gritty silicate rich in iron and potassium. Powdered seaweed, or liquid seaweed extract, helps to round things out by providing trace nutrients.

USING ORGANIC FERTILIZERS

There is no single perfect organic fertilizer, and it can be fun to experiment with different products in search of one that is a good fit for your soil, plants, and style of gardening. Always follow the application rates given on the label, because using too much of an organic fertilizer can damage plant roots and cause unnecessary water pollution. If you have very good-quality soil, you may need less fertilizer than the product's label suggests.

When using powdered or granular organic fertilizers, it is also important to thoroughly mix them into the soil. Organic fertilizers do not dissolve rapidly, so inadequate mixing can cause "hot spots" to form around plant roots.

Organic fertilizers break down slowly when soil temperatures are cool, and release more nutrients in warm soil. Sometimes weather conditions cause the sudden release of nutrients, so it's important to watch your plants for signs that they need more or less fertilizer. Underfed plants grow slowly, show pale leaf colors, and may begin blooming while they are still quite small. Overfed plants develop lush stems and leaves, and may produce few flowers and fruits.

SUPPLEMENTAL LIQUIDS

The slow, steady release of nutrients you get with blended organic fertilizers is fine for most plants. If you suspect that a plant is not getting enough nutrients, you can deliver fast relief in the form of a nitrogen-rich, water-soluble organic fertilizer, most of which are made from fish by-products. These nutrients are immediately available to plants, so liquids are good to have on hand—especially if you are growing a "heavy feeder" like spinach or broccoli in cool soil, or when growing anything in soil that's in the early stages of improvement. Plants get 14 nutrients from the soil, but when they are in need of nutrients, they also can take them up through their leaves. For this reason, be sure to drench both the leaves and roots when giving plants a booster feeding with a liquid organic fertilizer.

Fish-based fertilizers provide abundant, ready-to-use nitrogen, but you may want to feed plants nutrients other than nitrogen in a fast-release liquid form. Kelp and seaweed-based products contain plenty of potassium, but their greatest strength lies in their ability to provide micro nutrients and other growth-enhancing substances. Seaweed sprays are increasingly popular among tomato growers, and trees and shrubs may root a little faster when soaked briefly in water with a little kelp mixed in. Pepper and rose gardeners often supplement their plants' diets with weak Epsom salt sprays (1 tablespoon per gallon of water); Epsom salt is a good source of ready-to-use magnesium and calcium.

THE WHOLE GARDEN APPROACH

Don't let this discussion of fertilizers make you think you need to regard your garden as a giant chemistry set. Instead, simply approach soil as a living thing that needs care and nurturance. Healthy soil that contains plenty of organic matter does a superior job of retaining both nutrients and water, so the better your soil becomes, the less concerned you will need to be about the details of plant nutrition.

Six Inexpensive Soil Amendments

Material	What It Does	Special Attributes	Risks
Homemade compost	Increases organic matter and provides some major plant nutrients, along with many minor nutrients and enzymes that support strong growth.	The huge range of beneficial fungi and bacteria in compost made from yard and kitchen wastes can help suppress soil-borne diseases.	Weed seeds and some plant diseases can survive in compost that does not heat up as the materials rot.
Commercial compost	Increases organic matter and provides some major plant nutrients, which vary with the material used to make it.	Usually rich in beneficial fungi and bacteria. Large-volume processing creates high heat that kills most weed seeds.	Compost from community yard waste projects can contain slugs or unwanted debris, so check it carefully.
Mushroom compost	Quickly increases organic matter and overall soil fertility.	Usually made from manure-based compost, further "processed" by fungi (mushrooms), which break down potential contaminants.	Unpleasant odor disappears after several days. Working with heavy mushroom compost is often quite messy.
Spoiled hay	Increases organic matter, provides a few plant nutrients, and lightens soil texture by helping to hold in air.	Improves the way the soil handles both air and water due to the strawlike structure of grass stems, hay's main component.	Often contains dormant weed seeds, as well as fungi that can cause respiratory irritation. Wear a dust mask when handling spoiled hay.
Leaf mold	Increases organic matter, improves drainage, and lightens soil texture while enhancing water retention.	Weed free and easy to make at home. Kept moist, shredded leaves become leaf mold in 1 to 2 years.	Tends to acidify the soil's pH, which can be offset by adding lime. Clumps may need to be pulverized to make leaf mold easier to mix into soil.
Rotted sawdust or wood chips	Increases organic matter, lightens soil texture.	Very slow to decompose, which is useful in clay soils in warm climates, where more fine-textured soil amendments disappear quickly.	If not well rotted, may temporarily decrease available nitrogen in the soil. Additional fertilizer may be needed to offset this effect.

Getting to Know Your Soil

Soil is wonderfully alive. If you're new to organic gardening, that statement may surprise you. But beneath the surface, healthy soil is full of organisms that interact in a finely tuned living system. Explore your soil. Learn about its texture and structure, and meet the tenants that live there, too. You'll find there's a lot that your soil and its inhabitants can do for your garden—with just a little help from you.

Dig In and Learn

Unless you're the lucky owner of an old farmstead, you probably don't have great soil in your yard and garden. The soil around most modern homes is in trouble, either because of damage during construction or neglect by past owners. But how do you decide what your soil really needs? What would benefit your plants most? And where do you begin?

Get to know your soil. Once you start digging around, you'll find there's more to it than meets the eye. Healthy soil has lots of life in it, a good balance of nutrients available for plants' use, and a loose, open structure. The way you manage and work the soil affects all these aspects of soil health. This chapter introduces some of the organisms you may meet when you take a closer look at your soil. It also explains how to do a few simple tests that can tell you a lot about what's happening in the soil beneath your gardens, lawn, and landscape.

Discover which soil critters are good ones and which ones are bad news. Learn about the structure, texture, drainage, and pH of the soil that surrounds your home. Equipped with this knowledge, you can begin to make smart choices about the soil-care techniques that make the most sense for you, your gardens, your lawn, and your landscape.

The Good Guys in the Ground

As you dig into your soil and become more familiar with its characteristics, you'll undoubtedly encounter some of the many insects and other creatures of all sizes that dwell in the soil's depths. Although they make up only a minute portion of the soil by weight and volume, these living organisms play a vital role in the soil's health. When you meet any of the soil dwellers mentioned on this page (and on the next), squelch your impulse to squash, and let them go safely about their business. These are just a few of the good guys who give gardeners a helping hand in exchange for their housing in the soil.

When you see **fireflies** (*Photuris species*)—commonly called "lightning bugs"—twinkling on a summer evening, be glad for their hungry, soil-dwelling larvae. Resembling sowbugs, firefly larvae prey on slugs, snails, cutworms, and mites. The larvae live in the soil for one to two years before pupating inside a hard brown casing. Firefly adults emerge after about ten days and live for up to one week.

Many of the more than 3,000 species of ground beetles in North America prey on slugs, snails, cutworms, and caterpillars, but few are as voracious as the inch-long and extremely beneficial **fiery searcher** (*Calosoma scrutator*). Fiery searchers can live up to three years, and the adults will often climb trees in search of tent caterpillars to eat!

Millipedes (*Diplopoda* family) can range from ½ to 1½ inches long and move very slowly. Most feed only on decaying plants, breaking them down into organic matter for your soil. As predators, millipedes can eat many kinds of soil insects.

Down-'n-Dirty Soil Dwellers

Of course, not every insect you turn up with your shovel is a beneficial. And it pays to recognize the bad guys when you run into them, if only because it gives you the option of tossing them out onto bare ground where a hungry bird can find them.

Cabbage maggots (*Delio rodicum*) tunnel into the roots and stems of cabbage and related crops, causing wilting and generally poor productivity. The ¼-inch-long cabbage maggots can survive the winter as pupae in the upper layers of the soil; you can make them freeze to death by cultivating the soil in late winter to expose them to the air.

Symphylans (*Scutigerella immaculata*) are pests that eat the roots of asparagus, cucumber, lettuce, radish, and tomato seedlings. Sometimes called "garden centipedes," symphylans resemble true centipedes but are only ¼ inch long with 12 pairs of legs. Fortunately, symphylan populations rarely reach damaging levels. True centipedes are larger and darker with 15 or more pairs of legs and are beneficials that prey on pest insects and mites.

The **June** or **May beetle grub** (*Phyllophaga species*) feeds on the roots of strawberries and potatoes during the spring and summer and can grow as big as 1 inch long. The grubs may remain in the ground for two years or more before emerging.

There are many different kinds of cutworms, but perhaps the most troublesome and widespread in North America is the **army cutworm** (*Euxoa auxiliaris*). At over 1 inch in length, cutworms are hefty opponents for gardeners trying to protect

Do a Lawn-to-Garden Turnover

If your yard has too much lawn and not enough garden, turn things around by rolling up the turf like a rug.

Why not just till in the grass? Many lawn grasses can't be killed by simply turning them under, and the plant parts that do die will tie up soil nutrients as they decompose. Turf also hosts cutworms, grubs, and other insects that coexist peacefully enough with grass but can devastate tender seedlings. Removing the sod, along with a thin layer of soil, reduces these risks.

Sod is heavy, so begin by cutting the turf into smaller squares. It's easiest to peel sod from moist soil, so be sure to water the area lightly the day before you start this project. Also make appropriate plans for the sod you remove. If it's healthy, you can use it to patch thin areas in other parts of your lawn, or put it to work filling in low spots. Sentence weedy patches to your compost pile.

You Will Need

Tools:

Measuring tape, work gloves, garden spade, garden cart or wheelbarrow, digging fork, sturdy bucket, garden rake.

One 2-pound bag of all-purpose flour

10 cubic feet of compost (about four 40-pound bags)

1. Use the flour to mark a 4 x 6-foot rectangle on the sod you want to remove. Mark additional lines within the space to divide it into 16-inch-wide squares. Wearing shoes with thick soles, use the spade to cut straight down through the lines of flour.
2. Starting at a short end of the rectangle, push the spade into the soil diagonally around all edges of a square of sod. Firmly grab the two outside corners of the square and flip it over toward the inside of the rectangle. Use the spade to lightly chop into the soil to loosen attached clumps. Lift the square of sod straight up, shake out the loosened soil, and then place the sod in the wheelbarrow. Repeat this procedure with the remaining 15 squares.
3. Use the digging fork to loosen the soil to a depth of 10 to 12 inches. Remove large rocks or roots and place them in the bucket.
4. Spread the compost over the soil, raking it into a 4-inch-deep layer. Use the spade or digging fork to mix the compost into the soil, breaking up clods of soil as you work. You will probably need to turn the soil over twice. Rake the enriched soil smooth with the rake, and get ready to plant.

young plants. The cutworms feed just below the soil surface (or just above it), severing the stems of seedlings and transplants. Dig in the soil around the base of an injured plant and you're likely to find this culprit.

Down where your root crops live, you'll find the ½-inch-long adult **carrot beetle** (*Bothynus ligyrus*), which feeds on the stems and roots of beets, carrots, parsnips, and potatoes.

The small—only ¼ inch long—**subterranean termite** (*Reticulitermes* species) eats the decaying roots of plants and trees and builds tunnels in wood, which can include your house.

Northern mole crickets (*Neocurtilla hexadactyla*) are mostly destructive, chewing up the roots of crops, eating seeds, and severing the stems of tender transplants. But these 1- to 1½-inch-long crickets also eat other insects.

Colorado potato beetle (*Leptinotarsa decemlineato*) adults and grubs feed on the leaves of potatoes, eggplant, and related crops and spend their winters underground. The adults are ⅓ to ½ inch long, and the grubs are somewhat smaller.

Lawns are the favorite feeding ground for the grubs of the **Japanese beetle** (*Popillio japonica*), so you're most likely to see the ¾-inch grubs when you turn over sod for new garden plots. Treating your lawn with milky disease spores is a safe, long-term control for these pests.

The Wonder of Worms

It's easy to take earthworms for granted because they work out of sight, deep within the soil. But in a year, an acre of worms can move 20 tons of earth. Simply by tunneling through the soil, worms break up compacted earth so that air and water can circulate more freely. They chow down on dead leaves, bits of soil, rotting plants, and other nourishing debris (collectively called organic matter), grinding the material in their gizzards. What comes out the other end is a magical elixir that increases the amount of nutrients and minerals in the soil by as much as ten times the value of the plant debris there.

Worm droppings, known as "castings," are the richest food your plants' roots will ever find. Worm action also creates great texture in soil. As the worms turn raw organic material into humus, the soil becomes moist, loose, and more like the ideal loam plants love. If your soil is healthy, it will be full of earthworms.

Continued →

Worm Math

To get an estimate of the earthworm population in your soil, dig a hole 8 to 10 inches deep and a foot wide and count the number of earthworms you find in the soil you remove. More than ten earthworms is great, and six to ten indicates a moderately healthy soil, but if you have less than five you need to do some serious work on the soil! This could be an indication of low organic matter, pH problems, and/or poor drainage.

If your earthworm count is low, don't despair. Once you provide more organic material to feed them, they will return. Healthy soil can contain about 1.5 million worms per acre—even more reason not to underestimate the importance of these ambitious decomposers. And if you think that number sounds surprisingly high, consider that worms multiply extremely quickly—producing upward of 2,000 to 3,000 offspring per worm per year.

Hands-On Texture Tests

Pick up a handful of soil. Is it gritty? Sticky? Smooth or greasy? How your soil feels when you hold it in your hand is a function of its texture. Texture refers to the relative amounts of the different-size mineral particles in the soil. Clay particles are the smallest, silt particles are somewhat larger, and sand particles are the biggest.

But these different types of particles do more than make the soil feel a certain way when you stick your toes into it. The size of the particles determines how tightly they bind together and, therefore, how much space there is in the soil for air and water—and for growing roots.

Learning what texture your soil has is as easy as picking up a handful of soil and squeezing it. Start with this simple test: When the earth is moist but not wet, take a loose ball of soil about the size of a golf ball in the palm of your hand. First, squeeze the ball in your hand and release. If it crumbles, it has a reasonably balanced texture. If the soil ball holds its shape, it has a substantial percentage of clay.

Balancing the Soil

Fern Marshall Bradley

Organic gardeners should get down to ground level before they launch their planting plans. Soil care is the heart of the organic method. Fortunately, organic soil care is just a matter of following a few simple principles. The most important one is to build the organic matter content of the soil. In this chapter, you'll find expert tips on just that, as well as on evaluating the soil, cultivating, and dealing with soil problems.

Sizing Up Your Soil

A good first step is to get to know the soil in your garden. Since it probably won't be too talkative, we asked the experts to explain how to get the most from professional soil tests and how to try simple do-it-yourself tests to learn more about your soil.

TAKE YOUR BEST SOIL TEST

If you opt for a professional soil test, keep in mind that the test will only be as good as the sample you submit for testing. "Collecting a good representative soil sample isn't as easy as it looks," claims Vernon Meints, Ph.D., a co-owner of Agri-Business Consultants, a Michigan independent crop consulting firm. Here are three suggestions from Dr. Meints to help you collect the best soil sample:

1. **Divide your gardening space into sections according to what has been planted, then sample each section individually.** For example, take separate samples from areas where you grew fruits, vegetables, or ornamental crops. You may need additional samples within each crop group if you've tried different fertilizer application methods or other practices within them. Dr. Meints has found that even simple practices, such as mulching with organic materials, can alter soil test results.
2. **Sample only as deep as you till.** Dr. Meints says, "Many gardeners think they're tilling deeper than they are, since rotary tillage fluffs the soil." According to Dr. Meints, rotary tillers generally till no more than 3 inches deep, so only take a sample from the top 3 inches.

How to Covercrop

Leaving a cover crop in place for a full growing season gives the most added benefit, but even a short-term cover crop helps to reduce the potential for soil erosion and compaction. Here's how to raise a cover crop:

1. **Till or rake the planting site smooth.** As a rule, cover crops don't require added fertilizers unless soil test results indicate that soil is extremely poor. However, cover crops will benefit from a light application of compost. Treat legumes with the proper inoculant before sowing.
2. **Broadcast seeds by hand.** A shallow pass (1 inch deep) with a rotary tiller will help to bury seeds and improve seed distribution. You can create the same effect by raking lightly after sowing.
3. **If weeds outgrow the cover crop, mow the area with your lawn mower set on high.** The mower will skim over the tops of low-growing cover crops while chopping away the taller weeds. In a raised bed, use a scythe or another hand tool to cut away weeds or pull them by hand.
4. **Use a rotary tiller to mix in cover crops when they're less than 6 inches tall.** You can mow the crop first to chop the green matter before tilling. You can also dig it in by hand with a garden fork or shovel. If the crop is taller than 6 inches, working it into the soil will take more effort.

What's In the Bag?

While you're in the process of building up your soil, you may need to use fertilizers to help boost your plants. But how do you know if the fertilizer you're buying contains only organic products? Bill Wolf, the president of Necessary Trading Company, a Virginia company that manufactures and sells organic fertilizers, says one good way is to buy from a source you trust for good quality and service. Another good way is to look for the following clues on the fertilizer label:

The words "All-Natural Organic." Look at the fine print where the ingredients are listed. They should be natural ones such as blood meal, poultry litter, bonemeal, natural grains, seaweeds, and other organic products.

An analysis of readily available nitrogen (N), phosphorus (P), and potassium (K) that totals 15 or less. For example, the NPK ratios (listed as three numbers on the label) will be 5-5-5, 4-5-4, or 3-2-3 as a registered analysis. (Some organic lawn fertilizers contain as much as 10 percent nitrogen; the sum of their NPK ratios will be greater than 15.)

3. **Timing isn't critical.** "It's more important that the job is done," says Dr. Meints. You may find that fall is the best time to sample, because soils are generally drier in fall than in spring. Also, soil-testing laboratories are less busy in the autumn, and you'll have several months to consider the results and plan a soil-improvement program.

SNIFF FOR SOUR-SMELLING SOIL

Taking a good whiff of your soil can help you judge whether or not you need to worry about having it tested. Shepherd Ogden, a co-owner of The Cook's Garden, a mail-order seed company in Vermont, uses a sniff test to monitor soil pH. Soil pH, which is a measure of the alkalinity or acidity of a soil, is important because it affects how easily nutrients in the soil can be absorbed by plant roots. Most garden plants do best when the soil is in the neutral range, at a pH between 6.0 and 7.0. "When the pH is not right, garden soil smells vinegary or sour, or the odor makes your nose tingle," Ogden explains. If the soil smells good and sweet, Ogden trusts that the pH is probably appropriate for good plant growth. When the soil smells sour, it's time to do a formal soil test.

BREAKING UP (HARDPAN) IS HARD TO DO

Digging deep can reveal hidden problems with your garden soil. If you use a rotary tiller frequently, your soil may have developed a hardpan. A hardpan is a compacted layer of soil below the surface. Water and plant roots can't penetrate a hardpan. Plant growth may suffer, and soil won't drain well. Your soil may also have this problem if it has been driven over by heavy equipment—during construction, for example.

Bill Wolf, the president of Necessary Trading Company, a Virginia company that manufactures and sells organic fertilizers, offers advice on how to detect a hardpan. "Using a trowel or shovel, examine the soil around perennial plants, in the root zone. Look for roots that suddenly turn sideways: That's where the compacted layer is," says Wolf. You can also insert a probe, such as a metal crowbar, into your garden soil. When you feel sudden pressure—it's usually at the depth of tillage—you'll know you hit the hardpan. Note the depth to compaction at several sites. If you find a hardpan layer, you can break it up by digging through it with a garden fork. For large areas with hardpans, plowing with a chisel plow is a more feasible solution.

SHOULD YOU SQUASH OR SAVE?

Turn a shovelful of garden soil or just scratch the surface, and you'll discover an underground living world. Thousands of insects and related creatures thrive in the dark, moist soil environment. Linda Gilkeson, Ph.D., the Integrated Pest Management Coordinator for the British Columbia Ministry of Environment, explains that soil animals can be beneficials you should save or pests you should destroy. Most beneficials either help control pests or help decompose organic matter. "Many gardeners don't know that soil-dwelling beneficials, like ground beetles, are standing guard between their garden plants and the pests," says Dr. Gilkeson.

You'll help your soil and your garden plants by encouraging a diverse population of organisms in your soil. You can encourage the good guys by minimizing soil disturbance and using organic mulches. Take the time to learn to tell pests from beneficials so you'll know which creatures to preserve and which to destroy when you're digging in the garden. Here's a short squash/save list of common garden soil inhabitants.

Squash armyworms. Armyworms are greenish brown caterpillars with white stripes on their sides and dark- or light-colored stripes on their back. They feed on garden plants at night. During the day, they hide in plant foliage or just beneath the soil surface.

Save centipedes and millipedes. These are serpentine creatures from ½ inch to 5 inches long, with many legs. Both are important predators and decomposers in the soil ecosystem. They consume dead plant materials. You'll find them among leaf litter or in any damp, dark spot.

Squash Colorado potato beetles. Adults have yellow wing covers with ten black stripes. Larvae are orangey, humpbacked grubs, with black spots on their sides. Larvae eat potato foliage, quickly defoliating potato plants. You'll find adults and pupae in soil where potatoes are grown.

Continued →

Squash cutworms. These are fat, greasy-looking, gray or dull brown, 1- to 2-inch-long caterpillars with shiny heads. They are often confused with armyworms. They chew through stems of vegetable and flower seedlings at night. During the day, they rest just below the soil surface.

Save earthworms. Most garden species are less than 5 inches long. Look for red, gray, and brown worms at and beneath the soil surface. Many feed upon decomposing organic matter, transporting it through their burrows and redistributing it throughout the soil.

Save ground beetles. Adults are blue-black or brown, ¾- to 1-inch-long beetles. Larvae are dark brown or black and grublike but slender. Adults and larvae prey on other insects and pests, including slugs. Some species eat weed and vegetable seeds. Spread organic mulches to attract them.

Squash grubs. Grubs are the larvae of Japanese beetles, June or May beetles, and other beetles. They are wormlike, fat, C-shaped, and most often white with a dark-colored head. They munch on both living and dead plant roots. You'll find them in soil beneath lawns.

Save rove beetles. These resemble earwigs without rear pincers. The hard wing covers are shortened, leaving the abdomen exposed. Length ranges from 1/25 to 1/10 inch. Most rove beetles are insect pest predators. You'll find them under rocks, in moss or fungi, and in compost piles and organic mulches.

Squash slugs and snails. Both slugs and snails are soft-bodied and wormlike, measuring ⅛ to 8 inches long. Snails have a spiral-shaped shell into which they withdraw when disturbed; slugs lack a shell. Both lay clear, jellylike egg masses under stones and other debris. They feed at night on most aboveground plant parts, leaving behind a shiny trail of mucous slime.

Where's the Nitrogen?

Don't be surprised if your soil test results come back from the lab without a reading for nitrogen. Even though this nutrient is essential for healthy plant growth, most soil labs don't include nitrogen as part of their basic test. That's because the nitrogen content of your soil can change dramatically and quickly. If you want a test of the nitrogen in your soil, you usually have to request it; you'll pay a few dollars more for this test.

If test results show that your soil doesn't have enough nitrogen, you can help your soil and your plants by adding more organic matter in the form of compost and appropriate amounts of nitrogen-rich fertilizers such as animal manures, bloodmeal, or alfalfa meal.

Too Much of a Good Thing

When it comes to soil nutrients, experts agree that most gardeners go too far in boosting nitrogen. The result is big lush plants but few flowers or fruits. Plants will basically take up all the nitrogen you feed them, and those overfertilized plants are also more susceptible to insect and disease problems.

So, go easy on the nitrogen. An inch or so of compost per year—a little more if you have extremely sandy soil—is enough to maintain the necessary level of organic matter you need to get good yields in most northern soils.

Down South, however, it's a different story. Organic matter in the soil just burns right up in the hot, humid conditions and long growing season. As a result, southern gardeners can apply compost and manure much more freely.

And if a soil test reveals "excessive" nitrogen, simply cut back on the organic matter, grow lots of nitrogen-hungry crops such as sweet corn, potatoes, and lettuce and let the rain and those "heavy feeder" crops take care of the problem.

Building Soil Fertility

An easy way to boost soil organic matter content is to spread organic materials on the soil surface and let nature do the rest. One of the best organic materials to add is compost.

You can also use living plants to add to soil fertility. Green manure crops are crops that you sow specifically to turn back into the soil to boost soil health. Living mulch is a cover crop sown among your garden crops to help suppress weeds and conserve soil moisture. We asked the experts how to get the best results from added organic material, green manures, and living mulch.

GIVE SOIL A BOOST, NOT A BLAST

Just because a little of something is good for your garden soil doesn't mean that a little more is better. Paul Sachs, the owner of North Country Organics, a Vermont wholesale supplier of natural soil amendments, likes to remind gardeners of the saying "Everything in moderation." According to Sachs, "Everything you add to soil, including organic fertilizers and compost, has a threshold where it's not helpful anymore and possibly begins doing harm." For example, if you add too much phosphorus-rich fertilizer to the soil, the phosphorus can combine chemically with other important micronutrients such as iron and manganese, making them unavailable to your plants.

Always determine the proper application rate for soil amendments. Excess fertilizer is just another name for pollution. "Even compost will leach nitrates [soluble nitrogen compounds] into groundwater if you're not careful," reminds Sachs.

Use compost as a general-purpose garden fertilizer, but don't overapply. On bare soil, avoid spreading it more than 2 inches thick. You can apply more compost later in the season, when garden plants are established and ready to soak up nitrogen released from the compost.

PLANT A GARDEN OF BUCKWHEAT

Buckwheat is a versatile cover crop that you can use all season long. Miriam Klein-Hansen, who taught homestead gardening at the National Center for Appropriate Technology in Montana, suggests using buckwheat as a living mulch around cabbage-family plants. In spring, sprinkle buckwheat seed between broccoli, cabbage, and cauliflower transplants, leaving about 8 inches of bare soil around each transplant stem.

Klein-Hansen uses a hoe to cut the buckwheat from its roots at the midpoint of its flowering period, when bottom seeds have set. These seeds give a second buckwheat "planting" that prevents late weeds from getting established. Klein-Hansen's husband, David, turns the buckwheat under in the fall before planting winter rye over the whole garden. As they decay, the buckwheat plants feed the soil, particularly with phosphorus, which the plants accumulate as they grow. Klein-Hansen says, "I only have to weed about twice a season. After a couple of years of buckwheat/buckwheat/rye, we find almost no witchgrass [quackgrass]."

SET LIMITS WITH LIVING MULCH

Use caution with living mulch, or it can become a living nightmare. "The only good living mulch is one you've killed," says Robert F. Becker, a retired associate professor at Cornell University's New York Agricultural Experiment Station in Geneva. "Living mulches are hard to control. They can get away from you and begin competing with the crops." To avoid problems with having mulch that takes over the garden, Becker suggests waiting to seed the mulch after crops are already well-established.

Becker also recommends sowing oats as a cover crop in areas where you've harvested peas and other early crops. "The nice thing about oats is that they winter-kill," says Becker. "You don't have to deal with them in the spring. Unless, of course, it's a wet spring. The oat covering can impede drying of the soil, so I rake up the dead plants and remove them from the soil surface."

ADD NITROGEN NATURALLY

A great way to build soil fertility is to have your plants do it for you. Legumes like peas, beans, and alfalfa are plants that can transform nitrogen from the atmosphere into nitrogen compounds that can be absorbed by plant roots. Because of this, they don't need as much nitrogen added in the form of fertilizer. But to "fix" nitrogen, the legume roots must associate with certain kinds of soil-dwelling bacteria. You can add these bacteria to the soil—a technique known as inoculating soil. In mail-order catalogs and at some garden supply centers, you can find soil inoculants specifically formulated for various cover crops and leguminous vegetable crops. However, Marianne Sarrantonio, Ph.D., the legume project coordinator for the Rodale Institute Research Center in Pennsylvania, cautions

Soil Testing—The Ph.D. Level

Many soil testing services don't provide specific organic recommendations to remedy any problem your soil test reveals, but there are a number of soil testing services that will. For a slightly higher fee than most local testing services, these labs will provide a more complete and customized package of information and instructions. They'll tell you exactly how much of which organic amendments you need to add to your soil. So if you're looking for premium, top-of-the-line organic soil testing, here are three services to consider:

Peaceful Valley Farm Supply
P.O. Box 2209
Grass Valley, CA 95945
(916) 272-4769

Peaceful Valley offers an initial soil test (which includes all the usual things like pH, organic matter, etc.) along with a 15-page booklet, *Know Your Soil: A Handbook for Understanding Your Soil Test Report*, written by noted organic farm adviser Amigo Cantisano. The booklet is keyed to your soil test results; once you have the booklet, your cost for soil tests in future years is reduced. The staff will be glad to answer your questions.

Timberleaf Soil Testing Services
26489 Ynez Road, Suite C-197
Temecula, CA 92591
(909) 677-7510

Timberleaf's basic soil test includes all the major plant nutrients, plus organic matter, pH, and several special tests not usually included in the lower-cost state lab packages. Your test results also include a customized report that will tell you exactly how much of any recommended soil amendments to apply, and you are entitled to one year of free consultation, as well.

Wallace Laboratories
365 Coral Circle
El Segundo, CA 90245
(310) 615-0116

Wallace Laboratories' "basic" soil test includes the usual things like NPK, pH, and salinity, plus 27 other plant nutrients. Your soil is also tested for potentially toxic elements such as arsenic, aluminum, and lead.

Quick Tip

Every bag of fertilizer has three numbers connected with hyphens on the label, such as 6-2-0. Those numbers are the NPK ratio—the percentages of nitrogen, phosphorus, and potassium in the fertilizer. Organic fertilizers have lower numbers than synthetic types because the numbers show the amount of nutrients that will be available *in the first year.* Organic fertilizers release nutrients slowly, giving your plants more nutrients in the long run.

gardeners not to rely solely on inoculants to supply nitrogen for their bean crops. "Beans are poor nitrogen fixers," she explains. "They'll only fix about 30 to 50 percent of what they need."

Follow these four guidelines to get the best results with inoculants:

1. Be sure you buy the right inoculant for the legume you plan to plant. It's a good idea to buy the inoculant from your seed supplier to be sure of getting the right match.
2. Check for an expiration date. Store the inoculant in the refrigerator, and use it as soon as possible.
3. To use an inoculant, pour legume seeds in a bucket and mix them with enough water to moisten the surface. Add the inoculant and stir until the seeds are coated. You can refrigerate coated seed for short periods, but it is best to mix only enough to plant immediately. Plant as usual.
4. The bacteria can usually survive in garden soil for four years without a host. If you wait longer than that between plantings, re-inoculate.

Working with Your Soil

Is your soil everything you want it to be? Unfortunately, most of us will answer no. The organic matter content may be low, or perhaps the topsoil layer is only 3 inches thick. Or maybe your soil is so high in clay content that it is full of rocklike clods. What can you do? There aren't always easy answers, but we asked our advisers for schemes for improving problem soils. We also collected their opinions on the best ways to cultivate the soil.

CLAY CAN STRENGTHEN SANDY SOIL

Sandy soil can benefit from added clay and organic matter. "I follow the adage that 'a load of clay is like a load of manure to a sandy soil,'" explains Eliot Coleman, an organic farmer and author of *The New Organic Grower.* "If clay isn't readily available, adding organic matter is the next best alternative." You'll have to have some idea of how much clay your soil already contains and how much heavier you want it to be. For example, a sandy loam soil—considered excellent for gardening—is composed of roughly 65 percent sand, 20 percent silt, and only 15 percent clay.

Coleman figures it this way: You can boost a sandy soil's clay content 25 percent by spreading a 1-inch layer of clay over the surface of your garden and tilling it into the top 4 inches of the soil. Add less clay for a lighter effect. To keep your soil in good shape, add clay the first year, and follow it with annual applications of organic matter. Contact a local landscape supplier, who can deliver clay by the truckload. Be sure to specify that you don't want wet clay.

OUTSMART CLAY SOIL

Soils with high clay content can be heavy and hard to work. Nino Ridgway, the owner of Squeaky Green Organic Produce, who raises organic vegetables on a heavy clay soil in Wisconsin, offers three time-tested rules for dealing with heavy soil:

1. "The best way to improve a clay soil is to add organic matter. And the best way to add organic matter is to grow it in the field," says Ridgway. She sows cover crops, such as buckwheat or rye, then tills them in when they're several inches tall. Ridgway advises, "A good rule of thumb for gardeners is to keep 10 to 20 percent of their garden space in a cover crop each year."
2. Stay away when your soil is wet! If your soil is wet, don't even enter your garden. Ridgway says, "You're shooting yourself in the foot if you go ahead and work it, because it turns to concrete and requires one or more years to mend."
3. Maintain a surface mulch—even a thin layer—to break the impact of raindrops. The mulch will help prevent the crust that forms after a rainstorm. Ridgway says, "Even a light mulch of fine grass clippings is enough to improve the germination rate of fine-seeded crops like carrots, which don't like a soil crust."

IT COULD BE A SAND TRAP

Can you improve the rate at which your soil drains by mixing in sand? "That could be the wrong thing to do," says Bonnie Lee Appleton, Ph.D., an associate professor and extension horticulturist at Virginia Polytechnic Institute and State University. "A little sand impairs drainage," she says. "If you want to improve drainage using sand, it takes huge amounts—60 to 80 percent of the soil needs to be sand." For example, in order to boost the sand component of the top 5 to 8 inches of your soil by 5 to 10 percent, you would need to add 3 to 5 tons of sand per 1,000 square feet of garden. So skip the sand, and stick with a regular plan for adding organic matter, suggests Dr. Appleton.

TRY SIMPLE "SINGLE DIGGING"

If your soil is too sandy or is heavy with clay, double digging is the classic way to improve it. This method of shoveling aside the top layer of soil and loosening the subsoil improves aeration, and you can work in plenty of compost or other organic materials as you dig. However, at the Rodale Institute and Research Center in Pennsylvania, Eileen Weinsteiger, the garden project manager, found that double digging soil "wasn't worth it, because our soil was already in such good condition after many years of organic gardening." Weinsteiger explains, "Double digging improves poor soil, but it's time-consuming, so I don't recommend it unless you're gardening at an unproductive or unimproved site."

You may want to try the same simple method that Weinsteiger follows to manage soil in garden beds at the research center: Each spring, turn the soil to a depth of 1 foot. That's the depth of most garden shovels. Use your foot to push the shovel in, then turn the clump of soil. You can dig in compost or green manures at the same time.

Beds *don't* require annual digging if they're free of weeds and other vegetation or if the soil is in the fluffy condition that's best for planting. Do dig annually to bury cover crops and old vegetation, to add fertilizers, or to reshape the beds (if they need it) after a long winter.

TAKE IT EASY WITH TILLING

Frequent tillage at the same soil depth can cause the development of a hardpan, a compacted layer of soil below the surface. Hardpans prevent root penetration, and they're difficult to remedy. Paul Sachs, the owner of North Country Organics, a Vermont wholesale supplier of natural soil amendments, says, "Rotary tillage is not necessarily the soil's best friend. Overtillage really depletes soil organic matter. When you till, don't till too deeply, and alter the depth of tillage to prevent the formation of a hardpan." Sachs adds that rotating garden crops with green manure crops also helps alleviate soil compaction and maintain soil organic matter content.

Overtillage is hardest on soils with high clay content. The more clay your soil contains, the less you should till. If you're starting a new garden area, till the first year to break up sod or to work in loads of organic materials or soil amendments. In following years, continue adding organic materials or growing green manures, and work them in by hand whenever possible.

When you have to till, shallow tillage is better than deep. For example, the first tilling in spring could be to a depth of 4 inches. If you put in a second crop during the season, till only 1 inch deep to make a seedbed, or just rake the surface. Over time, you may find that your soil becomes loose and open enough that you can retire your tiller for good.

Soil-Care Secrets

If you've been piling a lot of stuff on your garden in the hopes of super-charging your soil, you could be unwittingly changing the soil's pH level or adding too much of one nutrient and not enough of another. On the other hand, if you've been largely ignoring your soil's fertility and hoping for the best, you may be cheating yourself out of optimum harvests, a lush landscape, or the best blooms. Check out the soil-care secrets in this section—you won't want to ignore your soil or overfertilize it anymore!

Getting Serious About Soil

Let's start with one of the best-kept secrets in gardening: the inexpensive soil tests available to most North American gardeners and farmers through their local cooperative extension offices or similar agencies. In most areas, you can get a fairly comprehensive test done for between $5 and $10—less than you'd probably spend for a bag of fertilizer. And a soil test may tell you that you don't even need to use that fertilizer (or that you need to exchange it for something different)!

GETTING TESTED

How you go about getting your soil tested—and the kind of information you'll get back from a soil test—depends on where you live. Start with a call to your local cooperative extension

Continued ➔

office or the soil conservation service office in your area. You'll usually find these agencies listed in the government pages of your phone book. If you find that soil testing isn't readily available in your region, ask about private testing labs near you. But get your soil tested as close to home as possible so that the recommendations you'll receive make sense for your climate and soil.

Exactly what's included in each area's basic test will vary because: 1) each region's system is set up differently; 2) different soil scientists attach higher significance to some things and less to others; and 3) soils and their problems really do vary from one region to the next—what might be a common problem in one locale might not even be an issue somewhere else. Take salt, for example. Because salts tend to build up in western soils from their lack of rain, western labs routinely measure a soil's salt levels. In the East, however, any salts in the soil are almost always quickly washed away by rain, so eastern labs don't routinely test for them.

Such regional differences are exactly why it pays to have your soil tested by a lab in your little corner of the world (or close to it). Some state labs even (or only) send a copy of your test results to your local county extension office; that way the agents there have immediate access to your report if you call asking for guidance.

Don't Forget to Inoculate

Some cover crops are special plants called legumes (sweet clover and alfalfa are two examples). Legumes transform nitrogen from the air into nitrogen compounds that plants can use, with the help of bacteria called nitrogen-fixing bacteria. This helps you because it means you don't have to work as hard to add nitrogen to the soil.

These special bacteria may or may not be present in the soil already. There are many different strains, and the only way to ensure that the right strain is there when you plant a legume cover crop is to put it there yourself when you plant. To do so, you'll need to buy an inoculant, a commercially produced powder that contains the bacteria. All you have to do is coat the cover crop seed with inoculant and then plant. Once you've grown a particular kind of legume in your garden, the nitrogen-fixing bacteria it needs will persist in the soil for three to five years.

A Crop That Feeds the Garden

Roger Yepsen

Even in chilly northern winters, the garden can be sown with annual rye (*Lolium multiflora*) as a cover crop that will resist erosion, control weeds, and then lend its organic matter to the soil. If done over a few winters, the result will be improved structure and aeration, and more activity by a variety of beneficial subterranean life from earthworms to fungi. Rye also contributes some nutrients, although it isn't a nitrogen builder like leguminous cover crops.

1. At summer's end, rake the beds to smooth the soil and remove plant debris.
2. Hand-sow 2 to 3 ounces of annual rye seed per 100 square feet of garden area. This will go more easily if you mix the seed with sand or friable soil.
3. Rake the seedbed.
4. In spring, from 2 to 4 weeks before you put out seeds or plants, mow the rye and turn it under.

WHAT SOIL TESTS TEST FOR

When you get a soil test kit from your extension office and mail off your soil sample, the lab runs tests to determine what your soil's pH level is and what nutrients are found. The test results usually describe whether the nutrients are present in low, medium, high, or excessive quantities. Follow the recommendations that come with the soil test results when you need to use fertilizers or amendments to build nutrient levels in the soil, or apply the amounts listed on the package. There's no advantage to overfertilizing your soil, and there is a good risk that you'll do more harm than good. Here are some of the nutrients most commonly tested for, along with tips on correcting deficiencies of these important plant "foods":

Phosphorus. Phosphorus is extremely important for healthy plant growth—without it, plants will be stunted. Sandy or shale soils that don't contain much organic matter are most likely to be phosphorus-deficient. If your soil test indicates a low amount of phosphorus, you can add bonemeal or rock phosphate to your soil and work it in to the top 6 to 8 inches. Follow the recommendations that come with your soil test results to know how much to add, and don't overdo it. Phosphorus doesn't leach out of the soil like some nutrients—once it's in the soil, it stays there. Applying too much phosphorus can throw your soil out of balance for a long time.

Potassium. Potassium helps plants fight disease, strengthens their stalks, and improves the quality of fruits and seeds. As

with phosphorus, the soil most likely to be potassium-deficient is sandy with little organic matter. To help correct low levels of potassium, add manure, seaweed meal, or greensand to the soil before you plant your spring garden.

Calcium. This mineral is a major component of a plant's cell walls. The most common soil that is low in calcium is acid, sandy soil along the sea coasts. Adding limestone to this soil type helps raise the calcium level and raises the pH, too.

Sulfur. Sulfur is a major part of all living organic matter, so it's no surprise that soils low in organic matter are low in sulfur. Plants need sulfur to make proteins to survive, and nitrogen needs to have enough sulfur to feed your plants. Without sulfur your plants are in big trouble, but you can easily increase soil sulfur levels by adding manures or gypsum.

Magnesium. Magnesium helps make up chlorophyll (the stuff that makes plants green), which helps plants make food. Sandy, acid soils may be low in magnesium and will benefit from additions of dolomitic limestone (also called magnesium lime), which also raises pH.

The Ups and Downs of pH

The most common factor that labs test soil for is pH level. A soil's pH is simply a measure of its acidity or alkalinity. A pH reading of 7.0 is neutral; numbers higher than 7.0 indicate your soil is alkaline; numbers lower than 7.0 mean your soil is acidic. If a soil is extremely alkaline, it doesn't matter how rich in nutrients it is because those nutrients will be tied up and your growing plants won't be able to absorb them. The ideal pH for most plants to grow in ranges from 6.2 to 7.0. This is the range where nutrients are most available for uptake by the plant's roots.

If your soil is too acidic, your soil test report will probably tell you to add lime to raise the pH. But another portion of the test results should determine what kind of lime you choose.

If your soil's magnesium levels are okay, the lab will probably tell you to add calcitic lime. But if your soil needs magnesium, you'll probably want to add dolomitic lime (also called magnesium lime) to correct both problems.

If your soil is too alkaline, the test results may tell you to add sulfur to lower its pH. For use as a soil amendment you'll want to choose pelleted or granular sulfur, which is also known as garden sulfur. Stay away from the very finely ground sulfur that is sold to be mixed with water and sprayed onto plants as a fungicide. It's so finely ground that it can be a health hazard if you don't wear protective equipment when you handle it.

Soil Amendments

Adding the recommended nutrients to your soil will benefit your plants, whether they're flowers, herbs, vegetables, or grass. But that's only part of the picture. You also need to deal with the texture of your soil—whether it's heavy clay, light and airy sand, or somewhere in between.

If your soil texture test reveals problems with compaction, low humus, poor drainage, or poor water and air retention, the solution is to add organic matter. You can choose from a wide range of materials to help you boost your soil's condition, so make your selection based on the availability, cost, and ease of handling of the amendments you're considering.

Compost. Compost is a popular amendment because it is so cost-effective. You can buy compost or make your own. When compost is mixed into soil, the soil resists compaction and drains quickly yet still retains an enormous amount of water. Compost is very easy to spread throughout the garden.

Leaves. If you don't want to bother with making a compost pile and have a lot of extra leaves on the ground, you have the next best thing to compost. Just shred up those leaves and dig them into your soil. Most leaves are acidic but will not add enough acidity to significantly affect soil pH.

Manure. The wonder of animal manure, with its large amount of nutrients, will never cease to impress gardeners, but you should only add manure that has been aged for more than six months.

Peat moss. Another soil amendment that can help your garden is peat moss. Peat moss has a very low pH—3.0 to 4.5—which makes it good to spread around acid-loving plants such as rhododendrons, blueberries, and pines.

Mulch—It's Good for Soil and Plants

Mulching is one of the best things you can do for your gardens—whether you're growing vegetables, flowers, shrubs, or trees. Covering your soil with a thick layer of organic matter can block weed growth, keep the soil cool and moist, and—as the mulch decays—feed both the soil and the plants growing in it. But it pays to know which mulch is the right one to use in each specific gardening situation.

Grass. Freshly cut grass clippings are rich in nitrogen and other nutrients that will feed your plants as the clippings decompose. Warm-loving crops like peppers, tomatoes, and eggplants all do well with grass-clipping mulch. If your lawn can't supply enough grass clippings for your garden, check with a local lawn care service or a neighbor and see if you can get clippings.

Newspaper. Remove and recycle the slick-paper color supplements from your Sunday paper and what you've got left is a super-effective weed-suppressing mulch. Paper can keep down weeds for two summers and can be used instead of black plastic to heat up cool spring sod. Use newspaper mulch around veggies such as sweet corn, soybeans, and tomatoes. Raspberries grow well with shredded newspaper mulch, too. And the moist, dark soil under a mulch of newspaper is an earthworm paradise!

Wood chips. You can chip them yourself with a chipper/shredder, or buy them. The best place to use wood chips is in perennial beds and on garden paths. They're durable and work

Continued

best where the soil isn't tilled or turned often. If you do use them in a vegetable garden, keep them on the surface. When turned under, wood chips can take up to a year to decompose and they tie up nitrogen so your plants can't absorb it.

Bark. Tree bark mulch lasts longer than wood chips because the bark sheds water rather than holding it. Bark also keeps the soil cool. Because bark has a nice appearance, use it to protect the soil in spots where you want to make a good impression—like your prized flowerbeds. Don't use bark around tomato plants; it can be harmful to them.

Pine needles. Pine needles can be a great mulch, and they're easy to get where pine trees grow. Boughs from spruce, fir, and pine trees make excellent winter mulch in northern flower gardens, protecting fall-planted pansies that you hope to overwinter and rebloom in spring.

Straw. Straw mulch has been proven to be a boon to tomatoes, preventing diseases such as anthracnose, leaf spot, and early blight from leaving their ugly marks on this favorite garden vegetable. Straw also works very well as an insulator, protecting crops such as carrots, parsnips, and potatoes that folks without root cellars leave in the ground during the cold months.

Others. Although compost, shredded leaves, and manure are most commonly used as soil amendments to add nutrients and improve soil texture, you can also use them as mulches. They provide nutrients and weed control, but many times they do more good when they're worked into the soil.

Soil Management

Care for the soil, and the soil will care for your plants. Plants growing in healthy, organically managed soil are lush, green, and vigorous. In contrast, plants growing in poor soil that lacks nutrients are often small and weak, sometimes even discolored, stunted, and deformed. Not a pretty sight!

Signs of Soil Trouble

In this chapter you'll learn to recognize some of the signals from plants that indicate nutrient deficiencies in the soil. And you'll discover how to use special plants called cover crops to build the richest soil ever.

Just as your doctor studies your symptoms to figure out the cause of an illness, gardeners learn to diagnose plant problems by looking for key signs. When nutrients are lacking in the soil, your plants will tell you. Not with words, of course, but by displaying symptoms that often point directly to the missing nutrient.

Some of these nutritional deficiencies look very similar, so to confirm your diagnosis, you may want to have your soil tested (that way you'll save the time and cost of adding nutrients that your soil doesn't need). And remember that overdoing nutrients can cause just as many problems as deficiencies can—more is definitely not better where fertilizers are concerned. Here are six deficiencies and what to do about them.

NITROGEN-DEFICIENCY SYMPTOMS

Tomatoes. Plants grow slowly and the leaves are small, light greenish and/or yellowish. Top leaves may be light green with purple veins. Flower buds turn yellow and drop off. Fruits are often small.

Corn. Leaves are light green (instead of a nice dark green) or have yellowish center streaks, and growth is stunted. The lower leaves are usually affected first; they will gradually become dry and brown and fall off.

Potatoes. The leaves and stems turn light green or pale yellow. The young top leaves may curl upward and the plant itself is stunted. At harvesttime, the tubers will be small.

Cucumbers. Leaves turn yellow. Vines don't get very much fruit, and any fruit that is produced is light in color and pointy at the blossom end (the part farthest from the vine).

NITROGEN REMEDIES

Fast fix. Scratch some alfalfa meal, composted animal manure, bloodmeal, or other high-nitrogen organic fertilizer into the surface of the soil around the plants. Or water the plants with a diluted solution of fish emulsion or spray it directly on the foliage. A warning here: If you add too much nitrogen, you'll get all plant and no fruit, especially with tomatoes. So be sure you don't overdo it.

Long-term cure. Growing and then turning under a nitrogen-fixing cover crop of clover, vetch, or peas is one of the best ways to add nitrogen to your garden. Another good way to build up the nitrogen content of your beds is with generous supplies of compost, well-rotted manure, or other nitrogen-rich organic materials, preferably added in the fall.

PHOSPHORUS-DEFICIENCY SYMPTOMS

Tomatoes. Plants grow slowly. Leaves are dark green on top but have purple undersides. Seedlings grow very slowly.

Corn. Stalks are small and the leaves turn purple at the tips and along the margins.

Potatoes. Leaves and stems are somewhat stunted and darker green than normal. Leaves may curl upward. At harvesttime, there may be irregular brown specks inside your potatoes, many radiating outward from the core. (Note: Viruses and/or extreme temperatures can cause similar specks.)

PHOSPHORUS REMEDIES

Fast fix. Foliar feed with liquid bonemeal or work dry bonemeal or rock phosphate into the soil where roots can reach it. If you

had this problem last year and haven't planted yet, add these materials to your planting holes and furrows as soon as possible.

Long-term cure. Low levels of organic matter and/or extremes of soil pH (too acid or alkaline) can worsen phosphorus deficiencies. Normally, earthworms, bacteria, and other soil-dwelling organisms will break down organic matter and release its plentiful supplies of phosphorus to the plants. But extremes of soil pH will limit the activity of these creatures and thus inhibit the availability of phosphorus. So test your soil's pH—it may have to be adjusted for any long-term remedy to be effective.

If your soil is too acid, work in some limestone; if it's too alkaline, add sulfur. Build up the organic matter content of your soil. You may also need to add some rock phosphate.

POTASSIUM-DEFICIENCY SYMPTOMS

Tomatoes. Leaves become dark green, stems stay small, and leaves are bunched together (the leaves themselves may crinkle and curl upward). Older leaves become yellow, then brown at the edges. Fruits fall off the vine soon after ripening, have hard, blotchy flesh, and ripen unevenly.

Corn. Lower leaf tips and edges will become scorched and brown. Plants will grow slowly and have poorly developed root systems. Stalks will be weak, diseased, or both and often become so stressed that they snap off.

Potatoes. Growth is slow and plant growth is stunted. Leaves are very dark green in color. The leaves may turn brown at the edges and eventually die.

POTASSIUM REMEDIES

Fast fix. Scratch kelp meal or wood ashes into the soil around plants. With wood ashes, be sure to apply them only once every two or three years in any particular area to avoid creating soil imbalances.

Long-term cure. Build up potassium levels in your soil by adding some well-aged compost and/or composted manure. You can also enrich your garden beds with granite meal (a fine rock powder obtained from granite quarries)—it's a good source of slow-release potassium.

CALCIUM-DEFICIENCY SYMPTOMS

Tomatoes. Blossom-end rot (the formation of a dry, brown spot on the part of the fruit opposite the stem). Tips of new shoots are stunted and distorted.

CALCIUM REMEDIES

Fast fix. Water tomatoes evenly and regularly to allow calcium to reach the tomato flower at time of fruit formation.

Long-term cure. Add crushed eggshells (do you live close to a restaurant that serves breakfast?) to your compost or work crushed oyster shells or ground limestone into your garden beds—preferably in the fall or at least before planting.

MAGNESIUM-DEFICIENCY SYMPTOMS

Tomatoes. Older leaves turn yellow while the leaf veins stay dark green. Yellow areas eventually turn brown and die. Very few flowers and fruits form on the plant.

Beans. Older leaves turn yellow while the leaf veins stay dark green. Yellow areas eventually turn brown and die. Very few flowers and fruits form on the plant.

MAGNESIUM REMEDIES

If your soil is also deficient in potassium, work Sul-Po-Mag (mined sulfate of potash-magnesia) into the root zone of the affected plants. If your soil is acidic (pH under 6), work in dolomitic lime to raise the pH and add magnesium at the same time.

IRON-DEFICIENCY SYMPTOMS

Tomatoes. Youngest leaves turn yellow between the veins. Later, the whole leaf turns yellow, but older leaves remain green.

IRON REMEDIES

Fast fix. Foliar feed with a liquid seaweed product.

Long-term cure. Alkaline soils that are poorly aerated or over-limed can be low in iron. Add sulfur to reduce soil alkalinity. If your soil is not alkaline, use iron sulfate.

Keep Soil in Shape with Cover Crops

You can help keep your soil healthy and your plants happy by planting cover crops in your vegetable and annual flowerbeds. Cover crops are crops grown to protect and enrich the soil and to control weeds. You "harvest" organic matter and nutrients from cover crops by tilling the plants back into the soil. The optimum plan is to have a vigorous cover crop growing whenever you're not growing vegetables or flowers. In most areas in the United States, that means late fall through early spring, although in some southern areas, it may mean exactly the reverse—growing your cover during summer.

Here are eight great reasons to include cover crops in your garden plans:

Cover crops provide nitrogen. Nitrogen is what puts the green in your greens. It's also the plant food most likely to be deficient in sandy soil or any type of soil that's low in organic matter.

Cover crops add organic matter. As you now know, a high level of organic matter in soil provides nutrients, helps conserve water, and improves soil structure.

Cover crops protect against erosion. The top layer of your garden soil—the most fertile part—can slip away when assaulted by the winds and rain of winter. A cover crop holds it in place.

Continued ➔

Cover crops catch nutrients. If your area gets heavy winter rains, important plant nutrients may literally be washed out of your soil. Plant a cover crop in the fall to take up these nutrients and release them back to the soil when you turn that crop under the following spring.

Cover crops break up compacted soil. Some cover crops, such as sweet clover and alfalfa, have thick, deep taproots, which can be very effective at breaking up hard soil.

Cover crops control weeds. Planting a vigorous cover crop such as vetches and crimson clover may well be the easiest way to beat troublesome weeds.

Cover crops attract beneficials. Many cover crops provide protection and food for beneficial insects that help control pests in your garden.

Cover crops can be an effective mulch. Grow vetch, rye, or a combination of the two in your garden, mow it or let it die back naturally (either by completing its life cycle or from winter cold) and you have a ready-to-go mulch that will retain moisture as it controls weeds. Till a narrow strip through it, or punch holes right into the mulch for your transplants.

PUTTING ON THE COVER

Now that you're convinced of the advantages of growing a cover crop on your garden, here's how to go about it:

1. **Sow it.** Seeds left on top of the soil tend to dry out, wash away, or be eaten by birds. Covering the seed with a bit of soil gives it a much higher chance of success. A well-prepared seedbed is ideal, of course, but when that's not possible—if you want to sow a cover crop between established vegetable rows, for example—just rake the seed gently with a hand tool. This is especially important for large-seeded covers such as fava beans or cereal rye.

2. **Water it.** Give your garden a good soaking after planting a cover crop if there's no rain in the forecast. Another watering soon after the cover comes up will give it a competitive edge.

3. **Dig it.** What you do with your finished cover crop depends on what you plan to grow in your garden. If you've planted a legume cover to provide nitrogen for a crop such as tomatoes, turn the cover under about the time it flowers (that's when its nitrogen levels peak). Winter annual legumes typically flower between mid-April and late June.

   If the cover crop hasn't flowered, but you're ready to sow or transplant some vegetables, you can turn it under anyway. You can plant right after turning under a legume—unless it has added a lot of bulky material to your soil. (In this case, let it decompose and settle a bit.)

   If your cover is not a legume, wait two to three weeks after you turn it under to plant. The decomposition of nonlegumes can tie up available nitrogen in the soil for a while.

   And just *how* should you turn it under? That depends on how tall it is. The average "tiller" (either a machine with tines or a gardener with a turning fork) can easily handle a low-growing cover crop such as clover.

4. **Or mow it, then dig it.** If your cover crop is a little jungle, mow it first and let it dry out for a few days before turning it under. If your lawn mower can't do the job, try using a string trimmer or a scythe.

Once the cover is cut, you can also consider setting aside the trimmings for use as a weed-smothering (and, with legumes, plant-fertilizing) mulch.

HOW AND WHEN TO PLANT COVER CROPS

After summer crops. Early flowers and vegetables such as sweet corn are generally finished producing by mid-August. If you don't intend to plant fall greens, clean up the bed and sow a cover crop by late August.

Overseeded into standing crops. If the vegetables or flowers in question will continue to produce until frost (or beyond), you can overseed the bed. Cast the seed into the standing crop in late summer as the weather starts to cool—remember, you want to have good growth before winter. Be sure that enough of it reaches bare ground to germinate and establish a cover. When you finally remove the spent crops, sow some more cover crop seed in this newly bare soil. You'll have a broader choice of cover crops—including more legumes—to choose from with earlier seeding.

In the spring. In areas with long, mild springs, sow a fast-growing cool-season cover such as a crimson clover, fava beans, or oats as soon as you can work the soil. To get your cover in earlier, you could even "frost seed"; just spread the seed on the bare, frozen ground and let the freezing-thawing heaving action of the warming soil "pull" the seed into the soil for you.

Summer fallow. If part of your garden is temporarily bare between spring and fall crops, put those long, warm summer days to good use with a quick-growing hot-weather green manure such as cowpeas, buckwheat, or Hubam white sweet clover. You can even overseed while growing to extend your cover crop's time in the garden.

Full-year green manure. If you feel that your garden is getting a bit worn-out in spots, it may be time to give those hard-pressed areas a rest. A one-year cover crop will build up the soil's organic matter and nitrogen reserves, interrupt disease and pest cycles, and give beneficial microorganisms, earthworms, and other helpful critters a boost. You can use perennials such as red clover and alfalfa or certain winter annuals such as crimson clover—if you remember to mow them before they flower. (If you mow after they flower, they'll die because they have completed their life cycle.)

Living mulch. Plant a low-growing perennial cover, such as white clover or a mixture of white clover and a low turfgrass, in

early spring or late summer. At the proper time, turn under strips of this green growth with a hoe or tiller and direct-seed your vegetables or poke holes in it for transplants. This is not recommended for gardeners who face water restrictions because the living mulch needs a lot of extra moisture.

Your Seasonal Soil-Care Calendar

JANUARY

Work out a three-year **rotation plan** for your vegetable garden. By changing the positions of plants in different plant families from year to year, you interrupt disease and pest cycles. Plan to **alternate deep-rooted plants** with shallow-rooted plants and heavy feeders with light feeders to avoid exhausting soil nutrients.

FEBRUARY

Order seeds for your soil-building cover crops. Save money by buying a big bag of seed and splitting the cost—and the seed—with your gardening friends or neighbors.

MARCH

Find a source for **compost**. Many counties and municipalities compost leaves and yard wastes for residents' use.

APRIL

April showers bring May flowers. They also bring **erosion** and **drainage problems**. Take a walk in the rain and watch for places where the water runs off the soil surface. If it's causing soil erosion, try to figure out how you might be able to stop the runoff in the future (possibly by mulching or changing the surface grading). And when the rain stops, take a **soil sample** and have it tested by your local extension office.

- Don't be tempted to work the soil too early when it's still cold and wet.
- Begin **soil-building activities**. If spring cover crops (such as oats and clovers) are in your rotation plan, plant them now.
- If you planted a **cover crop** last fall, incorporate it as soon as you can work the soil. Get as much compost as you can carry home and dig it into your vegetable and flowerbeds.
- Low **soil temperatures** mean slow seed germination and plant growth in spring. Early planting won't save you time, and it may actually stunt the growth of your plants.
- Plant **spring vegetables** and—to give **summer crops** such as peppers, melons, and tomatoes an earlier start—lay black plastic over the planting bed for a couple of weeks to warm the soil.

MAY

If you don't have a **compost bin**, build one. (Or just make a loose pile of compostable materials.) Then begin to fill it.

- Take corrective action based on your lawn and garden soil test results, using lime or sulfur to adjust pH and **organic fertilizers** to improve nutrient levels.
- Use straw or grass clippings to **mulch** around your vegetables.

JUNE

Mulch your landscaped areas. There are good reasons to wait until your soil warms, despite the fact that your neighbors applied mulch two months ago. Your plants will get a **healthier start** and you'll be giving desirable self-sowing annual flowers a chance to get going.

- As early **vegetable crops** go to seed, you can follow them with a **summer cover** crop (e.g., buckwheat, sudangrass, millet). Don't let these summer cover crops go to seed!

JULY

Let the **decomposers** do the work this month—you've worked enough. Lend them a helping hand by turning the compost occasionally.

AUGUST

As your vegetable crops mature, clean up the debris and plant a **fall cover crop** (for example, oats, crimson clover).

- **Cut down** your summer cover crops and turn them under the soil.
- Watch your compost steam (or turn it if it stops). Monitor its health by taking its temperature!

SEPTEMBER

You can still **plant fall cover crops** (for example, annual rye, vetch, winter wheat, crimson clover).

- If you've experienced lawn or garden problems, have your soil tested.

OCTOBER

Fertilize cool-season grasses and topdress your lawn with a thin layer of compost.

- If indicated on your soil test results, add lime or sulfur to adjust the pH of your soil.
- Top off your empty vegetable beds with raked-up grass clippings and **fall leaves**. Leaving soil bare exposes it to erosion and nutrient leaching.
- **Order some worms** and start an indoor worm composting bin for your kitchen scraps.

Continued ➔

NOVEMBER

Run over your **fallen leaves** with the lawn mower and either allow them to remain on your lawn or, if the leaf layer is too thick, drag them to your compost pile. You could also bag them to use as mulch next year.

DECEMBER

Feed the worms! Remember to make use of your **Christmas greens** by laying them over your perennials. Pine needles or shredded leaves also make good materials for a winter mulch, which helps to insulate the soil and protect your plants from frost heaving.

Soil Glossary

Aeration. The exchange of air in the pore spaces of the soil with air in the atmosphere. Good aeration is necessary for healthy plant growth.

Clay soil. Soil that is made up of very fine particles that hold nutrients well but are poorly drained and difficult to work.

Compaction. Soil condition that occurs when there is heavy traffic over an area, causing pore spaces, which normally make up about half of the soil's bulk, to collapse.

Compost. Decomposed and partially decomposed organic matter that is dark in color and crumbly in texture. Used as an amendment, compost increases the water-holding capacity and drainage of the soil, and is an excellent nutrient source for microorganisms, which later release nutrients to your plants.

Cover crop. A crop grown to protect soil from erosion while also building organic matter and controlling weeds.

Decomposers. Organisms, usually soil bacteria, that derive nourishment by breaking down the remains or wastes of other living organisms into simple organic compounds.

Double-digging. A technique used to prepare a garden bed that entails first removing a layer of topsoil, loosening the subsoil, then replacing the topsoil, mixing in organic matter in the process. This raises the soil surface and improves aeration in heavy soils.

Earthworms. Beneficial soil-dwelling worms that help to break down organic matter and, in the process, both loosen and aerate the soil.

Fertilizer. A natural or manufactured material added to the soil that supplies one or more of the major nutrients—nitrogen, phosphorus, and potassium—to growing plants.

Foliar feeding. A way to give grass a light nutrient boost by spraying plants with a liquid fertilizer that is absorbed through the leaf pores. Compost tea and seaweed extract are two examples of organic foliar fertilizers.

Green manure. A crop that, before it reaches full maturity, is incorporated into the soil for the purpose of soil improvement.

Humus. A dark-colored, stable form of organic matter that remains after most of the plant and animal residues in it have decomposed.

Legume. A plant that is a member of the pea family (including clover, alfalfa, beans, and peas), whose roots host nitrogen-fixing bacteria in a symbiotic relationship. By making atmospheric nitrogen available to plants, these bacteria improve the productivity of the soil.

Loam. The best texture of soil to have; it contains a balance of fine clay, medium-sized silt, and coarse sand particles. Loam is easily tilled and retains moisture and nutrients effectively.

Micronutrient. A nutrient plants need in very small quantities. Micronutrients include copper, chlorine, zinc, iron, manganese, boron, and molybdenum.

Mulch. A layer of an organic or inorganic material—such as shredded leaves, straw, bark, pine needles, lawn clippings or black plastic—that is spread around plants to conserve soil moisture and discourage weeds. As organic mulches decompose, they help to build the soil.

NPK ratio. The ratio of nitrogen (N), phosphorus (P), and potassium (K) in a fertilizer or amendment. For example, the NPK ratio for alfalfa meal is 5-1-2.

Organic. Materials that are derived directly from plants or animals. Organic gardening uses plant and animal by-products to maintain soil and plant health, and doesn't rely on synthetically made fertilizers, herbicides, or pesticides.

pH. A measure of how acid or alkaline a substance is. The pH scale ranges from 1 to 14, with 7 indicating neutrality, below 7 acidity, and above 7 alkalinity. The pH of your soil greatly affects what nutrients are available to your plants.

Raised bed. A garden bed raised above the soil surface to remedy poor drainage problems or to improve growing conditions. This can be done by double-digging the bed, or simply by loosening the top layer of soil and adding organic material.

Rototiller. A self-powered rotary tiller that pulverizes the soil with its rapidly turning blades. It is a useful tool for incorporating green manures and crop residues; however, overuse can damage the soil structure.

Sandy soil. Soil which contains more than 70 percent sand and less than 15 percent clay. Sandy soil is generally easy to work and well-drained, but it has poor nutrient- and water-holding abilities.

Silt. Refers to a soil particle of moderate size—larger than clay but not as large as sand.

Soil amendment. A material added to the soil for the purpose of making it more productive by improving its structure,

drainage, or aeration. An amendment such as compost can also be used to enhance microbial activity in the soil.

Soil dwellers. The living organisms that reside in the soil. These include decomposers such as bacteria, fungi and earthworms, beneficial parasites and predators, the larvae stages of many insects, and soil animals such as moles.

Soil structure. The physical arrangement of soil particles and interconnected pore spaces. Soil structure can be improved by the addition of organic matter. Walking on or tilling wet soil can destroy the soil aggregates and ruin the soil's structure.

Soil test kit. A set of instructions and a soil bag available through your state's Cooperative Extension Service. Test results indicate soil pH and specify what amendments and nutrients should be added to your soil to ensure success with your planned use.

Soil texture. The proportions of sand, silt, and clay in a particular soil.

Symbiotic relationship. A mutually beneficial relationship between two living organisms, such as plant roots and nitrogen-fixing bacteria.

Till. To prepare the soil for planting seeds or to disturb it in order to control weeds, either with a power driven rototiller or with a hoe, spading fork, or some other hand tool.

Weeds. Weeds are any plants that happen to grow where you don't want them to. Some perfectly fine plants can be considered weeds when they pop up in the wrong places.

The Benefits of Compost

Deborah L. Martin and Grace Gershuny

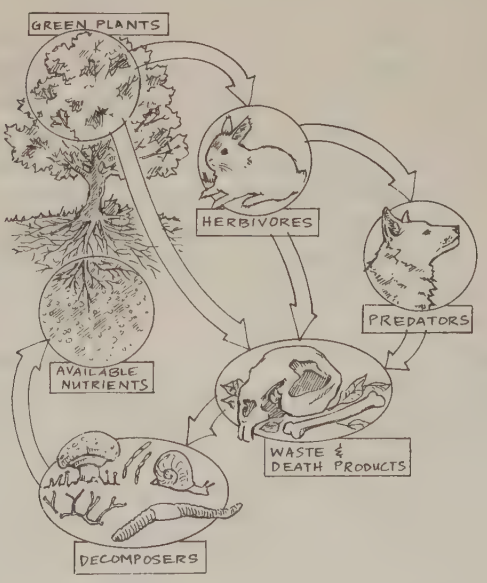
Plants, animals, insects, and people are all inextricably linked in a complex web of interrelationships with air, water, soil, minerals, and other natural resources playing vital roles. Compost, too, plays an important role. There is a cycle, a continuity to life.

We are only at the very beginning of an understanding of all the parts of this cycle of life. But we are learning that upsetting the life patterns of only one kind of plant or animal, even in a seemingly minor way, can have effects on many other living things. All of the environmental problems we face are rooted in a failure to appreciate the life cycle and to keep it intact. We can use our understanding of the interrelationships of living things in active ways, too, to increase the productivity of our fields, forests, orchards, and gardens. Composting is one way to work within the life cycle in the furthering of our welfare.

Compost is more than a fertilizer, more than a soil conditioner. It is a symbol of continuing life. Nature has been making compost since the first appearance of primitive life on this planet, eons before humans first walked the earth. Leaves falling to the forest floor are soon composted, returning their nutrients to the trees that bore them. The dead grass of the meadow, seared by winter's frost, is made compost in the dampness of the earth beneath. The birds, the insects, and the animals of field and forest contribute their wastes and eventually their bodies, helping to grow food so that more of their kind may prosper. The greenness of the earth itself is strong testimony to nature's continuing composting program.

The compost heap in your garden is an intentional replication of the natural process of birth and death that occurs almost everywhere in nature. It did not take long for people to learn to imitate nature by building compost piles. It is ironic that composting, the oldest and most universally practiced form of soil treatment in the world, should today be claiming so many converts. Perhaps this is nature's Restoration—a reaffirmation that people do, indeed, live best when they live in harmony with nature.

Because the compost heap is symbolic of nature's best efforts to build soil, and because compost is the most efficient and practical soil builder, it has become the heart of the organic method of farming and gardening. Composting is the single



In the forest, nutrients are recycled through the natural decomposition of plant and animal waste.

Continued →

most important task of the organic gardener or farmer because the health of the soil depends on the composting treatment it receives, and success in gardening and farming depends on the health of the soil.

Compost improves soil texture and structure, qualities that enable soil to retain nutrients, moisture, and air for the support of healthy crops. By increasing the soil's moisture-holding capacity, compost helps control erosion that otherwise would wash topsoil into waterways. Compost is the best recycler of biological wastes, turning millions of tons of our refuse into a food-growing asset. Compost provides and releases plant nutrients, protects against drought, controls pH, supports essential bacteria, feeds helpful earthworms, stops nutrient loss through leaching, acts as a buffer against toxins in the soil, controls weeds, and conserves a nation's nonrenewable energy resources. Every gardener knows that compost is valuable—but, until we understand more fully all the benefits of compost, we can never understand why it must be the single most important part of gardening and farming.

Life Inside a Compost Heap

Deborah L. Martin and Grace Gershuny

The two most important aspects of a compost pile are the chemical makeup of its components and the population of organisms in it. Compost piles are intricate and complex communities of animal, vegetable, and mineral matter, all of which are interrelated, and all of which play a part in the breakdown of organic matter into humus. Composting is the result of the activities of a succession of organisms, each group paving the way for the next group by breaking down or converting a complex biodegradable material into a simpler or more usable material that can be utilized by its successor in the chain of breakdown. Generally speaking, the more "simple" the molecular structure of the material, the more resistant it becomes to bacterial attack and, hence, the more biologically stable it becomes. Whether the decomposition process takes place on the forest floor or in a gardener's compost heap, the biochemical systems at work are the same, and humus is always the result.

Humus

Humus, the relatively stable end product of composting, is rich in nutrients and organic matter and highly beneficial to both the soil and crops grown in the soil.

The advantages of humus are twofold. First, when it is mixed with the soil, the resulting combination becomes a heterogeneous, loosely structured soil mixture allowing air and water to penetrate to soil organisms and growing plants. Because of its loose texture, humus-rich soil soaks up water in its pores so that less runoff occurs. Second, humus contains a number of chemical elements that enrich the soil with which it is mixed, providing nutrients for growing plants.

The major elements found in humus are nitrogen, phosphorus, potassium, sulfur, iron, and calcium, varying in amounts according to the original composition of the raw organic matter thrown on the heap. Minor elements are also present, again in varying amounts depending on the type of compost. The N-P-K percentages of finished compost are relatively low, but their benefit lies in the release of nitrogen and phosphorus in the soil at a slow enough rate that plants can use them and they aren't lost through leaching.

Soil mixed with humus becomes a rich, dark color that absorbs far more heat than nonorganic soils, making it a more favorable environment in which to grow crops and ornamental plants.

How Compost Is Produced

The road from raw organic material to finished compost is a complex one, because both chemical and microbial processes are responsible for the gradual change from one to the other.

Decomposition of compost is accomplished by enzymatic digestion of plant and animal material by soil microorganisms. Simultaneously, the chemical processes of oxidation, reduction, and hydrolysis are going on in the pile, and their products at various stages are used by microorganisms for further breakdown.

Bacteria use these products for two purposes: (1) to provide energy to carry on their life processes and (2) to obtain the nutrients they need to grow and reproduce. The energy is obtained by oxidation of the products, especially the carbon fraction. The heat in a compost pile is the result of this biological "burning," or oxidation. Some materials can be broken down and oxidized more rapidly than others. This explains why a pile heats up fairly rapidly at the start. It is because the readily decomposed material is being attacked and bacterial activity is at its peak. If all goes well, this material is soon used up, and so bacterial activity slows down—and the pile begins to cool. Of course, if the mass of the material is big enough, it acts as an insulator to prevent heat loss, and the high temperature may thus persist for some time after the active period is over, especially if the pile is not turned. Persistent high temperatures are the result of uneven breakdown.

The raw materials that you add to your compost heap will have to be of biological origin in order to decompose down to finished compost. Wood, paper, kitchen trimmings, crop leavings, weeds, and manure can all be included in the heap. As compost is broken down from these raw materials to simpler forms of proteins and carbohydrates, it becomes more available to a wider array of bacterial species that will carry it to a further stage of decomposition.

Carbohydrates (starches and sugars) break down in a fairly rapid process to simple sugars, organic acids, and carbon dioxide that are released in the soil. When proteins decompose, they readily break down into peptides and amino acids, and then to available ammonium compounds and atmospheric nitrogen. Finally, species of "nitrifying" bacteria change the ammonium compounds to nitrates, in which form they are available to plants.

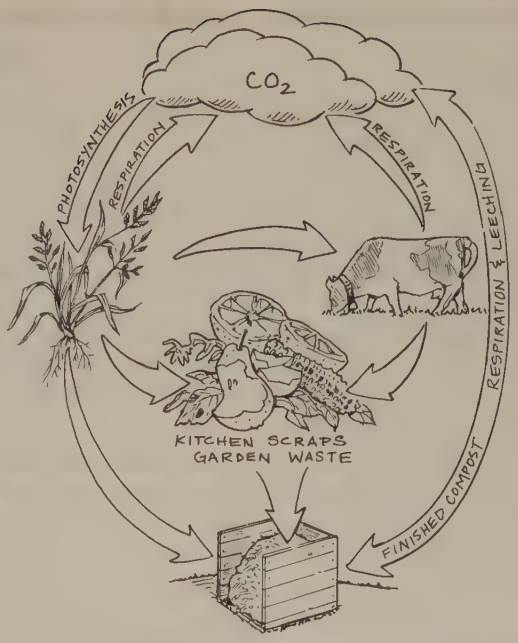
At this stage of decomposition, the heap is near to becoming finished compost, with the exception of a few substances that still resist breakdown. Through complex biochemical processes, these substances and the rest of the decomposed material form humus. There is some evidence that humus is largely the remains of microbial bodies.

The microorganisms of the compost heap, like any other living things, need both carbon from the carbohydrates, and forms of nitrogen from the proteins in the compost substrate. In order to thrive and reproduce, all microbes must have access to a supply of the elements of which their cells are made. They also need an energy source and a source of the chemicals they use to make their enzymes. The principal nutrients for bacteria, actinomycetes, and fungi are carbon (C), nitrogen (N), phosphorus (P), and potassium (K). Minor elements are needed in minute quantities.

These chemicals in the compost pile are not in their pure form, and certainly not all in the same form at the same time. For example, at any given moment, nitrogen may be found in the heap in the form of nitrates and nitrites, in ammonium compounds, in the complex molecules of undigested or partly digested cellulose, and in the complex protein of microorganism protoplasm. There are many stages of breakdown and many combinations of elements. What's more, microorganisms can make use of nitrogen and other elements only when they occur in specific forms and ratios to one another.

Nutrients must be present in the correct ratio in your compost heap. The ideal C/N ratio for most compost microorganisms is about 25:1, though it varies from one compost pile to another. When too little carbon is present, making the C/N ratio too low, nitrogen may be lost to the microorganisms because they are not given enough carbon to use with it. It may float into the atmosphere as ammonia and be lost to the plants that would benefit by its presence in humus. Unpleasant odors from the compost heap are most often caused by nitrogen being released as ammonia. Materials too high in carbon for the amount of nitrogen present (C/N too high) make composting inefficient, so more time is needed to complete the process. When added to the soil, high-carbon compost uses nitrogen from the soil to continue decomposition, making it unavailable to growing plants.

Affecting the interwoven chemical and microbial breakdown of the compost heap are environmental factors that need to be mentioned here.



THE CARBON CYCLE. *Green plants use carbon dioxide gas, water, and sunlight to make sugars and other carbon-containing compounds that animals use as food. Carbon compounds in plant and animal wastes provide food for decomposers in the compost pile. Materials that have passed through the decomposers' bodies and the microbial bodies themselves contain nutrients used by plants to continue the carbon cycle.*

Composting can be defined in terms of the availability of oxygen. Aerobic decomposition means that the active microbes in the heap require oxygen, while in anaerobic decomposition, the active microbes do not require oxygen to live and grow. When compost heaps are located in the open air, as most are, oxygen is available and the biological processes progress under aerobic conditions. Temperature, moisture content, the size of bacterial populations, and availability of nutrients limit and determine how much oxygen your heap uses.

The amount of moisture in your heap should be as high as possible, while still allowing air to filter into the pore spaces for the benefit of aerobic bacteria. Individual materials hold various percentages of moisture in compost and determine the amount of water that can be added. For example, woody and fibrous materials, such as bark, sawdust, wood chips, hay, and straw, can hold moisture equal to 75 to 85 percent of their dry weight. "Green manures," such as lawn clippings and vegetable trimmings, can absorb moisture equaling 50 to 60 percent of their weight. According to longtime composting advocate and researcher Dr. Clarence Golueke in *Composting*, "The minimum content at which bacterial activity takes place is from 12 to 15 percent. Obviously, the closer the moisture content of a composting mass approaches these low levels, the slower will be the compost process. As a rule of thumb, the moisture content becomes a limiting factor when it drops below 45 or 50 percent."

Temperature is an important factor in the biology of a compost heap. Low outside temperatures during the winter

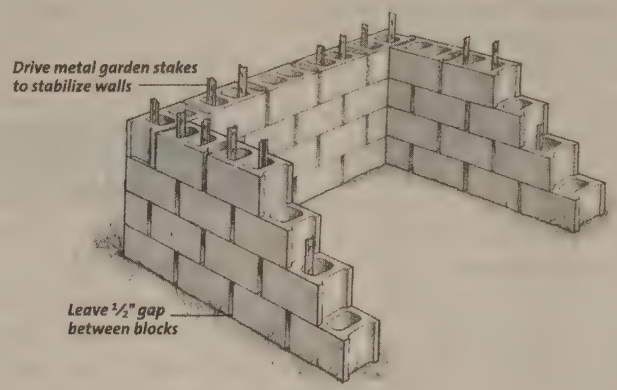
A Better Bin

Sure, you can make a simple compost bin out of a hoop of chicken wire (and you probably have!). But if you, like many gardeners, have found that composting is a cornerstone to a great yard, then you may want to build a more lasting structure. Concrete block is a humble but durable material. It's easy to make low walls of the block if they aren't going to bear a load; you just stack them up and drive metal garden stakes through the holes to keep them in place. There's no need for mortar, as is used in a foundation wall. If you want to always have some compost ready for taking and some in the process of decomposing, you can expand this bin to two or three bays. You'll only need concrete blocks (42 to build the bin as shown) and metal garden stakes to stabilize the bin.

1. Use a straight-bladed shovel to make the surface as level as possible.
2. Lay the first row of 12 blocks, taking care that the sidewalls meet the back at right angles. Leave a vertical gap of about ½ inch between blocks to allow air to circulate.
3. Lay the remaining three rows of 11, 10, and 9 blocks.
4. To stabilize the bin, use a sledgehammer to drive metal garden stakes through holes in the blocks and into the ground. If there is a chance that children will try climbing on the bin, use enough stakes to make it sturdy and pound them nearly flush with the top of the walls to prevent injury.



months slow the decomposition process, while warmer temperatures speed it up. During the warmer months of the year, intense microbial activity inside the heap causes composting to proceed at extremely high temperatures. The microbes that decompose the raw materials fall into basically two categories: mesophilic, those that live and grow in temperatures of 50° to 113°F (10° to 45°C), and thermophilic, those that thrive in temperatures of 113° to 158°F (45° to 70°C). Most garden compost begins at mesophilic temperatures, then increases to the thermophilic range for the remainder of the decomposition period. These high temperatures are beneficial to the gardener because they kill weed seeds and diseases that could be detrimental to a planted garden.

The bacterial decomposers in compost prefer a pH range of between 6.0 and 7.5, and the fungal decomposers between 5.5 and 8.0. Compost must be within these ranges if it is to decompose. Levels of pH are a function of the number of hydrogen ions present. (High pH levels indicate alkalinity; low levels, acidity.) In finished compost, neutral (7.0) or slightly acid (slightly below 7.0) pH is best, though slight alkalinity (slightly above 7.0) can be tolerated.

Lime is often used to raise the pH if the heap becomes too acidic. However, ammonia forms readily with the addition of lime, and nitrogen can be lost.

Composting Tools and Supplies

Truth is, you can make compost without any tools or equipment. But if you want to cook up big batches of "gardener's gold," compost bins, tumblers, frames, and other gadgets can help you do the job quickly and easily.

Good Investments

Compost happens. Just pile up your grass clippings, fallen leaves, garden wastes, and kitchen scraps and the materials eventually will decompose into rich, black humus.

Although equipment isn't essential for making good compost, it can help you manage your composting operation. Here are some reasons why you might want to invest in a compost bin, frame, tumbler, or other equipment.

Appearance matters. If you have a small yard and have to make compost in full view of your neighbors, you (and your neighbors) may be happier if your compost is under cover.

Bins boost production. Compost bins can help you organize your composting so that you can be more productive. For example, with a three-bin system, you can pile slowly decomposing yard wastes in one bin, mix kitchen scraps and finely chopped materials for fast composting in another bin, and keep finished compost in the third bin. Or, use one bin for finished compost, and turn your compost-in-progress from one of the remaining bins into the other.

Get finished compost faster. By turning and aerating your pile—using a tumbler, pitchfork, and other kinds of equipment—you can speed the process and turn garbage into gold in almost no time at all.

Build-It-Yourself Bins

Whatever your composting style, there's bound to be a bin, frame, or tumbler that'll meet your needs. If you're handy, you can build your own compost bin in almost no time at all. You can use almost any durable material, including wire, wood, slats, and cinder blocks. Here are a few ideas.

WIRE CAGE

Easy does it: Start with a 10-foot length of 48-inch, 12½- or 14-gauge welded steel wire fencing. Clip or wire together the ends to form a cylindrical compost bin 4 feet high and slightly more than 3 feet across. Pile your leaves, clippings, and other organic materials inside. (Use grass clippings sparingly, in layers no more than 1 inch thick, to avoid matting.) When the bin is half full, drive a stake into the center of the pile. Water will run down the stake, helping to keep the pile moist.

To turn the pile, simply unfasten the bin's ends, pull the fencing away from the materials, and set the bin back up next to the heap. Then, refill the empty bin, turning the materials from the top of the original pile to the bottom of the new pile and from the outside to the inside.

WOOD AND WIRE BIN

For a bit more structure, make a wood and wire bin, using untreated 2 x 4 lumber and ½-inch mesh hardware cloth or poultry netting. (*Never use pressure-treated wood*—toxic copper and arsenic will leach into your compost and eventually contaminate your garden soil; cedar is a good choice because it resists rotting.) Use the lumber to make four 3 x 3-foot or 4 x 4-foot identical open frames. Staple the hardware cloth to one side of each frame. Next, nail three of the panels together to form a back and two sides. Use the remaining panel to make a convenient door, by hinging the edges at one corner and placing the hooks and eyes on the opposite corner. To turn the compost ingredients, just open the hooks for easy access.

A variation of this is the wire and tomato stake bin. Make a 4 x 4-foot square by driving 4-foot-long tomato stakes into the ground at 1-foot intervals. Surround the stakes with the hardware cloth or wire netting, then loop baling wire around the whole thing to secure the netting.

Set up these bins close to where you need to use compost. When you've used up the compost, move the bin to another location in need of compost, and begin a new pile.

MOVABLE SLAT BIN

Perhaps the classic compost bin is the movable slat bin (sometimes called the New Zealand box). Because slat bins are constructed entirely of wood, they hold up better than wire bins.

The sides of these bins consist of movable slats that fit inside tracks. Spacers between the slats allow air to reach the compost materials, speeding the breakdown process. The slats make access easy: When you need to work with the composting materials, you just remove as many of the slats as necessary.

Many movable slat bins have three compartments for storing compost in various stages: freshly collected materials, partially decomposed materials, and finished compost. Having multiple bins allows you to produce a continuous supply of compost for all your garden needs.

The ideal size bin for making quick compost should hold 27 cubic feet of organic material. To keep out animals like raccoons and rodents, attach hinged lids to the top of each bin. Bins like these can be made with or without a floor. Your compost will break down faster, however, without a floor—just pile the materials directly on the ground.

(Remember, use cedar or another rot-resistant wood to make a wooden bin, instead of using pressure-treated wood.)

CINDER BLOCK BIN

If durability is your chief concern, construct a permanent bin from cinder blocks (or brick) and mortar. For a bit more mobility out of the bin, use just the blocks without the mortar.

Stack the blocks three or four high to form walls. You can leave one side open to form a U-shaped bin or enclose the bin on all four sides. If you enclose all four sides, lay the blocks apart—with spaces of 1 inch or more between them—to improve air circulation. Add one or more interior walls to create multiple bins. To turn the pile, simply remove the blocks from one side and fork the materials from one bin to another.

Cover the structure with a wooden lid or plastic tarp to keep rain out. If you make a concrete floor for your bin, make sure you slant it slightly to allow drainage. (Collect the resulting "compost tea" in a bucket and use it to feed houseplants!)

Continued →

For winter protection, consider recessing the bin into a slope that has good southern exposure. A 5 x 10-foot cinder block bin can hold 2 to 3 tons of compost.

MISCELLANEOUS BINS

Compost bins come in all shapes, sizes, and materials. Feel free to use whatever you have on hand. Resourceful gardeners have been known to use such things as pallets, picket or snow fencing, and straw bales to make quality compost bins.

Pallets. Recycled hardwood pallets provide a quick, easy—and commonly free—compost bin. Just stand the pallets on end in a square, pound in fence posts to hold the corners together, and use heavy-gauge wire to fasten the pallets to the posts.

Fencing. Fencing is sturdy and allows plenty of air to circulate inside the bin. Use steel or wooden posts for the bin's corners. Attach snow, lattice, or picket fencing for the sides.

Straw bales. You can make an all-organic compost bin by using straw bales—stacked two high—for the sides. Move away a bale or two to turn and access the compost. Over time, some of the straw itself will decompose, adding more carbon to your pile.

Ready-Made Composters

Ready-made composters may cost you more than the materials for making your own bin. But commercial composters can be quite attractive and durable. They also save you the time and effort you'd spend making your own. There are two basic types—bins and tumblers—with many variations of each.

COMMERCIAL BINS

Many of these composters are made of recycled plastic, which won't warp or discolor like wood. Bins made of dark-colored plastic catch and hold the sun's heat, making them good choices for those who live in frigid climates.

Some of these bins retain moisture, too. Their sides and top cover are slanted to catch just enough rain to maintain moisture levels without drenching the compost. And while you do have to turn the compost the old-fashioned way—using a pitchfork—you don't have to uncover the composter to do so. You just insert your fork through a mixing slot near the top, loosen and turn the material, then insert the fork into one of the lower slots to mix the material on the bottom. Removable doors on the sides allow you to scoop out the finished compost. With pliers, you can assemble the unit in about half an hour.

You can even buy an inexpensive—and "compostable"—cardboard container that will hold your compost for about a year before it's ready to become one with its contents. At that point, you can just toss it into another cardboard bin and start again!

COMPOST TUMBLERS

Tumbler or drum composters are plastic or metal containers that are usually mounted on elevated frames. Some models have gear-driven turning mechanisms; others spin on ball bearings. Another type resembles a large metal or plastic ball. To turn the contents, you just roll the ball on the ground.

Because tumblers make it easy to turn materials, they can produce compost quickly. They have at least one drawback, however: Their capacity usually isn't very large. When you've filled the tumbler to a certain level, you must stop adding fresh materials until the process has finished. During those 2 to 3 weeks, you'll need to stockpile your materials in another container or area. And because the contents rest on plastic rather than on the ground, you might want to add a few shovelfuls of soil or finished compost whenever you fill the bin. Otherwise, earthworms won't be able to get in to help the decomposition process.

DECIDING WHAT TO BUY

Don't choose a commercial composter based on its cost alone. Consider these factors, too:

Portability. Some models, especially the tumblers, are too large or heavy to move easily. Make sure you have a good site for such a bin before you buy it. Portable bins (like the ball type) allow you to make compost at several sites around the garden; they're especially good for gardeners who don't have a wheelbarrow or who garden over a large area.

Capacity. Choose a bin size appropriate to the amount of materials you expect to have for composting. Bigger isn't necessarily better if you have only small quantities of composting materials. If you have a lot of material to compost, however, two or three inexpensive cage- or open-type bins may be a better choice for you than a single large bin.

Ease of assembly. Some of the more complicated bins are sold unassembled and have dozens of pieces to screw and bolt together. If possible, read the assembly instructions before you buy.

Ease of use. If the bin has a loading door or lid, you should be able to lift or open and close it easily. The opening should be wide enough to accommodate bulky material. When considering a drum-type composter, check to see that there's enough room beneath the drum to park a wheelbarrow for unloading the finished compost.

Other Composting Tools

Besides the items in the following list, there are at least a few other tools that can help you make compost. For instance, you'll probably want a small bucket with a lid (for collecting and carrying kitchen scraps) and a pair of good-quality gloves. Many gardeners also find a chipper/shredder useful for chopping leaves and garden wastes into smaller pieces before adding them to the pile: The smaller the pieces, the faster they'll decompose.

FORKS

Use a pitchfork—which has three long, slightly rounded tines—to add materials to the pile, to turn the pile, and to transfer the finished compost to your wheelbarrow and beds. Use a straw fork (with five or six long rounded tines) for scattering light composting material.

WHEELBARROW

Of course you'll need a wheelbarrow (or garden cart) to transport your grass clippings, leaves, and garden wastes to the compost pile and to carry your finished compost to your garden. Wheelbarrows also are handy to work over when screening compost or potting up houseplants.

You'll find wheelbarrows easier to maneuver than heavy-duty garden carts because they have one wheel instead of two. And with plastic models, maintenance is minimal—they have no metal parts to rust.

SCREEN

A screen is useful for separating the finer particles of finished compost from larger, less-decayed chunks. Fine, screened compost is ideal for covering seedbeds. If it's aged (6 months or more), you can even use it in potting mixes. Throw the larger stuff back into the pile for further microbial breakdown, or—if the pieces aren't too big—use it as mulch or side-dressing for plants that are already established.

You can either buy a compost screen or make your own by stapling hardware cloth or fine-gauge chicken wire to a simple wood frame.

THERMOMETER

If you want to make compost quickly (in as little as 2 to 3 weeks), you'll need a compost thermometer to monitor the temperature of your pile. The hotter the temperature, the faster the decomposition. Another advantage of "hot compost" is that it kills weed seeds and disease organisms.

Use the thermometer to check the temperature every 3 to 5 days. When the temperature drops below 120°F, aerate the pile (by turning or using a commercial aerator) to get it cooking again.

You'll find compost thermometers at your garden center and in garden-supply catalogs. They're also useful for checking soil temperature.

AERATOR

The more air you get into your pile, the faster it'll break down. There may be other benefits, too: Some research indicates that aerating your pile regularly could even boost its nitrogen content and disease-fighting abilities.

Turning your pile with a fork a couple of times a week is one way to get air into it. Another is to use a tool designed specifically for this purpose. Commercially sold compost aerators come in several styles. All have a long shaft that you use to twist, turn, or bore holes into the center of the pile. Most are hand-powered, but at least one model is powered by a standard power drill.

A low-effort alternative is the compost "chimney." A compost chimney is simply a piece of PVC pipe about 4 feet in length—slightly longer than the height of your pile—with holes drilled in it. You just stick the pipe upright in the center of the pile to allow air to flow through the decaying materials.

HOSE

Moisture is essential to the composting process. Ideally, your pile should feel as moist as a damp sponge (no wetter!). When the materials begin to dry out—causing the process to slow—you'll need to remoisten the layers with a hose.

If you're buying a new hose, look for a durable rubber hose with solid brass couplings. Also, keep in mind that the more "plies" it has, the better it will hold up.

Materials for Composting

Deborah L. Martin and Grace Gershuny

Materials for composting are all around you. Many gardeners need look no further than the home grounds for a sufficient supply. Kitchen wastes, lawn clippings, weeds and plant debris, dog and cat hair, vacuum cleaner accumulations—nearly anything that once lived (and is thus organic) is a candidate for the compost heap.

After you have exhausted the home supply and still don't have all the materials you would like, you can begin to plan a series of foraging expeditions, beginning as close to home as possible and ranging out as far as you must in order to fulfill your requirements.

Manure should be the first item on your list, since it is by far the most important ingredient in any heap. If you try, you can get it free for the hauling or at a token fee at poultry farms, riding stables, feedlots, even zoos and wild game farms—any place that holds large numbers of animals in concentration. Even a friend with one horse and no garden can supply all the manure you'll need for a backyard pile.

Your chances of getting manure at a family farm are not as good, since farmers will probably want their manure for their own fields. Even if you seem to have all the home materials your compost heap can use, try to find a source of manure. Its tremendous bacteria content will bring your heap into biological and chemical balance and aid the rapid reduction of all the other materials.

But you don't have to stop with manure expeditions. In town, you can scavenge at grocery stores, city agencies, factories and mills, restaurants, and many retail operations. Ranging

Continued →

farther into the country, you can find materials in fields and along roadsides, streams, and ponds, at farms and orchards, at sawmills and canneries. Nearly any organic gardener can find ample composting materials by going no further than 5 miles from home. The farmer, of course, must make composting an integral part of his or her soil management plan, utilizing every scrap of home material and adding green manure crops as necessary. Even the organic farmer—especially one who has few animals or cultivates a small but intensive area—might need to look for supplementary materials. The materials listed in this section can be of use to both gardeners and organic farmers seeking to enhance their composting operations.

Where to Begin

Begin, of course, at home. Are you discarding any organic matter at all? Newspapers? Tea bags? Clippings from the children's haircuts? Dishwater? With the exception of human and pet excreta (addressed later in this section), you can use everything. Before foraging, be sure that your home recovery program is 100 percent effective.

Once you venture outside your own yard, the best place to start is with friends, neighbors, and relatives. Some diligent composters offer to cart away kitchen scraps after every social call. This is often a valuable community service for people who would like to compost their wastes but for one reason or another are not able to do so. Recycled plastic pails with tight-fitting lids, such as those used for wallboard compound, make excellent containers for storing a week's worth or more of goodies. A layer of peat moss or sawdust on the bottom helps absorb moisture and odors. You can offer to pick up the full pail regularly, and leave a fresh, empty one in its place.

Your expeditions away from home can continue with a trip through the business directory of the phone book. Go through it slowly, listing all possible sources of materials. Your search might end when you find that you can pick up manure at the local riding stable every Saturday morning and vegetable trimmings from the neighborhood supermarket every Tuesday and Friday afternoon. After your routine is established, it usually operates like clockwork.

Here is a partial list of away-from-home materials. You will come across others in your expeditions—but do consider these for starters.

Farms and Orchards. These can provide you with spoiled hay, corn silage, eggshells, manure of every kind, feathers, barnyard litter, spoiled fruit, spent mushroom soil, whey from dairy operations, and orchard litter.

Factories and Mills. Apple pomace is available from cider mills. Other available compostables include cannery wastes of all kinds, shredded bark, sawdust, and wood shavings from lumber mills and carpentry shops; botanical drug wastes from pharmaceutical firms; cement dust; cocoa bean hulls (good mulch); coffee chaff from coffee wholesalers; cottonseed meal; excelsior from receiving departments; felt wastes; fly ash from incinerators; agricultural frit from glass factories; grape pomace from wineries and spent hops from breweries; granite dust from cutting operations; leather dust; lignin from paper mills; spoiled meal from flour mills; peanut shells; slag from steel plants; spice marc (spent) from spice packers; tanbark from tanneries; tankage from meat-processing plants and slaughterhouses.

City Agencies. You may be able to acquire dried sewage sludge, leaf mold from parks department leaf depositories, fly ash from incinerators, aquatic weeds, and pulverized wood from tree-trimming operations.

Stables and Feedlots. Manure and stable litter of all kinds are valuable compostables.

Retail Stores. You can get vegetable trimmings from supermarkets and shops, hair from barbers and salons, pet hair from grooming parlors, food wastes from restaurants, excelsior from gift shops (used for packing breakables), plant wastes from florists, and sawdust from carpentry shops and lumber supply houses.

Roadsides, Fields, and Waterways. Old leaves, weeds, and water plants from streams, lakes, and ponds may be plentiful. A note of caution: Many native plants, even those viewed as weeds, are endangered species that are protected by law. This is especially true of plants growing near oceans or in wetlands; such areas often contain fragile ecosystems that should not be disturbed. In gathering materials in fields and wild areas, be aware of your ecological responsibility to avoid robbing natural areas of their native plants.

Regional Materials

Gardeners in certain parts of the country can avail themselves of materials abundant only in their regions. New Englanders can look for wool and felt wastes from mills, leather dust, and maple syrup wastes. Those along seacoasts can find greensand, fish scraps, and seaweed. Southwestern gardeners should look for cannery wastes, mesquite, olive residues, grape pomace from wineries, and citrus wastes. Southerners may have access to cotton gin trash, Spanish moss, peanut shell ashes, tung oil pomace, sugarcane trash, molasses residue, castor pomace, tobacco stems, rice hulls, and water hyacinth plants.

In collecting materials for your heap, not only will you be adding to your own soil's fertility and structure, but you will also be contributing to the recycling of wastes that might otherwise become pollutants in the environment. Many communities now have or are planning composting facilities for at least part of their trash. If yours is one of them, they probably make finished compost available free or at low cost to gardeners. If your town has not yet pursued this option, it may offer free delivery of leaves, shredded tree trimmings, and other

compostable municipal wastes. A large poultry farm might be paying to have manure and litter hauled away. Their trash can be your treasure.

Supermarkets and restaurants will be more than happy to contribute their organic wastes to you, since it lowers their disposal costs. Most important, however, these materials, instead of being dumped, buried, or burned, will find their way back to the soil.

Materials to Avoid

Although nearly any organic material can contribute to good compost, there are some that should be avoided, and others to be used only in limited amounts. First, you want your heap to be balanced among green matter, animal wastes, manure, and soil. If you build your heap of 80 percent tankage from the local meat-packing plant, not only will you have a putrid mess, but you will attract every stray dog, cat, and raccoon within a 5-mile radius. A truckload of grape pomace or a ton of wet hops from the brewery will be equally hard to handle, as will be the neighbors if your heap's odor wafts their way. Strive, then, for a commonsense balance in the materials you select, and be sure to add a layer of soil over the heap every time you add materials that might cause odor or attract vermin.

Human feces should not be used unless they have been properly treated and permitted to age sufficiently. Even then, concerns about disease pathogens make the use of such material dubious at best for the home gardener. Urine alone can be used quite safely, however.

Wastes from pet dogs, cats, and birds should not be used on the compost pile. Although dog manure is as rich in nutrients as other manures, it is more difficult and less pleasant to handle than the mixed bedding and manure of cattle and horses. In addition, it may carry organisms parasitic to humans. Special composters designed exclusively for dog droppings offer pet owners a safe alternative.

Cat manure is even more hazardous, especially to pregnant women and small children. Cat droppings may contain *Toxoplasma gondii*, a one-celled organism that, when transmitted to a pregnant woman, may infect her unborn child, causing brain and eye disease. *Toxocara cati* is a roundworm, also common in cat feces, that causes similar problems in children. Keep the contents of the litter box away from children and the compost pile.

Bird droppings have been similarly indicated as potential disease sources. Since they are most often mixed with bedding and dropped birdseed from the bottom of the cage, bird droppings will also tend to introduce unwanted weeds into your compost.

Materials that will not decompose readily—large pieces of wood, oyster and clam shells, large quantities of pine needles, rags, brush, cornstalks, heavy cardboard—should not be used in large amounts unless they are shredded first.

Large amounts of highly acid materials such as pine needles and oak leaves should not be used without the addition of enough limestone to neutralize the acid. For acid-loving crops, however, you might wish to build acidic compost by the deliberate use of these materials.

Be very careful about diseased plants—you may be better off burning them and adding the ashes to your compost than risking inoculating your whole garden with them. Weeds can generally be composted, but be careful to ensure hot composting temperatures if they have produced seed. A few species, such as quack grass and Canada thistle, reproduce readily from the tiniest bit of surviving rhizome and should be avoided entirely.

Don't use large amounts of grease and oil, since they not only attract animal pests but also inhibit the biochemical processes necessary to successful composting. The amount of grease and oil from a normal household will cause no problem. However, carting home tubs of spent grease from the local potato chip factory is unwise.

Do not use toxic materials. There is little sense in trying to build an organic soil by including pesticide-treated wastes in the compost heap. Plant debris from roadsides might have been subject to a broad, potent, and persistent herbicide applied by the highway department; or, if the highway is a busy one, plants might be coated with lead emissions from passing traffic. Be careful in choosing materials.

Materials for Enrichment

There are many substances you can buy to increase your compost's N-P-K content or control its pH. Although it is not necessary to add these materials to the heap, many gardeners find it worth the expense to ensure a high nutrient level in their compost.

Among the materials and products available at garden centers and through mail-order outlets are bagged manure, dried blood, bonemeal, limestone, cottonseed meal, greensand, hoof and horn meal, tobacco wastes, seaweed, peat moss, and other natural products that are valuable to the heap because of their nutrient levels or ability to correct pH.

Many people add lime to their compost in order to increase its pH. This is not often necessary or beneficial, and it is not a good idea if you are composting manure, since the lime reacts with the nitrates in the manure to drive off ammonia. If lime is needed, apply it directly to the soil or mix it with the finished compost for potting mixes. The microbes inhabiting your compost heap can often benefit from the calcium in lime, but other forms of calcium, such as eggshells or any marine animal (oyster, crab, clam) shells, pulverized as finely as possible, will serve as well. Bonemeal and wood ashes are also rich in calcium. Avoid all of these materials if you want compost for acid-loving plants such as rhododendrons, camellias, and blueberries, in which case you may want to use acid peat instead of soil in your heap.

Continued ➔

Rock or colloidal phosphates are excellent materials for enriching the mineral content of your compost. Microbial action makes their nutrients more readily available than they would be if added directly to the soil. They also contain significant amounts of calcium and micronutrients. Other rock powders such as granite dust and greensand, both sources of potassium and micronutrients, are similarly made more available to plants when first consumed by compost organisms.

Specific nutrients can also be added by using plants that are especially rich in those elements in your compost. Seaweeds, such as the kelps, are rich in potassium and are also good sources of such elements as iodine, boron, copper, magnesium, calcium, and phosphorus. If available locally, seaweed should certainly be added to the compost heap. The water hyacinths that grow so abundantly in the rivers of the South are especially rich in many of the elements that are more apt to be deficient in the soil. Leaves, discussed more thoroughly later in this section, are a teeming source of micronutrients that are not found in upper layers of soil; use them in compost whenever possible.

Activators

A compost activator is any substance that stimulates biological decomposition in a compost pile. There are organic activators and artificial activators. Organic activators are materials containing a high amount of nitrogen in various forms, such as proteins, amino acids, and urea, among others. Some examples of natural activators are manure, garbage, dried blood, compost, humus-rich soil, and urine.

Artificial activators are generally chemically synthesized compounds such as ammonium sulfate or phosphate, urea, ammonia, or any of the common commercial nitrogen fertilizers. These materials are not recommended.

There are two ways in which an activator may influence a compost heap: (1) by introducing strains of microorganisms that are effective in breaking down organic matter and (2) by increasing the nitrogen and micronutrient content of the heap, thereby providing extra food for microorganisms.

Those who follow the practices of biodynamic agriculture consider certain activators, made according to precise instructions, to be essential for producing the highest-quality compost. These preparations are used in minute quantities, as part of a holistic approach to working with soil, plants, and the energies of nature.

Claims have sometimes been made that special cultures of bacteria will hasten the breakdown of material in a compost heap and also produce a better quality of finished compost. Products are manufactured that are reported to be effective in improving the action of a compost heap.

Most independent tests, however—including those conducted at the Rodale Research Center—indicate that there is no benefit to be gained from the use of an activator that relies solely on the introduction of microorganisms. It seems that microorganisms will quickly multiply to the limit that their environment will permit. Since all the necessary microorganisms are already present in manure, soil, and other composting materials, there is no benefit to be gained from introducing strains in the form of an activator product. The best activator is a layer of finished compost from the previous heap or a generous amount of healthy topsoil.

NITROGEN ACTIVATORS

The cause of most compost heap "failures" is a lack of nitrogen. Almost invariably, a heap that doesn't heat up or decay quickly enough is made from material which is low in nitrogen. Nitrogen is needed by the bacteria and fungi that do the work of composting, to build protoplasm and carry on their life processes.

In experiments conducted at the Rodale Research Center, it was shown that increasing additions of blood meal (a high-nitrogen activator) produced associated increases in the temperature of the pile, indicating increasing bacterial activity. In the tests, 3 pounds of blood meal in a 31-pound pile produced the best results.

Good nitrogen activators include not only blood meal (which is expensive when purchased commercially at garden centers), but tankage, manure, bonemeal, and alfalfa meal. Human urine, which contains about 1 percent nitrogen, also makes an excellent compost activator. Just how much you should add to the heap depends on the nature of the material you are composting. Low-nitrogen materials such as straw, sawdust, corncobs, and old weeds should have at least 2 or 3 pounds of nitrogen supplement added per 100 pounds of raw material. If plenty of manure, grass clippings, fresh weeds, and other high-nitrogen materials are available to be mixed in with the compost, no nitrogen supplement will be necessary.

Common Materials

Here is a list of the more common—and some not-so-common—materials that can be used in composting.

Alfalfa

Alfalfa is a perennial herbaceous legume grown as livestock feed and as a green manure or cover crop. Alfalfa grows almost everywhere in the United States and is widely available as hay, meal, or dehydrated feed pellets. Its nitrogen content and absorbency make it an excellent addition to the compost pile.

In combination with leaves and/or household garbage, alfalfa serves as a good compost stimulant and activator; its 12:1 carbon/nitrogen (C/N) ratio helps bring the pile's overall C/N ratio into the desired 25:1 to 30:1 range. While expensive when sold as hay, alfalfa is moderately priced in the form of dehydrated pellets or meal, and these products can be purchased at most feed stores. Farmers and feed stores may also have rotted or spoiled bales, unsuitable as animal feed, that they will gladly give you.

Apple Pomace

Anyone who presses his or her own cider produces heaps of this sweet pulp. Yellow jackets, hornets, and bees love to zero in on the residues, so it's best to get the pomace into a working compost heap as soon as possible. Fresh pomace is wet and heavy and should be mixed well with dry leaves, hay, or other absorbent matter.

While low in nitrogen, pomace does contain valuable amounts of phosphoric acid and potash. Large numbers of seeds are also present in pomace; these storage organs contain reserves of phosphorus and nitrogen, adding to the nutrient value of the pomace.

If you collect pomace from commercial presses, look into the source of their apples and the pesticides applied to the fruit. Apple skins may contain residues of metallic sprays, especially if such sprays are used heavily. Spray residues can build up to toxic levels when large amounts of pomace are used.

Letting the Clippings Fall

Leaving grass clippings on your lawn some of the time provides the grass with natural fertilizer and saves work. It is recommended in Grasscycling, a lawn care plan promoted by the Professional Lawn Care Association of America. The low-maintenance lawn care plan is based on the highly successful Don't Bag It program originally developed in Texas. Leaving clippings does not cause thatch buildup as was once believed. Thatch is made up of dead roots, leaf sheaths, and rhizomes, not clippings. If you mow with a regular lawn mower, don't let the grass grow more than 1½ inches between mowings, and mow the grass only when it is dry. Even so, the clippings can be messy.

Mulching mowers eliminate the mess by chopping the clippings into fine fragments after they cut the grass. The fragments fall down into the lawn, where they decompose rapidly and release nutrients. Mulching mowers can also shred a few fallen leaves on the lawn while you are mowing and can be used to prepare piles of leaves for composting.

Bagasse

Bagasse is the waste plant residue left from the milling of sugarcane. Gardeners in the Deep South may have access to quantities of this valuable addition to the compost heap.

Banana Residue

The skins and stalks of this tropical fruit contain abundant amounts of phosphoric acid and potash. Banana skins also decompose rapidly, a sign that the microbes of decay are well supplied with nitrogen. Banana skins are usually a staple in kitchen scraps, and their use in a compost heap will guarantee lots of bacterial activity. Incorporate banana skins into the core of your compost pile, or cover them quickly with organic matter to avoid attracting flies.

Basic Slag

This is an industrial by-product formed when iron ore is smelted to make pig iron. The smelting process uses large amounts of limestone and dolomite that combine with impurities in the ore, rising as a sludge that coats the surface of the molten metal. Skimmed off, cooled, and hardened, the resultant slag contains numerous minerals also found in the soil—lime, magnesium, silicon, aluminum, manganese, sulfur, and iron. It also contains trace amounts of boron, chromium, copper, molybdenum, potassium, sodium, strontium, tin, vanadium, zinc, and zirconium. The exact percentage of these minerals depends on variations in the smelting process. The "Composition of Slag" table shows the main elements found in slag, the compounds in which they most often occur, and the average range of each mineral.

Composition of Slag

Material	Compound	Percentage
Lime	CaO	38–45
Magnesia	MgO	4–9
Silica	SiO_2	33–39
Alumina	Al_2O_5	10–14
Manganese oxide	MnO	0.2–1.5
Iron oxide	FeO	0.2–0.7
Sulfur	S	1.0–2.0

Packaged slag has been pulverized into a fine black powder so it can be used as a soil builder in gardening and farming. The material is alkaline and is popular as a liming agent. Tests show that slag is better for this purpose than lime because of its greater store of minerals.

Since slag is made up of finely pulverized but insoluble particles, it can be applied liberally to soil or compost heap with no fear of overuse. It won't burn plants or roots. Beans, peas, clover, vetches, alfalfa, and other leguminous crops will benefit from its application. Slags vary in content, so check the analysis before using them. Avoid slags with low or nonexistent amounts of nutrients and minor elements. Don't use slags containing excessive amounts of sulfur.

Beet Wastes

Residues from sugar beet processing are commonly used for livestock feed, though they will compost readily. The nitrogen content averages 0.4 percent, potassium content varies from 0.7 to 4.1 percent, and phosphoric acid content ranges from 0.1 to 0.6 percent. Dried beet pulp is also available at many feed stores.

Continued →

Bonemeal

A slaughterhouse by-product, the pulverized residue of bones is, along with rock phosphate, a major source of phosphorus for the farm and garden. Bonemeal also contains a large percentage of nitrogen, though the content of both minerals depends on the age and type of bones processed. Raw bonemeal usually contains 20 to 25 percent phosphoric acid and 2 to 4 percent nitrogen. Steamed bonemeal, the more commonly available variety, has up to 30 percent phosphorus and 1 to 2 percent nitrogen. Steamed bonemeal is finer than raw bonemeal, so it breaks down more rapidly in the soil or compost heap.

Bone black is charred bone that has been used as a filter for sugar refining. Bone black contains about 1.5 percent nitrogen, 30 percent phosphoric acid, and many micronutrients.

Bonemeals are most effective when mixed with other organic matter and added to well-aerated soils. They will also exert an alkalizing effect because of their lime content, so match their use to your soil's pH characteristics. Use them moderately in composting to avoid the volatilization of nitrogen to ammonia.

Buckwheat Hulls

Buckwheat is a cereal crop grown mainly in the northeastern United States and in Canada. Popular among organic farmers and gardeners as a green manure and bee forage crop, it grows well on even marginal soils. Buckwheat hulls, left after processing of the grain, are lightweight and disk shaped. They make good additions to the compost heap, though many gardeners prefer to use them as mulch. The hulls absorb water easily, stay in place once applied (a layer 1½ inches thick will suffice), and look like a crumbly loam.

Castor Pomace

Castor pomace is the residue left after the oil has been extracted from the castor bean. It is widely used as an organic fertilizer in place of cottonseed meal, because the latter is a valuable feed. The nitrogen analysis of castor bean varies from 4 to 6.6 percent, while phosphoric acid and potash have been found to be 1 to 2 percent, with greater variation occurring in the phosphorus content.

Where animal matter is unavailable, compost can easily be made with castor pomace and other plant matter. Moisten the pomace and spread it over the green matter in semiliquid form. The finer the plant matter, the quicker the bacterial action.

Citrus Wastes

Gardeners living near factories producing orange and grapefruit products should make use of this easily composted residue, though dried citrus pulp is also available in bulk from some feed stores. The nitrogen content of these materials varies according to the type of fruit and the density of the skin. The thicker the peel, the more nitrogen contained.

Orange skins contain about 3 percent phosphoric acid and 27 percent potash (surpassed only by banana skins, with 50 percent potash). Lemons are higher in phosphorus but lower in potash than oranges. Grapefruits average 3.6 percent phosphoric acid, and their potassium content is near that of oranges.

You may also use whole waste fruits (culls) in the compost pile, although their nutrient content will be lower due to the high water content. Citrus wastes will break down faster if shredded (the bagged, dried pulp sold as animal feed comes in dime-sized chips) and mixed with green matter and a source of nitrogen and bacteria like manure, lawn clippings, or garden soil.

Unfortunately, citrus crops are routinely sprayed by commercial growers. If the spray program is moderate, the chemicals should break down during the composting process without causing harm. To be absolutely sure of what you're adding to your compost, use only fruits and fruit wastes from organic growers.

Cocoa Bean Shells

These residues from chocolate factories are available in bulk from garden supply houses, but because they make such an attractive mulch, cocoa bean shells rarely find their way into the compost heap. They are rich in nutrients, though, and benefit the soil however they're used. Cocoa shell dust has 1.5 percent phosphorus, about 1.7 percent potassium, and 1 percent nitrogen—a high analysis of the latter considering the woody nature of cocoa.

If the shells themselves have been treated to extract caffeine and theobromine, the residues will have about 2.7 percent nitrogen, 0.7 percent phosphoric acid, and 2.6 percent potassium. Untreated raw shells show a higher nutrient content. Pressed cocoa cake has also been offered as fertilizer. It's higher in nitrogen, has less potassium than shells, and has a phosphorus content of nearly 0.9 percent. The nitrogen content of cake will vary according to its processing.

If you can locate a source of oil-free and theobromine-free cocoa wastes, you'll have a useful product for mulching acidic soils. The extraction process uses lime, so the shells will help raise the pH while adding moisture-retentive organic matter. Cocoa shells are also weed free and odorless.

To use them as mulch, spread the shells in a layer 1 inch deep. They are light brown, look nice around shrubs, evergreens, and flower beds, and offer excellent drought-proofing and insulative properties. Shells used in compost piles should be shredded or pulverized.

Coffee Wastes

Earthworms seem to have a particular affinity for coffee grounds, so be sure to use these leftovers on the compost pile,

in your worm box, or as a mulch. The grounds are acidic and can be used by themselves around blueberries, evergreens, and other acid-loving plants. Mix the grounds with a little ground limestone for plants needing alkaline or neutral soil.

The nutrient content of coffee residues varies according to the type of residue. Grounds have up to 2 percent nitrogen, 0.33 percent phosphoric acid, and varying amounts of potassium. Drip coffee grounds contain more nutrients than boiled grounds, though the potassium content is still below 1 percent. Other substances found include sugars, carbohydrates, some vitamins, trace elements, and caffeine.

Coffee processing plants sell coffee chaff, a dark material containing over 2 percent nitrogen and potassium. Chaff is useful either as a mulch or in compost.

Apply your coffee grounds immediately, or mix them with other organic matter. They hold moisture extremely well. Left standing, they will quickly sour, inviting acetobacters (vinegar-producing microbes) and fruit flies.

Corncobs

These residues used to be available in large amounts from mills, but modern combines now shred the stalks and expel the cobs right back into the field. Cobs contain two-thirds of the nutrients found in the corn kernel, but they must be shredded before composting or their decay will take years. Let the cobs age in open piles for several months, then grind them with a shredder or lawn mower.

Cobs have superior moisture retention and make effective mulches when spread 3 to 4 inches deep. Shredded cobs may also be used as a seed-starting medium. In longstanding, no-turn piles, unshredded cobs mixed with leaves and other dense materials will provide aeration and discourage caking and matting.

Cottonseed Meal

Cottonseed meal is made from cottonseed that has been freed from lints and hulls and deprived of its oil. Since cottonseed cake is one of the richest protein foods for animal feeding, relatively little is available for use as fertilizer. Although it is a rich source of nitrogen, most organic certification programs prohibit the use of cottonseed meal as a fertilizer. This is because cotton, as a nonfood crop, receives heavy applications of pesticides, some of which may accumulate in the seeds. Unless you have access to meal from organically grown cotton, you may choose to avoid cottonseed meal in favor of another nitrogen source for your compost pile.

Cottonseed meal is also commonly used to increase soil acidity for acid-loving specialty crops, but other materials, such as pine needles and peat moss, will serve the same purpose. Cottonseed meal has a nitrogen content of around 7 percent. Its phosphoric acid content is between 2 and 3 percent, while potash is usually 1.5 percent.

Dried Blood

Dried blood is a slaughterhouse by-product. It is high in nitrogen, about 12 percent, but its phosphorus content varies from 1 to 5 percent. Dried blood is used mainly as an animal feed, though most garden shops carry it for use as a fertilizer. The cost per pound can be quite high because it is tied to the price of meat. Dried blood can be applied directly to the soil around plants, but it should be kept several inches away from the stems to avoid burning. Dried blood may also be used in compost heaps. Sprinkled over layers of moist organic matter, its high nitrogen content stimulates decay organisms, especially when added to carbon-rich materials.

Felt Wastes

Check hat factories for discarded hair, wool, and felt. These materials may contain up to 14 percent nitrogen and will aid in making rapid, high-heat compost. Such wastes are quite dry, however, and will decompose slowly or pack down unless they are thoroughly moistened and mixed with bacteria-rich ingredients like manure or green matter.

Fish Scrap

Gardeners near oceans or fish-processing plants can usually truck home loads of this smelly stuff. It is well supplied with nitrogen and phosphorus (7 percent or above for each nutrient) and also contains valuable micronutrients like iodine. But, like all fresh residues, fish scraps easily turn anaerobic and are highly attractive to rodents, flies, and other scavengers.

Fish scraps must be handled carefully in the garden, either buried (covered with at least 4 inches of soil) or composted in properly built heaps enclosed by sturdy bins or pens. The trick is to use generous amounts of bulky, high-carbon materials such as shredded brush, straw, or sawdust to balance the high nitrogen and moisture of the fish, to increase aeration, and to discourage packing down.

Composting fish scraps in a pit is somewhat easier (once you've dug the pit, of course). Mix them with organic matter or

Continued ➔

soil, and cover them with enough dirt to discourage flies. The pit must also be enclosed by a sturdy fence or wall and topped with a scavenger-proof frame or lid.

Fish scrap presents difficult challenges to the composter on any scale, but it offers ample benefits when used with reasonable care and attention to providing adequate carbon and air. William F. Brinton, of Woods End Research Laboratory in Maine, has successfully demonstrated fish waste composting, with minimal odor problems, using a farm- or industrial-scale windrow method.

Garbage

Americans routinely throw away mountains of valuable food scraps, setting them out on the curb or grinding them up in disposals and flushing them into overworked municipal sewage systems. Yet kitchen scraps are truly a neglected resource, containing 1 to 3 percent nitrogen along with calcium, phosphorus, potassium, and micronutrients. The material is free, available in quantity every day, and relatively easy to handle.

Kitchen scraps may be dug directly into the garden. Alternatively, they may be composted in heaps or pits. You can conveniently save household garbage until you are ready to layer it into a new or existing compost pile. Use a plastic bucket with a tight-fitting lid, and each time you add garbage, cover it with a layer of sawdust or peat moss to absorb moisture and odors. When adding kitchen scraps to your compost pile, mix them well with absorbent matter like dead leaves or hay to offset the wetness. Use a predator-proof enclosure, and be sure to keep all scraps well into the pile's core, covering them thoroughly with dirt or additional materials to discourage flies.

Chop or shred all large pieces of matter (potatoes, grapefruit rinds, eggshells, and so on) to hasten decomposition. Do not use meat scraps, fat, or bones in compost piles, for these materials take too long to fully break down and are most attractive to scavenging animals.

Gin Trash

Gin trash is another by-product of the cotton industry. Once burned and discarded, these leaf and stem wastes are now being composted and returned to the soil. While cotton wastes contain many valuable nutrients and fibrous organic matter, their effect on soil health may not always be beneficial, depending on the type of cotton and the state in which it was produced. In some states, including Texas and Oklahoma, arsenic acid is applied as a defoliant and desiccant. Significant residues of this carcinogen are left in the gin trash, making it an undesirable addition to the compost pile. Normal arsenic levels in the soil run about 5 parts per million, but gin wastes may contain 40 times that amount.

Arsenic acid is no longer used in cotton production in California. Home composters who have access to gin trash should consider its source and the production methods used in their state before making gin trash a part of their composting program. Because of the timing of arsenic acid applications, contamination of the seeds does not occur; arsenic residue is not a concern with cottonseed meal.

Granite Dust

Granite dust is a natural source of potash that is superior to the chemically treated potash sold as commercial fertilizer. Granite dust or granite meal has a potassium content of between 3 and 5 percent, contains micronutrients, is inexpensive, and will leave no harmful chemical residues. Unlike chemically treated sources of potash, granite dust is slow-acting, releasing its nutrients over a period of years. It may be used in the compost pile or added to soil or sheet compost. Use it liberally directly on the soil, applying 10 pounds to 100 square feet when spreading. Choose a windless day for application, and wear a dust mask.

Grape Wastes

Wineries produce these residues of skins, seeds, and stalks by the ton during the pressing season. Vineyards also accumulate large amounts of grapevine pieces after annual pruning. While the nutrient content of grape wastes isn't that high, the sheer bulk of organic materials involved benefits the soil by promoting aeration and microbial activity.

The residues of pressing will be wet and mushy and should be mixed with absorbent plant matter. Additional nitrogen in the form of manure or high-protein green matter may also be necessary if you desire rapid, hot compost. The prunings are tough and must be chopped into pieces 3 to 6 inches long, or shredded, if they are to break down in a season.

Grass Clippings

This is one compostable—a true "green manure"—that most gardeners can produce or obtain in abundance. Even if you don't have your own lawn, your fellow citizens do; they'll leave bags of clippings conveniently lined up along the curbsides for your harvesting every garbage collection day.

Freshly gathered green clippings are exceedingly rich in nitrogen and will heat up on their own if pulled into a pile. But, because of their high water content, they will also pack down and become slimy. This can be avoided by adding grass clippings in thin layers, alternating with leaves, garbage, manure, and other materials, thus preventing them from clumping together. If you discover a mass of matted clippings when you turn your compost, just break it up with a garden fork or spade, and layer the pieces back into the pile. Grass clippings and leaves can be turned into finished compost in 2 weeks if the heap is chopped and turned every 3 days. You can also profitably mix 2 parts grass clippings with 1 part manure and bedding for a relatively fast compost, even without turning.

Clippings that have been allowed to dry out will have lost

much of their nitrogen content but are still valuable as an energy source and to absorb excess moisture. Clippings also make an excellent mulch in the vegetable or flower garden or around shrubs and trees. As a mulch, clippings look neat and stay in place, and only a light layer (3 to 4 inches) is needed to choke out weeds and seal in moisture.

If you have extra grass clippings on hand later in the season, use them as a green manure. Simply scatter them in an area that has already been harvested and turn them in immediately, along with any previously applied mulch. The fresh clippings decompose quickly in the soil and stimulate microbial activity by providing abundant nitrogen. More mulch should be added to the surface over winter to prevent exposure of bare soil to the weather. You can also use clippings as a green manure before planting a late crop, but give the soil a week or 10 days to stabilize before planting. When used this way, grass clippings greatly improve the physical condition of heavy-textured soils.

Not all grass clippings should be removed from the lawn; when left after mowing, their nutrients enrich the lawn itself, without the application of chemical fertilizers. However, most lawns do not need as much enrichment as a full growing season's clippings will provide. Collecting grass clippings also helps reduce weed growth by removing weed seeds from the lawn.

There is one environmental caution about grass clippings. Many homeowners use various "weed and feed" preparations or any of a half-dozen herbicides in striving for an immaculate lawn. The most troublesome of these chemicals is 2, 4-D, a weed killer that has caused birth defects in lab animals and may be carcinogenic.

Although this systemic, rapid-action plant hormone attacks broad-leaved plants like dandelions, literally causing them to grow themselves to death in hours, 2, 4-D doesn't affect grasses. The narrow-bladed leaves do absorb traces of the hormone but not enough to harm them. Much more 2, 4-D remains as a residue in broad-leaved plants, though even this should theoretically be broken down by soil microbes in a week. But beware of grass clippings that may have spray adhering to them from a fresh application. If used as a mulch, such clippings could cause herbicide damage to your garden plants—most of which are broad-leaved.

Ask your neighbors or whomever you gather clippings from what they used on their lawns. (If several mowings and some rains have occurred since the last application of herbicide, the clippings should be clear of 2, 4-D residue.) Use your own clippings if you have them, and look around for natural lawns showing a healthy crop of dandelions—a sign that the landowner wisely avoided using herbicides.

Greensand

Greensand is an iron-potassium-silicate that imparts a green color to the minerals in which it occurs. Being an undersea deposit, greensand contains traces of many (if not all) of the elements that occur in seawater. Greensand has been used successfully for soil building for more than 100 years. It is a fine source of potash.

Greensand contains from 6 to 7 percent of plant-available potash, but it is released very slowly when applied directly to the soil. Incorporating greensand into your compost improves the availability of its potassium and micronutrients. Good glauconite deposits also contain 50 percent silica, 18 to 23 percent iron oxides, 3 to 7.5 percent magnesia, small amounts of lime and phosphoric acid, and traces of more than 30 other elements useful to higher plant life. Unlike wood ashes, another frequently used source of potash, greensand does not have an alkalinizing effect.

Hair

Between 6 and 7 pounds of hair contain as much nitrogen as 100 to 200 pounds of manure. Like feathers, hair will decompose rapidly in a compost pile but only if well moistened and thoroughly mixed with an aerating material. Hair tends to pack down and shed water, so chopping or turning the pile regularly will hasten decay. Most barbershops or hair salons will be happy to supply you with bags of hair (though they may think your request is strange unless you explain).

Hay

Farmers often have spoiled hay available free or at low cost to gardeners. Hay is an excellent source of carbon for compost and also contains significant amounts of potassium, especially if it includes legumes such as alfalfa, clover, or vetch.

Hay is sometimes best used as mulch, especially around fruit trees. However, unless it was cut early, before seed heads began to form, it poses the hazard of introducing weed seeds into your garden. High, temperature composting will kill most weed seeds. In order to ensure that high enough temperatures (above 140°F, or 60°C) are reached, you should chop or shred the hay first, especially if it has matted in the bales. This can be done by spreading out the sections and running a lawn mower back and forth over them. You should alternate layers of nitrogenous materials such as manure with the shredded hay, to stimulate rapid heating. Make sure the materials are moist enough by giving each layer a good sprinkling. If high enough temperatures are not reached within a couple of days, the pile should be turned and relayered with an additional nitrogen source.

Hoof and Horn Meal

There are many grades of hoof and horn meal. The granular form breaks down with some difficulty unless kept moist and well covered; it also tends to encourage the growth of maggots because it attracts flies. Finely ground horn dust, which gardeners use for potting mixtures, is quite easily dissolved. The nitrogen content is from 10 to 16 pounds per 100-pound bag, or as much as a ton or more of manure, while the phosphoric

Continued →

acid value is usually around 2 percent. If available, this is a very handy source of nitrogen for gardeners with small compost heaps, because it can be easily stored, is pleasant to handle, and is less costly than other forms of bagged organic nitrogen.

Hops

Hops are viny plants grown and used for making beer. (Hops impart the characteristic bitter flavor.) Spent hops, the wastes left after the brewing process, are an excellent garden fertilizer, containing (when dry) 2.5 to 3.5 percent nitrogen and 1 percent phosphoric acid. They do have a strong odor when wet and fresh, but this dissipates rapidly.

Wet hops may be spread directly on the garden in fall or spring just as you would apply manure. Turn the matter under, mixing it with the top 4 to 5 inches of soil. Wet hops heat up rapidly, so keep them several inches away from plant stems to avoid burning. This tendency to heat up is, of course, desirable in making compost. Be sure to balance the sogginess of spent hops with absorbent matter.

Spent hops make a good mulch when dry. They resist blowing away and will not easily ignite if a lighted match or cigarette is tossed onto a pile. Many other mulch materials burn easily. A layer of dry, spent hops will break down slowly, staying put for 3 years or more.

Another brewery waste to inquire about is the grain left over from the mashing process. When wet, this material contains almost 1 percent nitrogen and decays rapidly.

Incinerator Ash

Incinerator ash, if available, can be a fine source of phosphorus and potash for the compost heap. Its phosphorus content depends upon what was burned but averages 5 or 6 percent; its potassium content is from 2 to 3 percent. As with many compostable materials, the source of the ash should be considered before it is added to the compost pile. Ash from apartment building incinerators may be acceptable, depending on the materials burned. It is best to avoid municipal incinerator ash, most of which is considered hazardous waste because the heavy metals and other toxic substances found in municipal solid waste often become more concentrated and soluble when burned.

Leather Dust

Available as a by-product of leather processing and as a commercial fertilizer from garden shops, leather dust contains from 5.5 to 12 percent nitrogen. Phosphorus is also present in considerable amounts. Use as a soil amendment, as a side-dressing around plants, or as a dusting over successive layers in the compost heap.

Leather dust is often contaminated with the heavy metal chromium, used in the tanning process. While one producer of leather dust fertilizer points out that the chromium in their product is in an immobile form, studies have not addressed the long-term effects of this material in the soil. Some organic certification programs prohibit the use of leather dust for this reason. Unless you have a source that produces leather dust with low or no levels of heavy-metal contaminants, it is best to refrain from using it on your compost or on soil in which food crops will be grown.

Leaves

Leaves are a valuable compostable and mulch material abundantly available to most gardeners. Because trees have extensive root systems, they draw nutrients up from deep within the subsoil. Much of this mineral bounty is passed into the leaves, making them a superior garden resource. Pound for pound, the leaves of most trees contain twice the mineral content of manure. The considerable fiber content of leaves aids in improving the aeration and crumb structure of most soils.

Many people shy away from using leaves in compost, because they've had trouble with them packing down and resisting decay. Leaves don't contain much nitrogen, so a pile of them all alone may take years to decay fully. But most leaves can be converted to a fine-textured humus in several weeks (or, at most, a few months) if some general guidelines are followed:

- Add extra nitrogen to your leaf compost since leaves alone don't contain enough nitrogen to provide sufficient food for bacteria. Manure is the best nitrogen supplement, and a mixture of five parts leaves to one part manure will break down quickly. If you don't have manure, nitrogen supplements like dried blood, alfalfa meal, and bonemeal will work almost as well. In general, add 2 cups of dried blood or other natural nitrogen supplement to each wheelbarrow load of leaves.
- Don't let your leaves sit around too long and dry out. As leaves weather, they lose whatever nitrogen content they may have had. This, combined with the dehydration of the cells, makes them much more resistant to decomposition than when used fresh.
- Grind or shred your leaves. A compost pile made of shredded material is easily controlled and easy to handle.

If you don't have a shredder, there are various other devices you can adapt to leaf shredding. Many people use a rotary mower for shredding. A mower that is not self-propelled is best and easiest to control. Two people can work together very nicely, one piling up leaves in front of the mower and the other running it back and forth over the pile. A leaf-mulching attachment on the blade will cut the leaves finer, but sometimes it is not necessary. You will be surprised how many leaves you can shred this way in 30 minutes or so.

Of course, some people use a mower with a mulching attachment to cut up leaves right on the lawn. This does not

make them available for compost or mulch somewhere else—like the garden—where they are more essential.

If you have so many leaves that you can't compost all of them—or if you don't have the time to make compost—you can make leaf mold. Leaf mold is not as rich a fertilizer as composted leaves, but it's easier to make and is especially useful as mulch.

A length of snow fencing or woven wire fencing placed in a circle makes the best kind of enclosure for making leaf mold. Gather leaves in the fall and wet them thoroughly; then tamp them down in the enclosure. Leaves are slightly acid. If your plants don't need an acid mulch, add some limestone to the leaves before tamping them down.

These leaves will not break down over the winter into the kind of black, powdery leaf mold found on the forest floor. By spring or summer they will be broken up enough to serve as a fine mulch. Some people, including nursery operators who require fine potting soil, keep leaves "in cold storage" for several years. When they come for their leaves, they find black, crumbly humus.

Leaf mold is ordinarily found in the forest in a layer just above the mineral soil. It has the merit of decomposing slowly, furnishing plant nutrients gradually, and improving the soil structure as it does so. Leaf mold's ability to retain moisture is amazing. Subsoil can hold a mere 20 percent of its weight in water; good, rich topsoil will hold 60 percent; but leaf mold can retain 300 to 500 percent of its weight.

Freshly fallen leaves pass through several stages, from surface litter to well-decomposed humus partly mixed with mineral soil. Leaf mold from deciduous trees is somewhat richer in such mineral foods as potash and phosphorus than that from conifers. The nitrogen content varies from 0.2 to 5 percent.

If you keep poultry or livestock, use your supply of leaves for litter or bedding along with straw or hay. Leaf mold thus enriched with extra nitrogen may later be mixed directly with soil or added to the compost pile.

A lawn sweeper is a good tool to use for collecting leaves. It is easier than raking and often does a better job. Hand-held leaf vacuums are also available at most lawn and garden stores.

Many municipalities are now composting leaves and yard wastes instead of dumping them into landfills. If your community has such a program, you can send in your surplus leaves with a good conscience and probably pick up finished compost in return.

Limestone

Limestone is an important source of calcium and, when dolomitic limestone is used, magnesium. It is commonly used to raise the pH of acid soils and may sometimes be appropriate when composting very acidic materials such as pine needles. However, compost made from a good variety of materials should have a pH near neutral without the addition of lime. Moreover, it is unwise to use lime with fresh manure or other nitrogenous materials, as it reacts chemically to drive off ammonia gas and thus lose some of the valuable nitrogen.

If your soil is acid, it is best to apply lime to it directly, rather than through compost. Any reliable soil test will tell you how much lime is needed. If you live in a humid region, lime should be applied every 3 or 4 years, preferably in the fall so it will become available first thing in the spring. Use a grade fine enough to pass through a 100-mesh screen. In drier climates, where soil pH is naturally neutral or higher, liming is rarely necessary. You may want to use some lime for making potting soil with your compost—use about 1 tablespoon for 20 quarts of soil mix.

Most vegetables and garden plants prefer a slightly acid to neutral pH, so laboratory liming recommendations generally strive for a pH of 6.5 to 6.8 (a pH of 7 is neutral). Some vegetables—legumes such as beans, peas, and alfalfa, for example—do better with slightly alkaline soil, while many berries prefer acid conditions. Organic matter in the soil tends to buffer the effects of pH extremes by making nutrients available to plants regardless of soil pH. Lime, therefore, should be used to supplement soil improvement through the addition of compost.

Manure

Manure is the most valuable ingredient in the compost pile.

Molasses Residues

The wastes from sugar refining are obviously rich in carbohydrates, but they also contain some mineral nutrients. Naturally occurring yeasts in the compost will ferment these sugars rapidly. Dry molasses is also available from feed stores.

Olive Wastes

Olive pits contain phosphorus, nitrogen, and some lignin (a woody substance related to cellulose). But the pits must be ground or chopped before composting, or they'll take years to decay. Pulpy olive wastes vary in nutrient density. One analysis showed the pomace (what's left after oil extraction) having 1.15 percent nitrogen, 0.78 percent phosphoric acid, and 1.26 percent potassium. The pulp is oily and should be well mixed with other organic matter.

Paper

Many kinds of paper, even those with colored inks, can be used for compost or mulch. You can save a lot on trash collection costs, and keep the valuable carbon for your soil, by recycling paper through your compost. Although the colored inks contain various heavy metals, one study found that their concentration is low enough to be negligible, even when glossy magazines are

Continued →

used as a garden mulch. If only a few colored-ink items are mixed in with newsprint, there should be no cause for concern.

The secret to using paper successfully is to shred or chop it as finely as possible. Matted layers of newspaper, like hay and grass clippings, will halt the composting organisms in their tracks. Various tools will work for this process, including shredders used for brush. If you don't have a lot of paper, a sharp machete will chop it adequately. And don't forget the office paper shredder—you may even be able to recycle preshredded office paper from local businesses. Dairy farmers in various regions are being encouraged to use newspaper, which they shred using silage-making equipment, as bedding for their animals. The newspaper is very absorbent and makes an excellent compost medium when mixed with manure.

Shredded paper should be incorporated into your compost in layers, alternating with garbage or other wet materials. Because it is almost pure cellulose, it requires a concentrated nitrogen source to stimulate decomposition, but once broken down it creates a high-quality humus that will improve the tilth of any soil.

Peat Moss

This naturally occurring fibrous material is the centuries-old, partially decayed residue of plants. Widely sold as a soil conditioner, mulch, and plant propagation medium, peat's major advantages are its water retention (it is capable of absorbing 15 times its weight in water) and fibrous bulk. Dry peat will help loosen heavy soils, bind light ones, hold nutrients in place, and increase aeration. But while its physical effects on soil are valuable, peat isn't a substitute for compost or leaf mold. Expensive, relatively low in nutrients, and acidic, peat is best used as a seed flat and rooting medium or as a mulch or soil amendment for acid-loving plants.

If a distinctly acid compost is needed for certain plants, substitute peat for the soil in your compost pile. Peat compost is beneficial for camellia, rhododendron, azalea, blueberry, sweet potato, watermelon, eggplant, potato, and tomato plants—all of which prefer acidic soil conditions.

Pea Wastes

Feeding pea shells and vines to livestock and getting the waste back as manure is an excellent recycling method. Otherwise, pea wastes can be rapidly composted since they are rich in nitrogen when green. Dry vines should be shredded or chopped before or during composting, to hasten decay. Diseased vines should be burned and the ashes returned to the soil. (Pea ash contains almost 3 percent phosphoric acid and 27 percent potassium.)

Pet Wastes

As discussed earlier in this section, the wastes of dogs, cats, and birds are potential carriers of organisms that may cause disease in humans. Such materials should not be included in the home compost pile. Wastewater from aquariums, however, contains a certain amount of algae and organic matter that can be beneficial to plants. Use aquarium water to add moisture to your compost heap or for watering plants.

Phosphate Rock

Phosphate rock is a mainstay in organic gardens and farms because of its value as a soil and compost pile amendment. While its chemical composition varies according to the source, phosphate rock generally contains 65 percent calcium phosphate or bone phosphate of lime. A diversity of other compounds and micronutrients important to plant development is also present.

Phosphate rock is a naturally occurring mineral, however; don't confuse it with superphosphate. The latter has been treated with sulfuric acid to increase its solubility. But many micronutrients are lost due to this processing, and the increase in the availability of sulfur stimulates the presence of sulfur-reducing bacteria in the soil. These organisms attack sulfur and also ingest a fungus that normally breaks down cellulose in the soil. Besides encouraging this microbial imbalance, superphosphate can also leave harmful salts in the soil. Furthermore, within a few days superphosphate will react chemically with calcium and other soil nutrients to become indistinguishable from the less-soluble rock powder.

Phosphate rock creates no such problems. It's slow acting, which makes nutrients available to plants for many years after a single application. Applied alone to vegetable or flower gardens, 1 pound to every 10 square feet of growing area will suffice for 3 to 5 years. It may also be sprinkled lightly over succeeding layers in a compost heap to add nutrients to the finished product. It is valuable when combined with manure and other nitrogenous materials, since it prevents loss of nitrogen in the form of ammonia. The nutrients in rock phosphate are more readily available to plants when it is added via compost, having first been incorporated into the bodies of countless microorganisms.

Pine Needles

Pine needles are compostable, although they will break down rather slowly because of their thick outer coating of a waxy substance called cutin. Pine needles are also acidic in nature, and for this reason they should not be used in large quantities, unless compost for acid-loving plants is desired. For best results, shred the needles before adding them to the heap.

Evergreen needles have been found to be effective in controlling some harmful soil fungi, such as *Fusarium* spp., when used as a mulch or mixed directly into the soil.

Potato Wastes

Potato peels are common components of kitchen scraps. They provide a valuable source of nitrogen (about 0.6 percent as ash) and minor elements for the compost pile. Rotted whole

potatoes, chopped or shredded, are also worthwhile compost pile additions. The tubers contain about 2.5 percent potash, plus other minerals. Use the potato vines, too; they can be either composted or dug back into the soil. The vines, when dry, contain approximately 1.6 percent potash, 4 percent calcium, and 1.1 percent magnesium, plus sulfur and other minerals.

Rice Hulls

Often considered a waste product, rice hulls have been found to be very rich in potash and to decompose readily, increasing humus content, when worked into the soil. The hulls make an excellent soil conditioner and a worthwhile addition to the compost heap. They also make a good, long-lasting mulch that does not blow away.

Gardeners in the Texas-Louisiana Gulf Coast area can often get ample amounts of this material from rice mills; occasionally it is free. Some mills make a practice of burning the hulls, and the residue from this operation contains a high percentage of potash, making it especially valuable as a composting material.

Sawdust

Sawdust is often useful in the compost heap, although it is better used as a mulch. Some gardeners who have access to large quantities use it for both, with equally fine results. In most areas, lumberyards will occasionally give sawdust free for the hauling. Sawdust is very low in nitrogen. One of the objections against using sawdust is that it may cause a nitrogen deficiency. However, many gardeners report fine results from applying sawdust as a mulch to the soil surface without adding any supplementary nitrogen fertilizer. If your soil is of low fertility, watch plants carefully during the growing season. If they become light green or yellowish in color, side-dress with an organic nitrogen fertilizer such as alfalfa meal, blood meal, compost, or manure. Regular applications of manure tea will also counteract any slight nitrogen deficit.

Some people are afraid that the continued application of sawdust will sour their soil—that is, make it too acid. A very comprehensive study made from 1949 to 1954 by the Connecticut Agricultural Experiment Station of sawdust and wood chips reported no instance of sawdust making the soil more acid. It is possible, though, that sawdust used on the highly alkaline soils of the western United States would help to make the soil neutral, a welcome effect.

When used for compost, sawdust is valuable not only as a carbon source but as a bulking agent, allowing good air penetration in the pile. This is true only of sawdust that comes from sawmills or chain saws; the fine material that results from sanding can become packed and anaerobic. Although sawdust is slow to break down, the larger bits you may find remaining in finished compost will not present problems when added to your soil and will improve the texture of heavy soils.

Seaweed

Coastal gardeners gather different types of seaweed by wandering the shoreline. Look for kelp (laminaria), bladder wrack (also called fucus), sea lettuce (ulva), and other varieties. Gardeners elsewhere can buy dried, granulated seaweed (kelp meal) or liquid concentrate. All these seaweed variants are rich in many types of micronutrients and are a boon to plants, soil health, and the compost pile.

Compared with barnyard manure, seaweed in general has a similar organic content. The proportions, however, vary—seaweed has more potassium than manure but has less nitrogen and phosphorus. Seaweed is perhaps most valued for its micronutrient content. An analysis of the seaweed most commonly used in seaweed meals and extracts identified the presence of some 60 elements, including all those important for plant, animal, and human health.

Use wet, fresh seaweed quickly because it deteriorates rapidly when piled haphazardly. Exposure to the elements will quickly leach out many of seaweed's soluble minerals. Dig the seaweed under, or mix it with nitrogenous and absorbent materials for rapid composting. Bacteria feast on the alginic acid found in the leaves, which makes seaweed an excellent compost pile activator. If composted with manure that is rich in litter, seaweed aids the speedy decay of the straw; very little nitrogen is lost, and all the other elements are preserved. Decay occurs rapidly.

If you have only a small amount of seaweed, chop it and soak it overnight in a gallon of hot water (160° to 180°F, or 71° to 82°C). Sprinkle this mixture over successive layers of the compost pile. The liquid can also be used as a fertilizer and as a seed-soaking solution.

Kelp meal can be used as an activator in compost, since its rich micronutrient composition stimulates microbial growth. Seaweed extract can be used to feed plants directly through their leaves, and may also be applied to compost in the course of moistening the layers. When used as a foliar feed, plant growth is also stimulated by seaweed's content of cytokinins and other plant growth hormones.

Sewage Sludge

Sewage sludge is the solid residue left after organic wastes and wastewater have been chemically, bacterially, or physically processed. Depending on how it is processed, sludge may contain up to 6 percent nitrogen and from 3 to 6 percent phosphorus.

Activated sludge is produced when sewage is agitated by air rapidly bubbling through it. Certain types of very active bacteria coagulate the organic matter, which settles out, leaving a clear liquid that can be discharged with a minimum amount of pollution. The resulting sludge is usually heat-treated before being offered as a soil amendment.

Digested sludge is formed when the solid matter in sewage is

Continued →

allowed to settle without air agitation, the liquid is drained off, and the sludge is fermented anaerobically. The conventional anaerobic digestion system takes from 15 to 30 days at 99°F (37°C) from the time the sewage reaches the sedimentation tank until the digested solids are pumped into filter beds for drying. The dried material is either incinerated or used for soil improvement.

Until recently, most sewage sludge was incinerated, buried in landfills, or dumped offshore. Now there's an increasing interest in using this potentially valuable material as a soil conditioner. This would be ideal if the residue were composed solely of the remains of human waste, but that isn't the case. Since industrial wastes are often treated in the same sewage plants as household wastes, sewage sludges are often contaminated with heavy metals that, when regularly incorporated into the soil, can build up to toxic levels.

All municipal sludge must be composted at high temperatures before it can be safely used as a garden fertilizer. Even then, avoid using it for edible crops, especially roots and leafy greens, since some viruses can survive hot composting temperatures. Any municipal solid waste composting operation should provide information on metals and other toxic compounds in its products if it offers them for sale to the public; most states prohibit distribution of uncomposted sludge to the public.

As restrictions on sewage waste disposal make it more difficult and costly, an increasing number of cities are establishing sludge composting programs. Gardeners who have access to the products of such programs should ask questions and get detailed answers about the content of the sludge, its chemical analysis, and how it has been processed. Unless you're absolutely sure of the chemical content of your community's sludge, don't apply it near or on food crops or anywhere that runoff might contaminate a garden, an orchard, or a well.

Soil

While not a necessity, soil is a valuable component in compost making. The thin (⅛-inch) layer called for in Indore heaps contains billions of soil organisms that consume plant, animal, and mineral matter, converting it to humus. Soil also contains minerals and organic matter, so it acts like an activator when added to compostables. You can achieve much the same results using finished compost saved from a previous batch.

Thin layers of dirt in the compost heap work to absorb unstable substances produced by fermentation, thereby slowing their loss to the atmosphere. And when the pile is built, a topping of several inches of topsoil will stop heat and water from leaving the pile. Don't add too much soil, however, or the finished compost will be quite heavy.

Other than your own property, sources for soil include nearby woods, fields, building excavations, and mud from streams and ponds free of industrial or agricultural pollution. Don't use pond or stream mud directly in your soil; it will have the same effect as adding raw manure. Mud is also easier to handle if you dry it before composting, by mixing it with layers of absorbent plant wastes.

There are many insects and animals that live in or near compost piles. Just like in your garden, most of these creatures are beneficial, so don't worry when you spot them—they're helping out or just enjoying the composting process.

Straw

Although straw will add few nutrients to the compost heap, it is widely used because it is readily available and adds considerable organic material. It is also unsurpassed as an aerating medium, as each straw acts as a conduit for air to circulate throughout the pile.

The fertilizer value of straw is, like that of all organic matter, twofold; it adds carbon material and plant food to the compost. The carbon serves the soil bacteria as energy food, while the plant food becomes released for growing crops. Where much straw is used, incorporate considerable amounts of nitrogen (preferably in the form of manures) so that the bacteria that break down the straw into humus do not deplete the soil of the nitrogen needed by growing plants.

If used in quantity, the straw should be cut up. Long pieces of straw mixed with other materials that hold water or composted with ample amounts of barnyard manure offer no trouble, though heaps cannot be turned easily. Straw compost must therefore be allowed to stand longer. For quicker compost, weigh down the material with a thicker layer of earth. This also preserves the moisture inside the heap.

If a large straw pile is allowed to stay outside in the field, it will eventually decay at the bottom into a crumbly substance. Such material is excellent for compost making and mulching. Some of the fungi it contains are of the types that form mycorrhizal relations with the roots of fruit trees, evergreens, grapes, roses, and so on, and a straw mulch will therefore benefit these plants not only as a moisture preserver but as an inoculant for mycorrhizae.

The nitrogen value of straw is so small that it need not be accounted for in composting. The mineral value of straw depends on the soils where the crops were grown.

Sugar Wastes

The most plentiful sugar-processing residue is burned bone, or bone charcoal, which is used as a filtration medium. Called "bone black" when saturated with sugar residues, this substance contains 2 percent nitrogen, more than 30 percent phosphorus, and a variable potassium content. Raw sugar residues, also known as bagasse, have over 1 percent nitrogen and over 8 percent phosphoric acid.

Tanbark

Tanbark is plant waste that remains following the tanning of leather. Its residues are shredded, heaped, and inoculated with decay-promoting bacteria. Thus composted, tanbark is sold in bulk as mulching material. Analysis shows nitrogen at 1.7 percent, phosphorus at 0.9 percent, and potassium at 0.2 percent; minor amounts of aluminum, calcium, cobalt, copper, iron, lead, magnesium, molybdenum, zinc, and boron are also present. Like peat, tanbark makes an excellent mulch but is generally too expensive to use extensively in compost.

Tankage

Tankage is the refuse from slaughterhouses and butcher shops, except blood freed from the fats by processing. Depending on the amount of bone present, the phosphorus content varies greatly. The nitrogen content varies usually between 5 and 12.5 percent; the phosphoric acid content is usually around 2 percent, but may be much higher.

Tankage, because it is usually rich in nutrient value, is especially valuable to the compost pile. However, it is also in demand as a feed additive and so is available only sporadically. Because it is an animal waste, tankage does require some special care in composting. Your compost must be kept in a secure, enclosed container, safe from four-legged scavengers. Use a good supply of high-carbon materials such as leaves, hay, or sawdust to absorb odors, with a layer of soil over each layer of tankage.

Tea Grounds

Useful as a mulch or for adding to the compost heap, one analysis of tea leaves showed the relatively high content of 4.15 percent nitrogen, which seems exceptional. Both phosphorus and potash were present in amounts below 1 percent.

Tobacco Wastes

Tobacco stems, leaf waste, and dust are good organic fertilizer, especially high in potash. The nutrients contained in 100 pounds of tobacco wastes are 2.5 to 3.7 pounds of nitrogen, almost 1 pound of phosphoric acid, and from 4.5 to 7 pounds of potassium.

Tobacco leaves are "stripped" for market in late fall, leaving thousands of stalks. Some farmers use their stalks to fertilize their own fields, chopping up the stalks and disking them into the soil. Some stalks are available for gardeners, however, and tobacco processing plants bale further wastes for home use.

These wastes can be used anywhere barnyard manure is recommended, except on tobacco, tomatoes, potatoes, and peppers because they may carry some of the virus diseases of these crops, especially tobacco mosaic virus.

Compost tobacco wastes, or use them in moderation in mulching or sheet composting mixed with other organic materials. They should not be applied alone in concentrated amounts as a mulch—the nicotine will eliminate beneficial insects, earthworms, and other soil organisms as well as harmful ones.

Water Hyacinth

Southerners who lack sufficient green matter for compost can often find quantities of the water hyacinth (*Eichhornia crassipes*) growing in profusion in southern streams. This plant is considered a serious menace to agriculture, fisheries, sanitation, and health in the South and other parts of the world where it grows with remarkable rankness. For best results, shred and mix it with partially decomposed "starter material" such as soil or manure.

Weeds

Weeds can be put to use in the compost pile. Their nitrogen, phosphorus, and potash content is similar to other plant residues, and large quantities can provide much humus for the soil. Weed seeds will be killed by the high temperatures in the compost pile, and any weeds that sprout from the top of the heap can be turned under. Be careful not to allow weeds to grow and set seed on your finished compost. Weeds can even be used for green manure, as long as they will not be stealing needed plant food and moisture. Some produce creditable amounts of humus, make minerals available, and conserve nitrogen.

There are some weeds that you are better off burning or piling separately from your garden compost, since they are extremely vigorous and hard to kill. This applies primarily to weeds that reproduce through underground stems or rhizomes, such as quack grass, johnson-grass, bittersweet, and bishop's-weed.

Wood Ash

Wood ash is a valuable source of potash for the compost heap. Hardwood ashes generally contain from 1 to 10 percent potash, in addition to 35 percent calcium and 1.5 percent phosphorus. Wood ashes should never be allowed to stand in the rain, as the potash would leach away. Wood ashes should be used very cautiously—it is not uncommon for home gardeners to create difficult nutrient imbalance problems by applying too much wood ash. It is a strong alkalinizing agent and also increases soil salinity. You should use it in the garden only if a soil test indicates acid soil and a lack of potassium.

Continued ➔

Wood ashes can be mixed with other fertilizing materials or side-dressed around growing plants. Apply no more than 2 pounds per 100 square feet. Avoid contact between freshly spread ashes and germinating seeds or new plant roots by spreading ashes a few inches from plants. Be similarly sparing with wood ashes in your compost—use no more than a dusting on each layer, if you must. Manure and hay are also rich in potassium, and they do not pose the dangers of wood ashes.

Wood Chips

Like sawdust and other wood wastes, wood chips are useful in the garden. In some ways wood chips are superior to sawdust. They contain a much greater percentage of bark and have a higher nutrient content. Since they break down very slowly, their high carbon content is less likely to create depressed nitrogen levels. They do a fine job of aerating the soil and increasing its moisture-holding capacity, and they also make a fine mulch for ornamentals.

Generally, the incorporation of fresh chips has no detrimental effect on the crop if sufficient nitrogen is present or provided. Better yet, apply the chips ahead of a green manure crop, preferably a legume; allow about a year's interval between application and seeding or planting of the main crop. Other good ways to use wood fragments are: (1) as bedding in the barn, followed by field application of the manure; (2) as a mulch on row crops, with the partially decomposed material eventually worked into the soil; and (3) adequately composted with other organic materials. Well-rotted chips or sawdust are safe materials to use under almost any condition.

Wool Wastes

Wool wastes, also known as shoddy, have been used by British farmers living in the vicinity of wool textile mills since the industrial revolution in the early nineteenth century. The wool fiber decomposes when in contact with moisture in the soil and, in the process, produces available nitrogen for plant growth. Generally, the moisture content of the wool wastes is between 15 and 20 percent. It contains from 3.5 to 6 percent nitrogen, 2 to 4 percent phosphoric acid, and 1 to 3.5 percent potash.

C/N Ratios and Nutrient Analyses

The following tables and lists provide information about the carbon/nitrogen nutrient contents of a variety of organic materials. The presence of a material in this section does not necessarily mean it is ideal for composting; neither does exclusion of a material mean that it cannot be composted. As mentioned at the beginning of this section, the best materials for composting may be those that are in close proximity to the compost pile.

Many items are listed as ash; since it is not always desirable or possible to reduce organic matter to ash, be aware that these materials are valuable compost pile additions in their natural conditions. Burning organic matter eliminates moisture, so nutrients are much more concentrated in ashed materials than in fresh. However, the significant advantages of adding fresh materials (moisture, microorganisms, and so on) and the restrictions most municipalities place on burning make ashed materials unlikely additions to most compost piles.

Since nearly all organic material contains some amount of nitrogen, phosphorus, potassium, and micronutrients, you don't need to worry a great deal about including all the plant nutrients in your compost pile. If you incorporate a good variety of materials into your compost, the necessary nutrients will be there. Compost not only provides nutrients, it also makes soil nutrients more available to plants. Only in instances where soil analysis indicates a significant nutrient deficiency should much effort be given to boosting levels of a certain nutrient in your compost.

NATURAL SOURCES OF NITROGEN

The materials listed below are grouped into representative classifications of organic matter; each group is ordered from highest nitrogen concentration to lowest. For specific nitrogen analyses, see the table "Percentage Composition of Various Materials" on page 084.

Manure

- Rabbit manure
- Sewage sludge
- Chicken manure
- Human urine
- Swine manure
- Sheep manure
- Horse manure
- Cattle manure

Animal Wastes (other than manures)

- Feathers
- Felt wastes
- Dried blood
- Crabs (dried, ground)
- Silkworm cocoons
- Tankage
- Fish (dried, ground)
- Silk wastes
- Shrimp heads (dried)
- Crabs (fresh)
- Fish scrap (fresh)
- Wool wastes
- Jellyfish (dried)
- Lobster refuse
- Shrimp wastes

Eggshells
Mussels
Milk
Oyster shells

Meal

Cottonseed meal
Gluten meal
Bonemeal (raw)
Wheat bran
Bonemeal (steamed)
Bone black
Oats (green fodder)
Corn silage

Plant Wastes

Tung oil pomace
Castor pomace
Tea grounds
Peanut shells
Tobacco stems
Coffee grounds
Sugar wastes
Seaweed (dried)
Olive pomace
Brewery wastes
Cocoa shell dust
Grape pomace
Potato skins (raw)
Pine needles
Beet wastes
Seaweed (fresh)

Leaves

Raspberry leaves
Apple leaves
Peach leaves
Oak leaves
Pear leaves
Cherry leaves
Grape leaves
Pea (garden) vines

Grasses

Cowpea hay
Vetch hay
Soybean hay
Pea forage
Alfalfa
Red clover
Clover
Millet hay
Timothy hay
Salt marsh hay
Kentucky bluegrass hay
Immature grass

NATURAL SOURCES OF PHOSPHATE (OTHER THAN PHOSPHATE ROCK OR BONEMEAL)

The following phosphate sources are listed in order from highest phosphorus content to lowest.

Shrimp wastes
Sugar wastes (raw)
Fish (dried, ground)
Sludge (activated)
Lobster refuse
Wool wastes
Dried blood
Banana residues (ash)
Apple skins (ash)
Orange skins (ash)
Pea pods (ash)
Cottonseed meal
Hoof and horn meal
Tankage
Castor pomace
Rapeseed meal
Wood ashes
Cocoa shell dust
Chicken manure
Rabbit manure
Silk mill wastes
Sheep and goat manure
Swine manure
Horse manure
Cattle manure

NATURAL SOURCES OF POTASH

The materials in each group below are listed in order from highest potassium content to lowest.

Natural Minerals

Greensand
Granite dust
Basalt rock

Continued →

Hay Materials

- Millet hay
- Cowpea hay
- Vetch hay
- Soybean hay
- Alfalfa hay
- Red clover hay
- Kentucky bluegrass hay
- Pea forage
- Timothy hay
- Winter rye
- Immature grass
- Salt marsh hay
- Pea (garden) vines

Straw

- Buckwheat straw
- Oat straw
- Barley straw
- Rye straw
- Sorghum straw
- Cornstalks
- Wheat straw

Leaves

- Cherry leaves
- Peach leaves
- Raspberry leaves
- Apple leaves
- Grape leaves
- Pear leaves
- Oak leaves

Manure

- Pigeon manure
- Chicken manure
- Duck manure
- Rabbit manure
- Swine manure
- Horse manure
- Sheep or goat manure
- Cattle manure

Miscellaneous

- Banana residues (ash)
- Pea pods (ash)
- Cantaloupe rinds (ash)
- Wood ash
- Tobacco stems
- Cattail reeds or water lily stems
- Molasses wastes
- Cocoa shell dust
- Potato tubers
- Wool wastes
- Rapeseed meal
- Beet wastes
- Castor pomace
- Cottonseed meal
- Potato vines (dried)
- Vegetable wastes
- Olive pomace
- Silk mill wastes

How to Make Compost

Composting isn't difficult. All you need are some raw ingredients, a tool for handling the compost, and a place to pile it. The organisms in the pile do most of the work for you—so you end up with a great (and free) soil amendment without having to put a lot of effort into it.

Recipe Fundamentals

The basic principles of composting are simple: Combine your ingredients to provide a good nutritional balance, keep the pile well-aerated and moist (not soggy), and let the compost microorganisms do the rest. An active compost pile, turned once a week or so, will heat up inside to a temperature as high as 160°F, but if you're willing to wait for your finished compost, you don't even have to turn it. How much easier could it get?

The compost pile has its own ecosystem, with various organisms playing a central role during different steps of the cycle. As the pile heats up, mesophilic bacteria—those that prefer some warmth—proliferate. When temperatures get above 120°F, thermophilic, or heat-loving, organisms do more of the work. At cooler temperatures, fungi and actinomycetes predominate. Earthworms and other visible macroorganisms do their jobs at cooler temperatures and on the edges of the heating pile.

You can choose from a wide selection of materials and methods to compost successfully. But the same basic principles apply to all of them. When you understand what the microbes need to flourish, you'll know what to do to help make compost happen. Before you know it, you'll have your own supply of "black gold."

Composting Basics

The aim of every composting method is simply to meet the needs of the microorganisms that do the work of turning raw organic matter into humus. Those basic needs are energy food (carbon) and protein food (nitrogen) in the right proportion: air, moisture, and warmth. A pile also needs to be a minimum size so that high enough temperatures can be maintained.

FEED THE DECOMPOSERS

The first step to successful composting is providing the right mixture of basic ingredients. Raw organic matter, the basic food for compost organisms, consists of carbohydrates (carbon) and proteins (nitrogen) in differing proportions. To keep the decomposers well-fed, you need to provide these two food groups in the right balance.

Carbohydrates, which provide energy and cell-building compounds, must make up the bulk of the diet. Protein, which is essential for growth and reproduction, is needed in much smaller quantities. A ratio of 20 to 30 parts carbon to 1 part nitrogen is ideal.

In general, carbon materials are brown or yellow and dry, bulky, or fluffy (that's why they're commonly referred to as the "dry browns"). Dry leaves, straw, hay, and sawdust are all high in carbon.

Nitrogen materials tend to be green and wet, succulent, dense, or sticky, which is why they're often called "wet greens." Fresh manure, grass clippings, fish wastes, and soybean meal are rich in nitrogen.

KEEP THE PILE MOIST

Your compost pile should be about as moist as a damp sponge. If you can squeeze water out of it, it's too wet. But the moisture level of your compost pile shouldn't be much of a problem if you're mixing the right proportions of dry carbon materials with wet nitrogen ones.

Here are some other ways to regulate the moisture level in your compost.

- For most areas, make sure your pile is in a well-drained site. For very arid regions, however, consider digging a shallow composting pit to trap more moisture.
- If your ingredients are dry, sprinkle each layer with a hose or watering can until everything is moist and has a good sheen.
- Shape your pile according to your climate. In a wet climate, round the top to shed rain. In a dry climate, make a shallow depression on top to trap water.
- To shed excess rainwater and protect the compost materials from the drying effects of the sun and wind, cover the pile with a little loose hay or straw, or use dark plastic. Or, make your compost in a container with a lid.

AERATE THE PILE

Most home compost piles depend on aerobic organisms, which require air to live. So proper aeration is critical to successful composting.

To make sure your pile is well aerated, start by choosing a well-drained site. Compost that sits in a puddle, even for a short time, will wick up the water into essential air spaces in the pile.

You'll also need to provide air passages beneath the pile. Layer brush, spent cornstalks, or other coarse materials at the bottom of the pile. Or, make a wire mesh bottom for your compost bin so that it sits a couple of inches above the ground.

The bulky carbon materials you use in your compost pile create air passages throughout the pile, improving air flow and supplying food. Straw is highly valued for this reason. But be careful about using large layers of leaves, paper, grass clippings, or other ingredients that tend to mat when wet. Before adding these materials to your pile, shred them to fluff them up a bit and to prevent them from matting together.

Turning is the traditional way to aerate compost, and frequent turning is the key to quick, hot compost. The more often you turn the pile, the faster the new materials will decompose and the higher the temperatures will become.

Easier Aeration

You can get air into the center of your compost pile without turning it at all! The trick is to run ventilation pipes—perforated PVC pipes—through the pile. (If you don't have PVC pipes on hand, you can substitute cornstalks or palm fronds—both of these plants have an open center.)

You'll need several pipes that are about 4 feet long, or a little longer than the width or height of your pile. Run one pipe horizontally through the middle of the pile. Insert parallel pipes vertically about 6 inches away, on either side of the middle pipe. As the pile heats up, withdraw a pipe and reinsert it in another part of the pile. Do this every few days, if possible.

Another easy way to open air channels without turning is simply to stab the pile with a pitchfork once a week or so.

SIZE UP THE PILE

Composting works best when the temperature inside the pile remains at about 140°F or higher. Things heat up fast with the right mix of materials, air, and water. But to keep things cooking, you need the pile to be of a certain size—at least 3 x 3 x 3 feet—to provide the necessary mass.

Percentage Composition of Various Materials

The presence of a C, N, or O in the C/N column indicates whether a material's effect on compost would be carbonaceous (C), nitrogenous (N), or other (O). Rock powders, for example, do not affect the C/N ratio and are designated O. C/N ratios of ashed materials represent their effects when fresh; when ashed, they are similar to rock powders.

Material	Nitrogen	Phosphoric Acid	Potash	C/N
Alfalfa hay	2.45	0.5	2.1	N
Apple fruit	0.05	0.02	0.1	N

**Dried manures are up to 5 times higher in nitrogen, phosphoric acid, and potassium.*

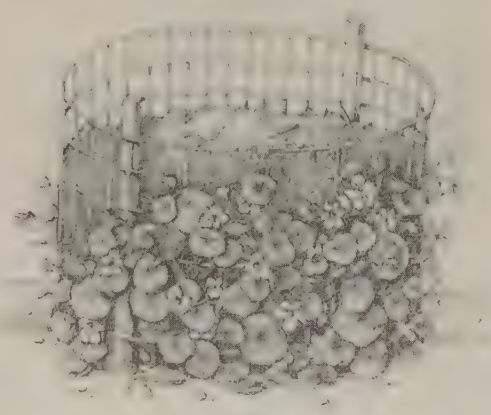
If the pile is smaller than that, the heat will dissipate before the pile can reach the right temperature for the thermophilic organisms. A pile that's much larger than that will be difficult for you to turn, and the interior can become anaerobic. Instead of making a pile that's too large, make two medium-sized ones.

Bacteria begin to go dormant and compost stops cooking when the compost temperature drops below 55°. But with a properly built compost pile, the interior temperature will stay well above that—even in freezing weather. Northern gardeners sometimes insulate their piles with leaves, straw, or even an enclosure of hay bales to keep things cooking in cold weather. Decomposition may slow for the winter but should speed up again and finish during the warmer months of spring.

5 Steps to Quick Compost

Raking up some fallen leaves in a corner of your yard and gradually adding garden wastes and kitchen scraps is a simple, low-tech way to compost. This laissez-faire method makes what's called "cool compost" because the pile literally stays cool. Just let the pile sit, and in about a year, you'll have sweet-smelling, dark brown, crumbly compost.

You may have seen your neighbors turning their compost piles and watering them. Why do they do these things? Because



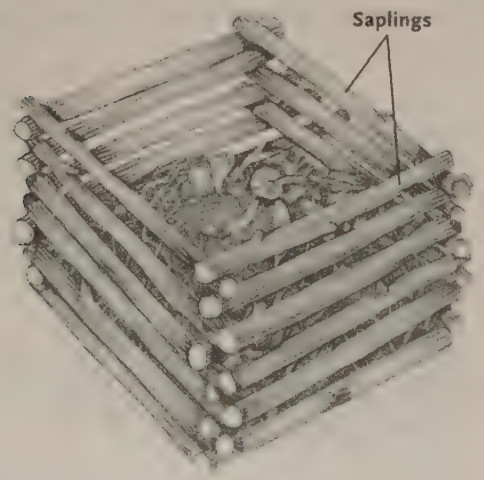
Screen a wire compost bin from view by planting nasturtiums or morning glories to twine up the fencing. Or plant sunflowers just outside the fence.

Continued ➔

they want compost fast—from start to finish in just a month. So they make an active, or hot, compost pile. The microorganisms that drive the composting process need a steady supply of water and air, and the more they get, the faster they work.

There are five key steps in making a hot compost pile. The more you're willing to work with your compost, the faster it'll decompose.

1. **Shred and chop.** Shred or chop materials as finely as you can before mixing them into your pile. For example, you can chop fallen leaves by running your lawn mower over them. The same strategy applies to kitchen scraps and the like—"the smaller the better" is always the rule for compost ingredients.
2. **Mix dry browns and wet greens.** The two basic types of ingredients for making compost are those rich in carbon and those rich in nitrogen. Carbon-rich materials, or "dry browns," include leaves, hay, and straw. Nitrogen-rich materials, or "wet greens," include kitchen scraps and grass clippings (which work best when used sparsely and mixed in well so they don't mat down). Your goal is to keep a fair mix of these materials throughout your pile. (If you try to make compost solely with wet greens or dry browns, you won't have much luck.)
3. **Strive for size.** Build your pile at least 3 x 3 x 3 to 4 feet so materials will heat up and decompose quickly. (Remember, though, not to make your pile too big, or else it will be hard for you to turn.) Unless you have this critical mass of materials, your compost pile can't really get cooking. Check the pile a couple of days after you make it—it should be hot in the middle, a sign that your microbial decomposers are working hard.
4. **Add water as needed.** Make sure your pile stays moist, but not too wet (it should look like a damp sponge). You may need to add water occasionally.
5. **Keep things moving.** Moving your compost adds air to the mix. One way to add air is to get in there with a pitchfork and open up air holes. Even better, move the entire pile over a few feet bit by bit, taking care to move what was on the outside to the inside of the new pile and vice versa. Or consider getting a compost tumbler—a container that moves the materials for you. A less labor-intensive way to add air is to put a homemade "chimney" in the center of the pile.



After cutting down saplings, stack them to frame a compost pile. You can also harvest sunflower stalks—just cut off the heads and stack them log-cabin style.

Compost: Hot or Cold?

There's more than one way to make compost. The best method for you depends on many factors, such as the time and effort you're able to give, the space you have available, and the amount of compost you need. Composting methods range from quick, hot composting that requires more effort and attention to slow, cool techniques that are less trouble. Both hot and cold composting have advantages and drawbacks.

HOT STUFF

The biggest advantage of hot composting is its fast turnover—generally less than 8 weeks and as few as 2 weeks. To achieve that fast breakdown, the pile needs aeration: The more air it gets, the hotter it becomes (and the more hospitable to thermophilic bacteria). The object is to maintain a temperature of 113° to 158°F until decomposition is complete. You can use a thermometer to monitor the temperature or simply feel the inside of the pile with your hand. If it feels hot to the touch, you're in the ballpark. But when the temperature drops below this range, you must turn the ingredients to get the process going again.

With hot composting, you can process six or more batches in one season, even in cool climates. If you need lots of compost but have limited room to produce it, this is the way to go.

The other major advantage to hot compost is its temperature. Few weed seeds and pathogens can survive thermophilic temperatures, especially if they're maintained for several weeks.

The major disadvantage of hot composting is the labor required. Not everyone is willing or able to turn the pile every few days. Hot compost also demands specific conditions: If the moisture level or carbon-to-nitrogen ratio is wrong, you have to make adjustments. Another drawback is that you have to build the whole pile at one time. If you don't have the materials on hand to make a pile of the proper size, you must accumulate and store them until you're ready to build a new pile.

Finally, hot compost usually contains less nitrogen than cold compost. Turning allows more nitrogen to escape into the air in the form of ammonia gas.

Studies also have shown that compost produced at high temperatures is less able to suppress soil-borne diseases than cool compost. That's because the beneficial bacteria and fungi that attack pathogens can't survive the higher temperatures.

Hot Versus Cool: Compost Pros & Cons

Hot Pros

- Produces finished compost quickly
- Uses space efficiently
- Kills most weed seeds and pathogens

Hot Cons

- Labor intensive
- Requires careful control of moisture and carbon-to-nitrogen ratio
- Requires enough materials to build a 3 x 3 x 3-foot pile at one time
- May contain less nitrogen
- Doesn't contain as many disease-fighting organisms

Cool Pros

- Needs little maintenance
- Spares disease-fighting microbes
- Conserves nitrogen
- Allows for materials to be added gradually

Cool Cons

- Takes 6 months to 2 years to produce finished compost
- Doesn't kill pathogens or weed seeds
- Needs a balance of carbon and nitrogen materials to be added to the pile
- Contains more pieces of high-carbon materials that haven't decomposed
- May lose nutrients because of extended exposure to rain and sun

Do You Need a Compost Inoculant?

Will using one of the bacterial "compost starter" inoculants give you compost faster? No, say university researchers. According to recent tests, raw compost materials already contain more than enough bacteria to get your compost mixture cooking.

The researchers performed their tests on four compost piles, all containing a typical backyard compost mix of 2 parts leaves to 1 part grass clippings.

One pile received a standard commercial inoculant; the second, a "premium" commercial inoculant; the third, some year-old compost; and the fourth, no inoculant. All four compost piles were turned and watered weekly, and all heated up to 130°F. At the end of 2 months, all four piles contained equally finished compost. The university researchers concluded that the inoculants offered no benefit to a typical grass and leaves compost pile.

THE COOL ALTERNATIVE

If you have the space but not the time or stamina to play with your compost, you can take the passive approach and make "cool compost." Cool compost will still heat up at first, but it won't reach the high temperature that actively turned compost will. The maximum temperature of cool compost is about 120°F. At that temperature, the mesophilic organisms do most of the work of making humus, which will be complete in 6 months to 2 years, depending on climate, materials, and aeration.

The advantages and disadvantages of cool composting mirror those of hot composting. Cool composting takes less work, but you'll need to wait longer to get the finished product. Cool composting also fails to kill pathogens or weed seeds but spares disease-fighting microbes.

One big plus of cool compost is that it can contain more nitrogen than hot compost. Some research has shown that "no-turn" compost contains as much as 13 percent more nitrogen than composts that are turned twice a week. In an unturned pile, microbes convert nitrogen into a stable form, so less escapes into the air as ammonia gas. To maintain that higher nitrogen level, however, you *must* cover your compost to protect it from rain. Otherwise, much of the nitrogen will leach away in the rainwater.

Another advantage of cool composting is that you can add materials a little at a time, as you accumulate them. The drawback is that you must be careful to balance carbon and nitrogen materials as you go, or you risk creating anaerobic conditions (which can cause an unpleasant odor). To prevent that from happening, keep a supply of dry carbon materials on hand to layer in when you add kitchen scraps or grass clippings.

To build a cool compost pile, follow these steps.

1. First lay a base of brush on a well-drained site.
2. Add ingredients as you accumulate them, keeping a good mix of carbon and nitrogen materials. As you add new materials, moisten them lightly, if needed, and cover them with a bit of soil.
3. When the pile has reached 3 x 3 x 3 feet, cover it with a layer of straw or leaves and let it rest for 6 months to a year, or more.
4. Before using, screen out any pieces that haven't decomposed.

The Lowdown on Manure

Farmers and gardeners have been fertilizing their soil with animal manure for centuries, and animal manure has long been recommended as a good source of nitrogen for compost piles, too. After all, animal manure is a rich source of soil nutrients, and it adds precious organic matter to soil. But for all the benefits that animal manure can offer your garden, it has a big drawback. Some may contain toxic bacteria.

Continued →

KEEPING IT OUT OF YOUR PILE

If you add fresh animal manure to your compost pile, you run the risk of contaminating it with a virulent strain of *Escherichia coli* bacteria: *E. coli* 0157:H7. This bacteria lives in the intestines of cows and some other animals and appears in their manure. We humans have *E. coli* in our stomachs, too, but *E. coli* 0157 is a new, dangerous form that produces a toxin that can cause severe illness, especially in small children, the elderly, and people with compromised immune systems.

So until scientists learn more about this new strain of *E. coli*, you may want to avoid using raw manure in your home compost pile, unless you are *certain* that your compost will heat up to over 140°F (the temperature needed to kill off harmful pathogens).

The good news, though, is that you don't need manure to make compost. Fresh grass clippings are an excellent, readily available, alternative source of nitrogen that you can add to your compost pile. Vegetable-type kitchen scraps are usually a good source of nitrogen as well. And alfalfa and soybean meals (available at farm supply stores) are just two examples of commercial products you can purchase to give your compost pile a boost of nitrogen.

Don't Contaminate Your Compost!

Most organic wastes make good compost fodder, but some materials are likely to contain toxic residues (herbicides, pesticides, fungicides, or heavy metals) that could contaminate your compost and your garden. Keep these out of your compost pile:

- Grass clippings from neighbors or businesses that use herbicides
- Grass clippings from golf courses
- Highway trimmings
- Florist shop wastes
- Leather meal
- Cottonseed meal (unless from an organic farm)
- Paper mill sludge
- Coal ash
- Sewage sludge
- Municipal incinerator ash

Never spread manure over vegetable gardens that have already been planted, and don't use pet feces in your pile—dogs and cats can carry parasites that, in rare cases, can be transmitted to humans. And always wash your hands well after working in the garden—as well as any fresh produce you harvested.

What Not to Put in the Compost Pile

Although you *can* compost nearly any organic material, you should avoid or limit the use of certain materials, such as the following:

Meat scraps. These can attract unwanted animal visitors and create unpleasant odors.

Fats, oils, and grease. Large amounts of fats, oils, or grease will give your microbes indigestion, slowing down the composting process. They also may attract rodents and other pests.

Droppings from caged birds. Bird droppings may contain dangerous disease pathogens. And because they're mixed with bedding and dropped birdseed from the bottom of the cage, these droppings also can introduce weed seeds into your compost.

Droppings from dogs, cats, or other carnivores. These could contain disease organisms harmful to humans. Hot composting kills most pathogens, but some may be able to survive even prolonged heat. Cat droppings, in particular, can be hazardous to pregnant women and small children. These droppings may contain *Toxoplasma gondii*, a one-celled organism that can infect an unborn child, causing brain and eye disease. *Toxocara cati*, a roundworm common in cat droppings, can cause similar problems in children. Avoid these problems by keeping the litter box away from the compost pile and children.

Human waste. The potential for spreading disease makes the use of human waste in the compost pile too risky.

Diseased plants. Yes, hot composting kills most plant pathogens. But why risk it? Instead, burn diseased plants and add their ashes to the compost pile. Or send them to the landfill.

Weeds. Weeds that have set seed can cause trouble unless your pile is hot enough to kill the seeds. Better not to risk contaminating your whole garden with them. Certain weeds should be kept out of the compost pile entirely. Canada thistle, quack grass, couch grass, Johnson grass, bishop's weed, comfrey, and Jerusalem artichokes can all reproduce easily from the tiniest bit of surviving root or rhizome.

Allelopathic plants. Some plants contain chemical compounds that inhibit the growth of other plants. In time, most of these compounds break down during the compost process. But to be on the safe side, you might want to avoid composting any materials from these plants, which include black walnut, sunflowers, and eucalyptus.

Large or slow-to-decompose materials. Large pieces of wood, bones, oyster and clam shells, rags, brush, cornstalks, heavy cardboard, and the like will just get in the way. If you want to compost them, shred or crush them first to speed their decay.

Highly acidic materials. If you want to use materials that are very acidic, such as fruit pomaces, add some crushed limestone to the pile to neutralize the acid. *Exception*: For acid-loving plants, such as azaleas and blueberries, you might want an acidic compost. In that case, skip the limestone.

Keeping Toxins Out

What about those widely available but questionable materials, such as floral shop waste or grass clippings from neighbors and golf courses? If the materials have been treated with herbicides or insecticides, can you poison your compost and garden by adding them to your pile?

These are good questions. Unfortunately, there are no easy answers. According to the University of Illinois Center for Solid Waste Management Research, some commonly used herbicides can remain active for a full year.

And a researcher at the Connecticut Agricultural Experiment Station says crops can take up some of these herbicides after the herbicides have been introduced to the garden. So, theoretically, you could get traces of these toxins in the food you grow.

Scientific research on how pesticides and herbicides break down in the compost pile is just beginning. But the consensus is that some of these substances may survive the composting process. Whether they do or not depends on which pesticide or herbicide was used—different chemicals break down at different rates. And the conditions within the compost pile (such as heat, moisture, and pH) also affect the rate at which they disappear.

Avoiding Tainted Compost

With all of these variables, there's just no way for the average home gardener to tell when (or if) compost ingredients that started out tainted become safe for organic food growing. So the answer for true organic gardeners is "no"—just don't do it. Don't add any herbicide- or pesticide-treated materials to your compost pile.

In case this warning comes too late and you've already added some treated golf course trimmings to your pile, don't despair. You can speed up the breakdown process and get rid of toxic residues as fast as possible (and more completely) by revving up the composting process.

According to an Ohio State University researcher, herbicide and insecticide molecules are more readily degraded under aerobic conditions. And the best way to achieve those conditions? Turn, turn, turn. The more often you turn your compost pile, the more air you add, and the faster the herbicides and pesticides will break down.

Composting Techniques and Recipes

It's no secret that there are plenty of different ways to compost. As long as you use the right ingredients—chopped or shredded "dry browns," "wet greens," air, moisture, and time—any method will work.

Here are several tried-and-true methods and a few new recipes that some ingenious gardeners concocted. Try a couple on for size, then choose the best one for you—or devise your own variation. You can't go wrong!

GOOD OLD GRASS AND LEAVES

One of the simplest techniques for making good-quality compost requires only four ingredients: dry leaves, fresh grass clippings, water, and soil.

1. Collect dry leaves and some fresh grass clippings.
2. Mix two to four buckets of clippings with 10 buckets of leaves.
3. As you work, spray the materials with a hose so that the mix feels wet, but not soggy, when you touch it. Also, add a shovelful of good garden soil as you go to introduce friendly composting bacteria to the pile.
4. Repeat Steps 2 and 3 until your pile is finished.

If you turn this mix weekly and add more water if the pile starts to dry out, you should have rich, beautiful compost in just 1 to 2 months.

GARBAGE CAN COMPOST

No space in your yard for a big compost pile? Then make compost in a can. Use a sturdy plastic or metal garbage can. Punch several holes in the bottom and sides of the can. Stand the can on bricks set in a large pan (to catch any liquid that might drain out). Layer 3 inches of soil, 2 to 3 inches of kitchen scraps, and then 2 inches of grass clippings, shredded newspapers, or chopped leaves. Repeat the layers until the can is full, finishing with a layer of soil. The finished compost will be ready in about 3 to 4 months—with no turning required! One caution: With this method, the compost may produce odors as it breaks down, so put the can in an out-of-the-way spot.

TERRIFIC TUMBLER COMPOST

The secret to success with a tumbler is to stockpile materials until you have enough to almost fill the tumbler. Here's the technique:

1. Start stockpiling kitchen wastes in a 20-gallon garbage can (put the can right by your tumbler). In about 2 weeks, you should have enough for a batch of compost.
2. Transfer the kitchen wastes to the tumbler drum, and then add equal volumes of chopped leaves and grass clippings.
3. Rotate the tumbler a few times every day for 2 weeks. (You should also be stockpiling a new batch of kitchen wastes during this time.)
4. Unload the finished compost and load in new materials to start the next cycle.

When you reach October, you can load the tumbler one final time. That batch will be ready at about the end of the following April, and you can begin the 2-week routine again.

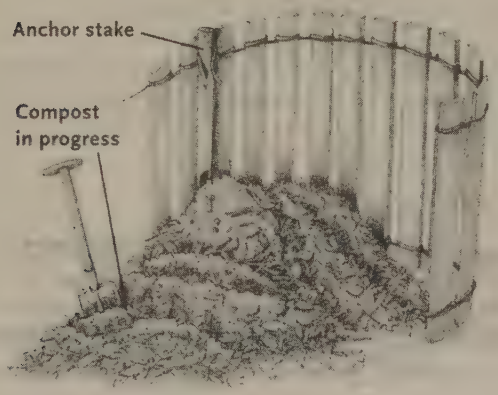
Continued ➔

BLENDER BOOSTER

To jump-start your compost pile, whiz up a batch of "liquid compost." As kitchen scraps accumulate, put them in a blender, add just enough water to cover them, then blend until finely chopped. Pour the resulting liquid into a bucket with a lid.

When you're ready to add it to your compost pile, dig a shallow hole into the center of the pile, then pour in the liquid. Cover the mixture with a shovelful of compost.

Or, if your gardening space is limited and you don't have room to make a traditional compost pile, pour the liquid gold directly into trenches dug in the garden. Cover with a shovelful of dirt.



For a compost bin that will stand up over the years, build it out of concrete block.

SHEET COMPOSTING

Another way to make compost without a traditional compost pile is to use the "sheet" method: Your garden beds serve as your compost pile. The idea is to clean up the bed at the end of the season, spread yard and garden waste over the bed, and then dig it all in.

By spring, your bed will be rich with compost. But because you lose the benefit of a heap's heat, you must be extra careful about the materials you use. Don't bury any diseased plants or weeds that have gone to seed. And, if you use kitchen scraps, bury them at least 8 inches deep so critters won't dig them up.

Follow these five steps to successful sheet composting in your garden:

1. Collect your yard waste. Remove large stalks and dense, fibrous matter, and then place the rest on the bed you've chosen.
2. Shred the material or run a lawn mower over it.
3. Add some high-nitrogen material, such as grass clippings or manure. Mix it all together.
4. Work the mixture into the top foot of soil, using a spade or tiller.
5. Turn the soil again in spring.

THREE-BIN COMPOSTING

If you have a three-bin composter, you can cook up a steady supply of compost for your soil. The following week-by-week schedule will help you get the most from your composter. Remember to check the moisture content when you transfer compost from bin to bin. Add dry material if it seems too soggy and water if it seems too dry.

Week 1: In the center bin, build a traditional compost pile. Spread a base layer of dry leaves or straw in the holding bin on one side; toss in kitchen wastes or garden trimmings as you collect them.

Weeks 2 and 3: Remove a few front boards from the center bin and stir the compost. Keep adding to the holding bin.

Week 4: Remove all front boards from the bins. Using a fork, transfer the compost from the center bin to the empty bin. Then transfer the contents of the holding bin to the now-empty center bin. Spread a new layer of dry matter in the now-empty holding bin. Replace the front boards.

Week 5: Check the compost in the end bin. It should be ready to use.

COLD-WEATHER COMPOSTING

When the weather turns cold in the fall, you can still keep your compost pile working by insulating it. Simply gather bags of fallen leaves from the curbsides around your town and heap them in a circle about 4 feet in diameter around a low compost pile. The bags provide some heat; the contents of the bags will decompose slightly and the center of the circle should stay unfrozen all winter, so you can keep dumping your kitchen scraps there.

You can also insulate a compost bin by piling straw bales around it and covering the whole thing with a large sheet of plastic.

Troubleshooting

Because compost is so integral to organic gardening, the creation of a "perfect" pile is a goal to which many gardeners aspire. But what if your results are less than perfect?

Don't throw in the towel. Here are some common compost problems and what to do about them.

WET, SOGGY, SLIMY COMPOST

Nothing is worse than cold, slimy compost! How does it get this way? Usually there are three contributing factors: poor aeration, too much moisture, and/or not enough nitrogen-rich materials in the compost pile.

A compost pile that is overburdened with materials that mat down when wet—such as grass clippings, spoiled hay, and unshredded leaves—can become so dense that the pile's center receives no air. If you leave this pile uncovered during prolonged rain (and don't turn it to introduce some air into the center), you'll end up with a cold, soggy mess.

Aerobic bacteria—the tiny, friendly, air-loving creatures that make compost cook—can't live in such an oxygen-poor environment. That kind of pile welcomes anaerobic bacteria, instead. These creatures will eventually make compost of your mess, but they work much more slowly than aerobic bacteria and the compost will be slimy and soggy during the 2 to 3 years it will take to decompose.

Actually, soggy compost is fairly easy to fix. If endlessly wet weather is part of the problem, cover the pile with a loose-fitting lid or tarp. You'll also need to turn the pile and fluff it up thoroughly. If you have some nitrogen-rich ingredients (such as fresh manure or shellfish wastes) and fibrous, nonmatting materials (such as shredded corncobs or sawdust), add them to help get things cooking.

DRY, DUSTY COMPOST

This opposite version of soggy, slimy compost is extremely common from May through October in areas that receive little summer rainfall. No matter what materials you pile up, the stack just doesn't get enough moisture to support the bacterial life necessary to fuel the composting process. Luckily, curing dry, dusty compost is as simple as turning on a spigot. That's right—water your compost pile until the materials feel about as wet as a damp sponge.

Put an oscillating sprinkler on top of your dry compost pile and run it for about an hour. This will moisturize the materials better than running an open hose on top—especially if the outer layers are made up of materials such as straw or grass clippings, which tend to shed water when they dry out. After sprinkling, check the center of the pile to make sure it's moist. To moisten the entire pile, you might need to turn it and water the layers as you go.

No Space To Compost? Try Trenches

If you don't have room for a compost pile, you may find that trench composting is the best way to add nutrients to your soil. How do you trench compost? Just dig a hole in your garden every day, about 8 inches deep, and bury kitchen scraps. If you start along one side of a garden row, you'll actually be side-dressing or fertilizing nearby vegetables as well as boosting soil texture and fertility for next season.

You shouldn't have a problem with animals digging up what you've buried if you avoid adding meat, fat, and bones. If dogs do begin to dig in your trenches, just use a roll of chicken wire to cover your buried treasure. Roll it out over one hole at a time, along the row. Because the roll moves gradually, it also marks where you buried something last.

Compost in a Bag

Even if you live in an apartment and have absolutely no space for composting, this recipe for compost in a bag can help you recycle some of your kitchen wastes into fertilizer for your houseplants. It's also a great way to teach children about composting.

Start with a medium-sized plastic bag and a twist-tie. Watertight, self-sealing bags also work well.

Place 1 cup of shredded organic matter in the bag. Use your imagination and your available resources here—try coffee grounds, tea leaves, fruit peels, leaves, grass clippings, apple cores without seeds, carrot or potato peels, wood ashes, and so on—any kind of organic material you might normally throw away. The more finely you can chop up or tear these items, the more effective your mini-compost bag will be.

Add ½ cup of garden soil to your bag. This is important for providing the microorganisms that will do the composting "work." Well-decomposed leaf mold or finished compost will work here, too. Don't substitute sterile potting soil; all its microorganisms have been sterilized away.

Add 1 tablespoon of alfalfa meal or alfalfa pellets (available as Litter Green cat box filler or as rabbit or hamster foods).

Pour in 1 ounce of water, and seal the bag. Shake the bag to mix all the contents thoroughly. Squeeze the bag daily to mix your compost (the equivalent of turning a compost pile).

Every other day, leave the bag open for the day to let air in. Without air, your organic matter will decompose improperly and will smell bad. If the contents of your bag smell, they may be too wet or in need of more mixing. In 4 to 6 weeks your compost should be finished and ready to use.

Turning and watering your pile should spring it to life fairly quickly. If not, you might have other problems, such as a lack of nitrogen-rich materials. If that's the case, tear the whole thing apart, add some grass clippings, manure, or bloodmeal to get it going, and pile it up again. When the pile starts cooking, don't let it dry out again. As those tiny organisms multiply, they use up a lot of water. You might have to water your compost almost as often as you water your roses during a heat wave.

BUGS!

Pill bugs and sow bugs are small crustaceans (not insects) that live on decaying organic refuse. If you turn your pile and see thousands of tiny, gray "armadillos" with seven pairs of legs each, you've discovered a nest of the primitive creatures. (Pill bugs roll up into a ball when threatened and sow bugs don't—otherwise, there isn't much difference between the two.)

Continued →

These bugs won't harm your compost. In fact, they're actually helping to break it down. But if you don't remove them from the finished mixture before you spread it on the garden, you might find them snipping off the emerging roots and leaves of your garden plants.

Ants and earwigs also invade compost piles. Like sow bugs and pill bugs, they are essentially harmless to the composting process. Their presence may indicate that the breakdown process has nearly finished. Or, if you still have lots of material that hasn't broken down, these insects can simply mean that your pile is on a slow track to decomposition.

To get these bugs out of unfinished compost, raise the pile's temperature to above 120°F. Turn the pile over and rebuild it, watering it as you go. If it contains lots of slow-to-decompose materials, such as leaves or straw, mix in a nitrogen source, such as bloodmeal, manure, or shellfish wastes. It should soon start heating and, when it does, the bugs will depart for a more comfortable place.

But what if your sow-buggy compost is already finished and you want to use it on the garden without endangering small plants? Do you have to start all over again? Not if you de-bug it first! To do so, spread the compost in a thin layer on a tarp in direct sunlight and leave it there to dry.

By the way, if the dominant creature in your compost pile is the earthworm, give yourself a pat on the back! This is a sure sign that your compost has fermented, has decomposed, and is ready to spread. Transfer such worm-laden richness gently to your garden—the soil-churning activity of these organic heroes is something to encourage and be thankful for.

BAD-SMELLING COMPOST

If your pile emits the sharp, nose-twisting stench of ammonia, it contains too much nitrogen-rich material (raw manure containing lots of urine is one likely culprit). It could also be too wet to allow aerobic bacteria to thrive. If it just "smells rotten" and there are lots of flies hanging around it, you've most likely added too many kitchen scraps or canning wastes without chopping them first or mixing them in thoroughly. For both cases, you should remake the pile to bring your stinky compost under control.

If too much "liquid nitrogen" is the problem, turn the pile and add absorbent materials—such as straw, shredded tree leaves, or sawdust—as you go. Rebuild the pile to a height of 3 feet to get it cooking again.

If kitchen scraps, canning waste, or large amounts of other mucky stuff are producing offensive odors, you can turn the pile without adding anything. As you turn, break up all that mucky stuff and mix it in well. Remind yourself that you'll avoid this unpleasant task in the future by first finely chopping these materials and then by mixing them thoroughly into the heap.

OVERHEATING

In cold weather, an active compost pile will emit steam, causing many beginning composters to think their pile is burning. What it's really doing, though, is "breathing" its warmth into the frosty air.

But if your compost is too nitrogen-heavy, the center can overheat and dry out, leaving visible white streaks. These white streaks are actually the dead bodies of millions of microorganisms. And, if they hadn't been cooked, they would have been busy turning your pile into finished compost!

Sometimes called "fire fanging" or "burning" by old-time gardeners, this phenomenon is quite common in piles that have been overloaded with fresh manure (especially from chickens or horses). Regular turning and watering will help you keep such a nitrogen-rich pile under control. To correct an already fire-fanged pile, rebuild it completely, adding some slow-working, absorbent material, such as shredded corncobs or sawdust. Sprinkle the new materials with water as you add them.

RACCOONS, OPOSSUMS, AND OTHER CRITTERS

If you spot raccoons, opossums, dogs, skunks, rats, or bears at your compost pile, they're probably going after the fresh, edible kitchen scraps you recently buried.

To avoid attracting animals, remember to keep meat scraps and fat out of your pile. Mix other kitchen scraps with soil and/or wood ashes, then bury them deeply into the hot center of the pile.

If animal scavengers have grown accustomed to getting a free meal from your compost pile, you could have trouble breaking them of the habit. And unfortunately, this is one problem that can't be solved simply by turning or rebuilding the pile. You'll probably have to build or buy a covered container for your compost.

PLANTS GROWING IN THE PILE

Young plants can emerge from a pile of finished, or nearly finished, compost. Invariably, a few seeds will survive the composting process (even a hot pile doesn't always heat up enough to kill all seeds). And the temperature, moisture, and fertility of the maturing compost are just about perfect for seed germination and seedling growth.

If the sprouts are weeds, just pull them out and add them to your next compost pile. (Green plants of any kind will provide nitrogen.) But if the young plants are vegetable or flower seedlings, go ahead and transplant them. Just be aware that they may be the offspring of hybrid parents and could, therefore, grow up to be something other than what you grew last season.

To avoid sprouts in future compost piles, don't add anything that contains seeds.

I CAN'T TURN MY COMPOST PILE!

Most garden experts will tell you that a hot compost pile should be turned at least twice a month and as often as twice a week to keep it cooking.

But that turning can be difficult work. Seniors, disabled gardeners, and those who can garden only on weekends may be unable to do this.

If you can't turn your compost pile, relax—you can create this valuable soil amendment without turning. After all, nature doesn't need your help to decompose organic materials. And, if you build your cold pile correctly from the start, you'll avoid problems, such as bugs and unpleasant smells. Here's how.

Ensure complete breakdown of the materials that go into the pile by shredding and mixing them *before* piling them up. Put everything through a chipper/shredder, run a lawn mower over it, or use a pruning shears to cut up any large, coarse stems and stalks.

If that isn't possible, build the pile in layers—alternating "browns" (carbon-rich materials like leaves and straw) with "greens" (nitrogen-rich materials like grass clippings and kitchen scraps). Mix them together as you go.

Try to include some finished compost or rich topsoil in the mix to get things going, and water your pile as you build it. Keep the moisture level as even as possible. If the compost pile begins to dry out, water it with a sprinkler.

After 6 months to 1 year, you'll have finished compost—without ever turning the pile.

Composting with Earthworms

Deborah L. Martin and Grace Gershuny

If you let them, earthworms will do most of your composting work for you, in the garden, on the farm—or even in your basement.

Earthworms are amazing creatures, capable of consuming their own weight in soil and organic matter each day, and leaving behind the richest and most productive compost known. The castings of earthworms contain from 5 to 11 times the amount of available N-P-K as the soil the worms ate to produce those castings. How do earthworms perform this magic? The secretions of their intestinal tracts act chemically to liberate plant nutrients with the aid of soil microorganisms. And what earthworms do for the major plant nutrients, they do for the micronutrients, too. Earthworms literally tunnel through your soil, day and night, liberating plant nutrients wherever they go. Let loose in a compost heap, they will quickly reduce it to the finest of humus. Mulch your garden with organic matter of nearly any kind, and earthworms will never stop working on it until they have reduced the mulch to dark, rich humus. If you encourage earthworms to stay in your soil, or work with them in producing compost, they will virtually ensure that you produce successful compost.

The secret in producing compost with earthworms is in learning a little about earthworms and their needs. If you buy 1,000 red wigglers and thrust them into the middle of your compost pile, you will likely have 1,000 dead red wigglers the next day. Most earthworms, you see, cannot tolerate the heat of an actively working compost heap. You will also want to learn to distinguish among the various major earthworm species, since their needs are quite different, and so are their capabilities in helping you make compost.

Most of the information in this section comes from *The Earthworm Book* by Jerry Minnich. This section will suggest ways to use earthworms in composting, but the gardener or farmer who wants to learn more about the topic should consult *The Earthworm Book* for greater detail.

Most people see earthworms as a welcome natural addition to their composting efforts and also as affirmation that they are doing things right. But gardeners could make better compost if they saw the earthworm as a necessary component of the whole process, just as important as air, water, or organic matter. The earthworms can do much of the work and make composting faster—but in return, the gardener must learn to make compost with the earthworm's needs in mind, and discover which species of worms are suitable for various composting situations.

The Right Worm

It is important to be aware of the different species of earthworms and what they can, and cannot, do:

Red worms (*Lumbricus rubellus*) and brandling worms (*Eisenia foetida*) are the species usually sold by earthworm breeders. They are commonly sold for fish bait under such names as red wigglers, hybrid reds, Georgia reds, and so on. Any name that suggests a red-and-gold or banded worm is likely to indicate a brandling worm. The others are probably red worms. These cannot survive in ordinary garden and farm soils for very long, but they will thrive in compost heaps and manure piles. They can be used to good advantage in an Indore heap and can greatly reduce the time required to produce finished compost and eliminate the need to turn the heap. However, many will be killed off or driven away when the organic matter begins to heat up from bacterial action.

Field worms (*Allolobophora caliginosa*) and night crawlers (*Lumbricus terrestris*) will attack compost heaps and manure piles from the bottom but prefer to retreat into the soil after having done so. They will not thrive in active compost and are killed by the heating process more easily than red worms and brandling worms. Night crawlers demand cool soil temperatures and will not inhabit compost and manure piles. If they are thrust into active compost, they will simply die and melt.

The data on the *Pheretimas* are still incomplete, but they seem to have requirements similar to those of the field worm and the night crawler. They are soil-living species.

Continued →

Earthworms in the Indore Method

Earthworms will naturally be attracted to an Indore compost heap, attacking it from the bottom. The base layer of brush will soon become reduced in bulk and filled in with finer debris. Field worms and night crawlers will quickly infiltrate this layer, to turn and mix the earth with the organic matter. They will also reproduce quickly, increasing their population many times over. If the heap is maintained for a year or more in one location, the earth below it will become rich, friable, and loaded with earthworms. With each rain, some of the nutrients from the compost will leach deep into the soil spreading out from the actual edges of the heap. Earthworms will mix these nutrients into the soil and stabilize them for growing plants. This enrichment of the soil beneath the heap is also a good reason for changing its location every year or so. Any prized plants grown where an old compost heap was built will flourish beyond reasonable expectations.

As the materials in the heap decompose and turn to humus, field worms will advance further up into the heap. Still, they will not flood the entire heap, as will the manure-living species. The limiting factor is the high temperature; even an inactive, above-ground heap will not be attractive to field-living species. Night crawlers like even cooler temperatures but will feed at the bottom of the heap. If in autumn and early spring they penetrate a well-advanced heap, you know you can use it for soil improvement.

Although manure-type worms can work at higher temperatures than field-living species, even they will be killed in the intense heat of a working compost heap, where temperatures can reach 150°F (66°C). Do not introduce them until the interior of the pile has cooled down to the outside temperature. Normally this will be about 3 weeks after the last materials have been added to a well-constructed heap. At this point, dig holes at various points in the heap, and drop 50 to 100 worms in each. About 1,000 worms (a convenient number to order) will serve to inoculate a 4-by 6-foot pile. If manure-type worms and their castings were well supplied in manure that went into the heap and have survived the heat, there will be no need to introduce worms from an outside source.

In a matter of days, the worms will be consuming the organic matter, leaving rich castings wherever they go, and reproducing at a high rate. In a well-tended compost heap, 1,000 reds or brandlers can increase to 1 million in a year or two.

Manure-type worms will do much better in the Indore heap if larger quantities of manure are included in the mixture. Instead of the 2-inch layer usually recommended, add 4 or 6 inches. If no manure at all is used, the worms will still have a good chance to thrive, although their progress will be slower.

NO-HEAT INDORE COMPOSTING

A variation of the Indore method makes it possible to produce compost quickly with very little heating, using earthworms. Construct the heap so that it is longer and wider than a normal heap, but only 12 to 18 inches high. Shred all materials as finely as possible, and introduce manure-type worms immediately. They will go to work right away, and the heap will never heat up greatly because of the large surface area; the center of the heap will be too close to the cooling effects of the outside air. The major disadvantages are that it takes up more ground surface area, and the shredding of materials takes time and requires fossil energy to operate a gasoline-powered shredder or rotary mower. Also, any weed seeds present will remain viable.

MAINTAINING THE EARTHWORM POPULATION

When removing finished compost for use on garden plots or farm fields, be certain to save a good number of earthworms for future composting operations. There are several ways to do this. The easiest is to remove only half the heap at a time, spreading out the remainder to serve as the base for the new heap. If your manure worm population is not as great as you wish it to be, you can save even more by "scalping" the heap in several steps. Earthworms are repelled by light; if exposed, they will quickly dive down beneath the surface. Remove finished compost from the outer parts of the heap, to a depth where worms are exposed. Wait for about 30 minutes, then take another scalping. Continue in this manner until you have removed as much compost as you want. The earthworms will have been driven into a compact area at the bottom of the heap. At this point, spread out the remaining compost containing the earthworms, and cover it immediately with new manure and green matter. If, as so often is the case, the outer scalp of the heap has not composted fully (since it is the newest material), then set aside this first scalp and put it back after you have finished the operation. It will be the first material to be attacked in the new heap.

Earthworms in Bins and Pits

Red worms and brandling worms cannot survive northern winters without some kind of protection. Further, earthworms are the favorite food of moles, which can easily penetrate an Indore heap and decimate your earthworm population in an amazingly short time. The answer to both dangers is a compost pit dug beneath the frost line and outfitted with a heavy, coarse screen on the bottom to keep out moles but allow the free passage of soil-dwelling earthworms. Manure-type worms will not migrate deep into the soil.

Often, bins and pits are combined. The earth is dug out to a depth of 16 to 24 inches (deeper in areas such as Minnesota and Maine), and boards are used to extend the pit into an aboveground bin.

For the gardener who seeks to build a compost/ earthworm pit for the first time, here are some basic instructions:

1. Stake off an area 3 to 4 feet wide and as long as you wish the pit to be.
2. Excavate the earth from this area to a depth of 16 to 24 inches. (If you live where winter temperatures get to -10°F

[-23°C] or colder, make it 24 inches.) Pile the excavated soil to one side, in as compact a heap as possible, for later addition to the pit.

3. Drive 2 x 4 stakes into the four corners of the pit, if you will be using boards. (Scrap lumber from old buildings is fine.) A layer of ¼-inch, rustproof wire mesh in the bottom of the pit will protect your earthworms from moles.
4. Nail boards all around the pit. Keep one end open so you can work with the material. Use stakes to hold loose boards in this area. Add boards on top of each other, leaving about ¼ inch between each for aeration. Add boards only as the pile of materials requires them for support. The boards aboveground need never be higher than 16 inches above the ground surface; if the pit is 16 inches deep, this will mean a total of 32 inches of vertical board area. (Remember that these earthworms will not work more than 6 to 8 inches below the surface of the heap, no matter how high it is built.)
5. If you elect to use concrete blocks instead of wood, excavate the soil to a depth of one or two blocks, and add no more than two layers of blocks above the ground. At this low height, the blocks can be set in loosely, without mortar. Allow a little space between them for aeration.

Many gardeners find it helpful to divide the pit into two sections, one for new compost and the other for old. As finished compost is removed from one section, the earthworms are transferred into the newer heap on the other side, and a new heap is begun in the just-emptied side. In this way, there is always a ready supply of compost for garden use, and the earthworms are constantly maintained. An ideal setup would comprise two double pits.

Some gardeners outfit their bins with loose-fitting board lids, hinged on one side so that they swing up and open easily. This device keeps out the sun and protects the surface of the heap from excessive heat during the summer, enabling the worms to work nearer to the surface where new material is deposited. It also keeps out predators during the night and conserves moisture during hot and dry periods. When a lid is used, keep a constant check on moisture. Add water as necessary, or—better—open the lid during rainfalls if moisture is needed.

WINTER PROTECTION IN THE NORTH

In the South, where winter temperatures rarely go below 20°F (-7°C), red worms and brandling worms can be maintained easily in outdoor pits with a minimum of protection. A few layers of burlap bags and a mound of straw piles over the beds will offer all the insulation needed, even if they are occasionally covered with snow. In places like Minnesota, Montana, and Vermont, however, where winter temperatures routinely dip to -20°F (-29°C), special protection is a must.

A good winter-protection system is explained fully in the booklet *Let an Earthworm Be Your Garbage Man*. It is essential reading for any northern gardener who decides to construct earthworm pits.

For winter protection, the booklet recommends digging a compost pit 16 inches deep and lining it with two layers of concrete blocks below ground, with a third layer aboveground. Pile the removed soil at the edge of the pit, and cover it thickly with straw. Line the bottom of the pit with garbage, and cover it with 2 to 3 inches of soil, then with burlap bags. Water if needed. The pit can be covered with wire mesh weighted down with bricks or concrete blocks.

In the winter, cans of garbage are added to the pit under the burlap and covered with a layer of soil.

Even in 20-below weather, the earthworms keep working and the composting process continues. By spring, the kitchen refuse added the previous autumn is ready for use in the garden.

Indoor Composting in the Winter

Earthworms can also be used indoors in the winter to produce a small amount of compost from kitchen garbage, dust from a vacuum cleaner bag, even newspapers. Generally, 1 pound of earthworms will eat 1 pound of garbage and produce 1 pound of compost each day, although this varies. There have even been a few commercial earthworm composting units placed on the market, but a simple homemade system is both easy and inexpensive and just as effective. It can be used anywhere, winter or summer, and it can be expanded into as large an operation as you wish.

This method is detailed by Mary Apelhof in her manual *Worms Eat My Garbage*. Her rule of thumb suggests that 1 square foot of surface area is needed to digest each pound of waste material generated per week. It is best to begin on a modest scale. Construct a wooden box 2 feet wide, 2 feet long, and 1 foot deep. Or get a vegetable lug box from your local supermarket, and if it has large spaces between the boards, tack in plastic screening to hold the earthworm bedding. If you construct your own box, provide for drainage and aeration by drilling a half-dozen ⅛-inch holes in the bottom and some more around the sides. A box 2 feet square and 1 foot deep will accommodate 1,000 adult worms (or "breeders," as they are called in the trade), or you can order a pound of pit-run worms (all sizes) that will do as well.

You can prepare a bedding as follows: Wet a third of a bucketful of peat moss thoroughly, and mix it with an equal amount of good garden loam and manure; add some dried grass clippings, hay, or crumbled leaves, if you wish. (Don't use oak or other very acid leaves.) Soak this mixture overnight.

The next day, squeeze out the excess water, and fluff up the material (which we will now call bedding). Line the bottom of the earthworm box with a single layer of pebbles or rocks. Then place 4 inches of the bedding material rather loosely on top of the pebbles, and wait for a day to see if any heating takes place. If initial bacterial action forces the bedding temperature much

Continued ➔

above 100°F (38°C), all the worms will be killed. Any heating that does occur will subside within 48 hours.

When you are satisfied that the bedding will present no serious heating problems, push aside the bedding material, place the worms and the bedding from their shipping container in the center, and cover them loosely with your bedding. Place a burlap bag, several layers of cheesecloth, or wet newspapers over the top of the bedding, and moisten it with a houseplant sprayer or sprinkling can.

Keep the bedding moist but never soggy. If the container begins to drip from the bottom, place some sort of container, such as a plastic dishpan, under the box to catch the drippings. Use the drippings to water your houseplants.

Start out by feeding the earthworms cautiously. If you give them more than they will eat in a 24-hour period, the garbage will sour, creating odors and attracting flies, or it will heat up, killing the worms. Begin with soft foods, such as cooked vegetables, leftover cereal (including the milk), vegetable soup, lettuce, bread scraps, soft leaves of vegetables, even ice cream. A little cornmeal will be appreciated, and coffee grounds can be added at any time. Do not use onions, garlic, or other strongly flavored foods.

Place the food on top of the bedding, and tamp it gently into the bedding. After a week or two, your earthworms should have adjusted to their new home and should be on a regular feeding schedule. You can help them along, and build better compost, if you add a thin layer of partially decayed manure from time to time (being sure that it is past the heating stage but not completely composted).

Every 2 weeks, the bedding in the box should be turned and aerated. Reduce the amount of food after such turnings, since the worms will not come to the surface as readily for a day or two after having been disturbed.

After a month, you can add another 2 inches of bedding material to handle the increased worm population, and after 3 months it will be time to start another box.

When you are ready to divide the box, prepare a second box as you did the first. Then arrange a good-sized table under a 100-watt hanging light so that the light comes to within 2 feet of the table surface. Lay a plastic sheet on the table. Dump the worms and bedding on the plastic, and heap them into a mound that peaks to within a foot of the light bulb. Pick off the pebbles and return them to the first box.

Any worms that have been exposed in turning the box will quickly react to the light by digging toward the center of the mound. This will allow you to scrape much of the bedding into a bucket. Wait another 10 minutes, then scrape away another layer of compost. After several such scrapings, all the worms will have dived into a compact ball at the bottom of the mound, where they can easily be divided and put back into fresh bedding in the two boxes.

Boxes can be stacked in tiers by affixing ½-inch-square wood strips, 14 inches high, into the four corners of each box. The strips on one box will support the box on top of it. The boxes can be watered easily with a small houseplant hose or with a portable insecticide sprayer. The drippings from all but the bottom box will fall into the box beneath it.

An even simpler method of indoor worm composting involves a plastic garbage can with some small modifications. You can make holes for ventilation and drainage with a hot knitting needle, being careful not to breathe the fumes. Air enters through holes in the lid, and water drains from holes 3 inches above the base. The bottom 6 inches should be filled with a coarse material such as gravel, sitting in 3 inches of water. A wooden barrier between this drainage area and the worms' living quarters prevents you from intermingling the materials when renewing the worms. Be sure to leave some holes to allow water to drain. Proceed to introduce worms and garbage as previously described.

Earthworms on the Farm

In the 1940s, U.S. Department of Agriculture scientists Henry Hopp and Clarence Slater found some very poor clay subsoil, containing no earthworms and virtually no organic matter, and by adding lime, fertilizers, and manure, grew a modest stand of barley, bluegrass, and lespedeza on two separate plots. On one, they left the growth untouched, while on the other they cut the top growth to form a mulch, and they added some earthworms to the soil.

By the following June, the plot containing earthworms was covered with a rich stand of all three crops, while the section without worms supported almost nothing but weeds. The total vegetation in the wormed plot was *five times* that of the wormless one. The plot with worms also had far better water-absorbing and water-holding capacity, and twice as many soil aggregates—all the result of earthworm action.

The lesson learned here is one of which every organic farmer should be keenly aware. No soil should be left unprotected over winter. Large-scale mulching and sheet composting will protect earthworm populations, and the earthworms will improve the soil structure and crop-growing capacity.

Compost Structures

Deborah L. Martin and Grace Gershuny

Gardeners have designed a host of imaginative structures for composting. Compost can be made in cages, in block or brick bins, in pits and holes, in revolving drums, in garbage cans, and even in plastic trash bags. A compost structure can be designed to be beautiful, to make compost in the shortest possible time, or to be moved from place to place with the least effort. It can

be designed to make compost with no turning required, or to suit the needs of earthworms. Compost structures, in short, are designed to suit the user's needs and resources.

For most home composters, building a bin that makes use of existing or readily available materials is the most practical course. A composter in California constructed a bin using the aluminum sides of an old aboveground swimming pool. Even using bales of spoiled hay to form a temporary structure is a way to make the most of your resources in creating a composting structure, as well as the compost pile itself.

The choice of compost structure is, then, a personal decision, one that should not be made without some prior research and, perhaps even more important, some experimentation. It is experimentation that leads to new structures.

The first decision to be made is whether a structure is needed at all. The gardener or farmer with plenty of room, ample materials, and sufficient time may need no compost enclosure of any kind. In this case the traditional Indore heap is quite suitable.

If yours is a city or suburban lot, however, you might find that the open heap takes up too much room or offends neighbors and family. If space is limited, an enclosure can produce more compost in a smaller land area. It can be more attractive and keep out animals and flies. If you cannot devote a permanent spot to compost making, you will want to investigate portable structures that can be broken down and moved in minutes. If your garden is located where winter temperatures are severe, a compost pit dug below the frost line can enable you to compost all winter long. If you want to work with earthworms in composting, then you will need to consider some special outdoor structures, and perhaps others for basement composting. Perhaps a commercially built revolving drum suits your needs because age or infirmity prevents you from turning the heap, or simply because the drum produces quick compost and attracts no pests. Perhaps you even prefer to make compost in plastic bags because of its simplicity.

It is certainly true that one compost structure is not best for everyone. It may even be that everyone needs a structure designed especially for him or her. We hope that by describing different structures, we will give you some insight into matching construction with your individual needs. If you are like most gardeners, you will take one of these suggested forms, adapt it to your needs, use it for a year or two, and then make your own adjustments until you have evolved the perfect structure for you.

Pens and Bins

By far the most common compost forms are bins and pens. To simplify, let us call a bin any container with concrete, brick, wood, or masonry sides that is fairly substantial and permanent, and a pen any structure with wire or hardware cloth sides that is a less permanent installation. Not that they're that easy to classify—there are many kinds of structures called bins and pens.

In general, pens have the advantage of allowing for free circulation of air. Their disadvantage is that they also allow for free circulation of flies and four-footed pests. Bins are more stable and protecting structures, but they are often insufficiently ventilated. Neither the bin nor the pen has as great a tendency to go anaerobic as the pit, and both are easier to keep tidy than open composting forms.

A shady, sheltered spot not far from either garden or kitchen is an ideal location for either pen or bin. Often a space between house and garage or garage and shed allows the right amount of room. A three-compartment bin with tight floor and sides and with each compartment measuring a cubic yard in size makes for the neatest and easiest handling of turning. In such a structure there is at all times one batch working and one being used.

An advocate of bottom aeration claims to have made a free compost bin in 1 hour using available cement blocks and some leftover strong iron piping, plus surplus 1 by 2-inch wire mesh. The 4 by 8 by 16-inch cement blocks were laid horizontally with plenty of air between each block. Unlike other composters, this gardener preferred to have his compost bin in a sunny spot, feeling the compost would heat up faster in the sun.

The pipes were thrust across the bin from side to side over the third course of blocks, to provide the pile with a strong bed. On top of the pipes, two lengths of wide wire mesh were laid to hold a bottom layer of coarse garden debris and twigs. This layer and the mesh and pipes held back finer material and allowed for bottom aeration. The gardener never turns his compost but mixes materials together.

LEHIGH-TYPE BINS

The Lehigh-style bin is easy to erect and disassemble. It is adjustable in size, attractive, portable, long-lasting, and it provides for proper ventilation and protection.

Construction is of alternating 2 x 4s with the corners drilled out and held together with ⅝-inch rods. Five 36-inch 2 x 4s to a side will make a bin capable of producing approximately 1 cubic yard of compost at a time.

There have been several variations of the Lehigh bin, some using logs or poles instead of 2 x 4s. However it is designed, the low cost, effectiveness, and portability of this structure has made it one of the most popular in use today.

CAGE-TYPE BINS

Cage-type bins are simple and inexpensive to build, allow good air circulation, are portable, and allow quick turning of the heap because of a removable front panel. The Lehigh bin lacks this last feature.

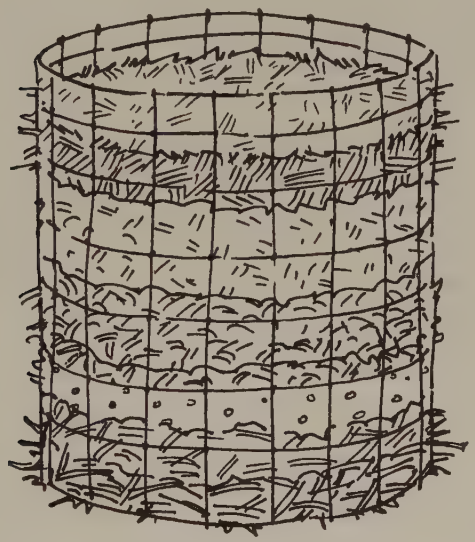
There are many variations of cage-type bins, all of which require relatively little lumber, since wire screening forms most of the panels.

The wire-and-wood bin can be built using scrap 2-inch lumber covered with ½-inch chicken wire mesh. The bin is

Continued

formed by two L-shaped sections held together with screen-door hooks.

To turn the pile, unhook the sides and reassemble the two sections next to the now free-standing pile. Layers can be easily peeled off with a pitchfork and tossed into the empty cage. Keep a hose handy during turning, to add moisture as needed. A properly built and maintained pile in this well-aerated bin can produce 18 to 24 cubic feet of finished compost in 14 days.



A cylinder of wire fencing can be used as a simple compost bin.

THE NEW ZEALAND BIN

Perhaps the classic among compost bins is the wooden New Zealand box that was originally designed by the Auckland Humic Club to admit as much air as possible from all sides. It can be used to make several batches of compost in different stages of decomposition, ensuring a continuous supply, and it can be a very attractive structure.

There are several variations of this box, but the simplest one is a wooden structure 4 feet square and 3 feet high or higher with neither top nor bottom. The frame is held together by 2 x 4s. The wooden sides consist of pieces of wood 6 inches wide by 1 inch thick. A ½-inch air space is allowed between every two boards so that air may penetrate into the heap from all sides. The boarding in front slides down between two posts so that boards can be removed one by one when complete access to the contents is needed for turning or loading. The open side may also be built up gradually as the pen is filled. Cover the top of the pen with hardware cloth, rolled canvas, burlap, or screen.

If you are using a single bin like the New Zealand box, be sure to allow for a working space in front of the box equal to two or three times the floor area of the box. This much space is needed for turning the pile. You pile up the material outside the bin and then replace it within the bin, mixing so the outside material is placed toward the inside of the new pile.

One variation on the New Zealand box holds four separate bins for compost in different stages. The dividers between the compartments are removable to permit quick and easy shifting of compost from one bin to another.

BLOCK AND BRICK BINS

Block and brick bins are permanent if mortared, but cement block bins can be constructed without mortar and can then be moved at will.

The block or brick bin is easily constructed. Usually, blocks are laid to permit plenty of open spaces for air circulation. But they can also be closely stacked, set into the ground, and mortared together, or formed into a cylindrical shape with an access gate at the bottom.

Gardeners who insist on a well-groomed compost area may prefer to have a large, rectangular, brick or block, chimneylike structure with several compartments. Use wooden hinged lids to cover the structure. In a three-bin unit, the first two bins are used in turning while the third stores finished compost. The bottom of the bin, if made of concrete, should slant one way so drainage may be caught in a gutter leading to storage cans. A combination of bricks and boards may be used, with boards set into slots along the front opening. Boards can be removed for access to the compost.

Rough stones laid with or without mortar in an open-fronted, three-fourths cylinder shape (like a larger edition of a state park barbecue pit) make an attractive rustic bin.

THE MOVABLE SLAT BIN

Another type of portable bin can be constructed of wooden slats. This bin needs no hardware for support—no hooks, nails, or screws.

To make it, cut 10-foot-long 1 by 10-inch boards into 60-inch lengths. Slot each board 4 inches in from the end, 4⅝ inches across its width, so the boards can be nested. The finished bin is 50¼ inches square and 18¼ inches high inside—perfect for even the smallest lot.

WINTER BINS

Winter composting does not have to be confined to a pit. An existing compost bin, well insulated with bales of straw or hay and covered for protection from the elements, can continue the composting process during cold temperatures, although at a slower rate than during warmer weather. Structures similar to cold frames can also be used for cold-weather composting, using south-slanting glass lids to catch the rays of the sun and protect the heaps from rain, snow, and drying winds. Manure added to such bins helps to keep temperatures high enough for microbial activity.

PENS

The very simplest pen can hardly be called a structure at all. It is, however, quick to make, neat to use, and it costs little. You just buy a length of woven-wire fencing and, at the site of the compost heap, bring both ends of the fencing together to form a cylinder large enough to surround the heap. Fasten the ends of the cylinder together with three or four small chain snaps that you can find in a hardware store. Remove the cylinder to a free-standing position, and start building the heap inside the cylinder. When it is half full, drive a stake into the pile. The stake should be as long as the total desired height. You can disassemble the cylinder for easy turning by removing the snaps. You set the cylinder up again and once more turn into it, shifting the ingredients from outside layers to inside, reversing the position of the material. The stake not only helps maintain the shape of the pile, but also aids in directing water into the heap.

A partly anaerobic version of the woven-wire cylinder is lined with a length of roll roofing that is wired to the fencing. The roofing is durable and prevents small bits and pieces from falling out of the bin.

After the bin is full, it is covered with a layer of 6-mil black plastic and left to decompose. Turning is not necessary with this system, although composting will take longer and high temperatures will not last long enough to kill weed seeds.

A refinement of the all-wire pen is the wire-and-tomato-stake pen in which ½-inch mesh poultry netting is placed inside an enclosure made by driving 4-foot tomato stakes 1 foot apart in a 10 by 5-foot rectangle and looping baling wire around the top of each stake to weave all stakes together. Small pieces of wire hold the poultry netting to the stakes. Use additional lengths of wire to reinforce the top. These pass from side to side and keep the stakes from spreading apart under the pressure of the compost. These wires are removed when the compost is turned. This type of structure is movable and reusable. However, neither pen will resist large dogs or tunneling rats.

Recycled hardwood pallets make excellent compost bins. They can be quickly assembled by driving in fence posts at the corners. A chicken wire or hardware cloth liner serves as a rodent barrier.

Other materials that can be used to construct pens include snow fences, lattice fencing, steel posts and chicken wire, furring strips, prefabricated picket fence sections, woven-reed or rattan fence sections, heavy window screens, storm windows with hardware cloth replacing glass, and louvered house blinds.

Pens and bins can be made to fit the contours of uneven land. One such structure consists of three bins in stair-step order going up a hill, partially cut into the bank. Composting starts in the highest bin. Turning is done by dropping the partially decomposed compost down a step, inverting it in the process. The third box receives the product of the second turning. From it the finished compost is used.

Garbage Can Composting

Use this system to compost kitchen scraps during the winter, or use it year-round to compost all the waste produced by a small yard and garden.

Directions

Use a hammer and a large nail to punch holes in the bottom, sides, and lid of a garbage can. Place the can on a large tray to catch draining liquid if desired.

To start the composting, place a 3-inch layer of finished compost or soil in the bottom of the can. Add finely chopped kitchen scraps followed by an equal amount of shredded newspaper, grass clippings, and/or shredded leaves. Add more material as available until the can is full, then layer new materials into another can and allow the first to finish composting—about 3 to 4 months.

Tips to Make Your Composter Work Its Best

- Protect the composter from freezing temperatures—put it in a garage or cellar.
- Start with soil or finished compost, and add a little more on top of each addition.
- Chop, shred, or even blend all additions as finely as possible.
- Add kitchen scraps before they start to smell.
- Mix the composting material after each addition and every few days. If you don't, it may produce unpleasant odors. Stir with a stick, roll the can back and forth on its side a few times, or use a "compost turning tool."
- Add water sparingly and only if your materials are very dry.

Pits

Pits for composting are dug into the ground and may be partially—or wholly—underground. The chief advantage of the pit form is its stable, secure, insulated structure. A masonry-lined, covered or coverable pit is secure from dogs, rats, clever raccoons, most flies, and wind and rain storms. Pit composting is ideal for severe winter weather because subsurface ground warmth and the heat-retaining properties of concrete enable bacteria to go on working longer. Some northern composters have a pen for summer and a pit for winter.

Continued ➔

However, proper composting does not take place in a pit when compost becomes soggy and anaerobic. Provide some drainage to lessen the possibility of anaerobic conditions. Improper aeration and the greater possibility of anaerobic conditions remain, however, the two greatest drawbacks to pit composting. If you have the time to turn frequently and don't mind the extra strain on your back muscles in raising forkfuls of material from a lower-than-normal position, you may find ways to avoid these problems. Some pits are large and wide enough so that a person can stand at pit-bottom level while turning.

A compost pit can be built of concrete or masonry. Other materials such as tile and pressure-treated wood are also occasionally used as pit liners. A pit must have subsurface walls to prevent drainage water from entering the compost from the soil or the ground surface. Such drainage water would leach nutrients from the compost.

Some experts suggest that a concrete pit bottom is a necessity to prevent leaching, while others prefer a natural dirt bottom that serves as a source for worms and microorganisms. Some concrete-bottom proponents advise using a bottom layer of earth over the concrete, and others say the masonry walls absorb bacteria from manure and help to inoculate new compost materials as they are added.

A useful combination of a composting method and a compost-containing structure is the earthworm pit. Earthworms help aerate and mix the materials, thus eliminating some of the drawbacks of anaerobic pits. The pit, in turn, helps protect the worms from cold weather.

One gardener combined the earthworm pit with the movable-box method. He dug a rectangular hole about 18 inches deep in a flower bed. At earth level over the pit he placed a rectangular, bottomless and topless, wooden box of slightly larger dimensions than the hole. The hole was filled in layer style with kitchen garbage, manure, and green matter. When the frame was filled, too, the composter placed a board over the top and watered well. In 3 weeks, when the heat of the pile had decreased, earthworms were added.

Another successful pit is the one used by a New York State gardener. It is 4 feet wide, 4 feet deep, and 6 feet long with concrete sides and bottom. The bottom has an inset drainage grid similar to those used in basements and showers. Walls are 8 inches thick and project 18 inches above the ground. The top is made of tongue-and-groove boards nailed to 2 x 4s. A hinged lid provides access. Earthworms do the work of aeration in this pit, and garbage and leaves are the chief materials used.

An inexpensive pit may be made by digging a section of a masonry flue liner into the soil, leaving about 3 inches of it projecting above ground level. A thin layer of concrete poured into the pipe serves as the floor. A small flue liner 2 feet square may not require bottom drainage if earthworms are used, but check frequently for anaerobic conditions.

Terra cotta tiles are also useful for lining pits. These can be used for the sides in combination with a hardware cloth bottom to prevent rats from getting in from underneath. Build twin pits to make the turning job easier.

Drums

Where space limitations or offending odors are concerns, composting in drums provides an alternative to bins, pens, and pits. A metal or plastic barrel, with drainage holes in the bottom, can be raised off the ground with bricks or blocks to permit aeration. Layering kitchen wastes with absorbent materials like shredded paper or straw can help control odors; without turning or rolling, this method produces compost slowly but does provide a place for waste disposal.

Structures for City Composting

Is there any perfect form of compost making for a city gardener? Helga and Bill Olkowski, in *The City People's Book of Raising Food*, suggest a well-built two- or three-bin brick structure set between two houses. Runoff is caught in sawdust at the bottom of the bin, and the sawdust is turned with the pile. As garbage accumulates on its way to the bin, the Olkowskis layer it with sawdust in 5-gallon cans with tight-fitting lids. Sawdust is added every time fresh garbage is put into the can. The sawdust controls odor and putrefaction. In loading the bins, however, you should remember to compensate for the high-carbon content of the sawdust by using more high-nitrogen wastes.

Other city gardeners, who lack even a small space between houses, have composted successfully in garbage pails and metal drums. The danger with these methods is that they may quite easily become anaerobic and ferment. If you think it is hard enough dealing with garbage in a city, you should try to take care of a huge drum of fermented garbage. If, however, you really need to try these methods, provide aeration and drainage with holes in the bottom and sides of the drum or can. Set it in the basement or another protected area, preferably outdoors or on a flat roof. Elevate the can or drum on bricks or concrete blocks, and set a pan, larger in diameter than the drum, underneath it to catch drainage. Layer garbage with high-carbon-content materials just as you would in a regular pile. Composting is not really an indoor activity, and turning is especially hard to do in a limited space.

Trash cans can be used more readily for outdoor composting by cutting out the bottoms and setting them firmly into the ground to prevent tipping. California composter Helene Cole suggests using several of them and simply waiting 6 to 12 months for the finished product. Chopping your wastes first will speed up the process. A few air holes drilled in the lid will keep the earthworms that do most of the work in this system happy.

Another much more sensible indoor method is the earthworm box. Worms are easily raised in basements where fairly stable temperature conditions can be maintained. Worms

do the turning in worm boxes, and the results of their labors are rich worm castings for compost and perhaps a little extra income for you during fishing season. If you live in an apartment, discuss composting or worm-raising plans with your landlord before launching your career.

Commercial Composters

A number of very good commercially produced composting units are now on the market. Generally built on the revolving-drum or upright-cylinder principle, these structures are designed to produce high-quality compost quickly and with a minimal effort on the part of the user. Recent articles in the *Wall Street Journal* have noted that commercial composting units represent overkill for most people, since similar composting conditions can be created without a commercial bin. Constraints on space, time, and physical ability, however, will continue to make such products appealing to many home composters.

The Green Cone, produced by Eco Atlantic, is a smaller, cone-shaped composter designed to decompose kitchen wastes. This closed, sun-heated composter features a below-ground basket for contact with the soil and a double-walled plastic cone to collect heat from the sun. Small and innocuous looking, the Green Cone can be located close to the kitchen for easy waste disposal, but according to the manufacturer, it is not meant to handle yard wastes and produces very little compost.

In general, these composters are designed for small-lot gardeners who want to make compost quickly and without offending the neighbors or attracting animals. Although such conditions can be met with a homemade bin, commercial composters offer valid alternatives to the gardener who is willing to pay $100 or more for an efficient, attractive composting unit.

The Joy of Composting

Joan Benjamin and Deborah L. Martin

Recycling your food and plant "wastes" by making compost for your garden is the single most important thing you can do to grow bountiful yields of great-tasting food and beautiful flowers. And it's easy, fun, and free! Compost provides a perfectly balanced fertilizer to feed your crops, improve the soil's structure, and protect your plants against drought, diseases, and insect pests.

This section gives you recipes for the full range of composting techniques. You can use fancy equipment or just pile ingredients directly on the ground. You can use an ultra-easy technique like sheet composting—spreading layers of grass clippings or leaves over the soil where microorganisms and earthworms will break it down. Or you can let a few bags of fall leaves decay behind the garage until they turn into dark, crumbly compost.

Since compost ingredients decompose, or "cook down," fastest when they're combined in just the right proportions, many of these recipes are formulated to help you produce rich, sweet-smelling, finished compost in as little as two weeks! Others take a more relaxed, "let-it-happen" approach that emphasizes ease over speed.

Whether your compost is made quickly or slowly, with carefully measured ingredients or whatever you have on hand, remember that turning organic matter into compost requires water and air.

Things to Keep Out of Your Heap

One of the most satisfying things about making compost is being able to recycle kitchen scraps and garden wastes—stuff you'd probably *throw away* otherwise—into something that's great for your garden. But that doesn't mean that every bit of household waste belongs in your compost pile. Balance the ingredients you add to your heap—you can have too much of a good thing, like grass clippings. And avoid materials that might carry diseases, materials that attract pests, and materials that slow the composting process or make it more difficult.

What to Avoid	Why
Cat droppings	May carry diseases and parasitic organisms; especially dangerous for pregnant women and young children
Coal or charcoal ashes	Contain amounts of sulfur and iron that are toxic to plants
Diseased plants	Require high-temperature (hot) composting to ensure that disease organisms are killed; otherwise may reinfect your garden when compost is spread
Dog droppings	May carry parasitic organisms; unpleasant to handle
Fish, meat, or cheese scraps	Break down slowly; attractive to foraging animals
Grease or oil	Break down slowly; inhibit composting of other materials
Weed seeds/rhizomes	Require hot composting to ensure that seeds are killed; otherwise may sprout wherever compost is applied; weeds like Canada thistle and quackgrass grow back from very small pieces of rhizome and are very hard to control

Continued ➔

The amount of moisture in your compost pile is almost as important as the ingredients you use. The microorganisms that do all the work in your pile need moisture to survive. But too much water can cause the compost ingredients to mat together, preventing air—another essential ingredient—from circulating.

Air is necessary because the desirable microorganisms in compost need oxygen in order to do their thing. Without air, other microorganisms will prevail (these will do the decomposition work, too, but with a lot more smell and slime). Use coarse ingredients like straw or cornstalks to keep air flowing all the time, and turn or stir things occasionally to give all the ingredients a breath of fresh air.

Combine these basic composting techniques with any of the following recipes and you'll be spreading nature's best all-natural fertilizer on your crops in no time!

Dry-Weather Compost

Your compost pile can't cook when it's dry and dusty. And it can't become the rich, crumbly soil food you seek when it's wet and waterlogged. The methods you use to keep the moisture in your pile at just the right level—it should be as damp as a wrung-out sponge—will depend on where you live. In a dry climate or during a long period of dry weather, composting in a pit in the ground or in a solid-sided bin will help keep the pile moist. Even frequent turning—with all its benefits—can cause your compost pile to dry out too quickly. Choose from among these moisture-managing methods to keep your microorganisms happy and your compost cooking.

Ingredients and Supplies

Pit or solid-sided bin

Compost ingredients

Pole or stake, approximately 5 feet long

Directions

1. Place ingredients in the pit or bin. Making your compost in a bin with solid sides or in a pit in the ground reduces the amount of moisture that will be lost to evaporation.
2. Spray the pile lightly with water after each addition. It's easier to start your pile with moist ingredients than to get the whole thing wet enough after it's built.

   Note: Try one—or both—of these techniques to make the most of rainfall to keep your heap moist:

   - Drive the pole or stake into the center of your compost heap to help direct rainfall into the pile.
   - Dig a shallow "well" in the top of your compost pile to catch any rain that does fall.

Wet-Weather Compost

If your weather is wet, cover your compost pile to prevent it from becoming too soggy. A soggy heap will still turn to compost, but the process is a lot smellier and messier. When steady rain threatens to make your compost pile sodden and yucky, top your heap with water-shedding ingredients or a protective tarp.

Ingredients and Supplies

Compost ingredients

Straw, hay, or plastic or canvas tarp

Directions

1. Place ingredients in a pile.
2. Cover the compost pile with a layer of rain-shedding straw or hay (later, it becomes an ingredient in your compost!) or throw a tarp over the pile.
3. Check your heap for moisture periodically. If your pile becomes too wet in spite of your efforts, turn your compost frequently to let in more air and to help return moisture to an appropriate level.

The World's Easiest Compost

"The magical thing about composting is that it happens no matter how much attention you give or don't give to your pile," explains Maria Rodale, author of *Maria Rodale's Organic Garden* and daughter of the late Robert Rodale, long-time editor of *Organic Gardening* magazine. Maria, who gardens at her home in Emmaus, Pennsylvania, just a block away from *Organic Gardening*'s editorial offices, says she thinks of her compost pile as her "home waste disposal system."

Ingredients and Supplies

All yard wastes, including weeds, spent garden plants, leaves, and grass clippings

Kitchen scraps, including peelings, seeds, rinds, cores, and cobs, but excluding fats, meats, and dairy products

Any corner in the yard, with or without a bin

A little patience

Directions

1. "Just throw everything on the pile," Maria advises. She does recommend keeping meat and dairy products and greasy or fatty foods out of the compost pile, since these break down very slowly and tend to attract pests and pets (like Maria's dog) to the pile.
2. Sit back and wait. Don't bother with measuring, chopping, shredding, turning, or other kinds of compost fussing! In time (within a month or two), dark, rich, crumbly compost will begin to form at the bottom of the pile as the ingredients decompose.

CONTAINING COMPOST-BOUND KITCHEN WASTES

Unless walking to your compost pile is your daily exercise program, you'll want a way to store up a few days' worth of kitchen scraps for less-frequent trips to the heap. In her kitchen, Maria Rodale uses a 5-gallon, lidded bucket to hold scraps for trips to the compost pile every other day or so. "A tight-fitting lid is crucial for controlling odors and fruit flies," she points out. She adds a second container when cold weather arrives: "In the winter, we also keep a medium-size garbage can with a lid outside our back door for kitchen scraps. We take this down to the pile every few weeks or so—if it's cold, there's no smell. That way, we have to take it to the main pile only when we're feeling like a walk and when the weather is cooperating!"

Simple Shovel Compost

You need nothing more than a shovel and a spot to sink it in to put this quick and easy composting technique to work in your garden, says garden writer and photographer Deb Meager of Nevada City, California. Deb's method works well when you have only small amounts of kitchen and garden waste to compost.

Ingredients and Supplies

1 bucket kitchen scraps and lawn and garden wastes

Shovel

Directions

1. Choose a spot in your garden where you want to improve the soil.
2. Dig a small hole, removing 2 to 5 shovelfuls of soil. The deeper you bury kitchen scraps for composting, the less likely it is that they'll be unearthed by foraging wild animals or pets.
3. Dump the kitchen scraps and yard wastes into the hole and chop them up a bit with the shovel.
4. Return the soil to the hole, covering the scraps and chopping a bit more with the shovel to mix some soil down into the buried scraps. The organic wastes you've put into the hole will gradually become soil-enriching compost—with no pile, no watering, and no turning!
5. Repeat this process as often as possible.

Note: In your garden, it's easy to dig a row of these holes, or a shallow trench, in the path space next to a crop row. Next year, plant your flowers or vegetables in the "compost row," and "plant" compostables where your crops once grew.

Variation: Try "Simple Shovel Compost" on your lawn, too. Use your shovel to cut loose a flap of sod, then fold it back and dig a hole. Pour in the kitchen scraps, chop them a little with the shovel, and replace the soil. Then firmly press the sod back into place. Water the spot well. Don't worry if there's a lump left behind when you're through—it will quickly disappear because the scraps shrink as they compost.

Super-Simple Straw Bale Composting

In this method, the straw bales you use to make your compost bin will become ingredients in your next batch of compost. It's recommended by Maine's master organic grower Eliot Coleman in his highly-acclaimed book, *The New Organic Grower*. Eliot says he gets consistently high-quality compost from his straw-bale bins. "I began using this straw bale method after reading about it in a book called *Intensive Gardening*, by Rachel Dalziel O'Brien," he says. "I consider it to be one of the best books ever written on market gardening."

Ingredients and Supplies

8 (or more) straw bales

Loose straw

Assorted green plant wastes

Soil

Directions

1. Stack straw bales like bricks, 2 or 3 bales high, to build a 3-sided enclosure of whatever size you want. You'll need about 8 bales to make a bin that's 2 bales high. The bales make a perfect bin because they keep all the ingredients moist and warm while still letting in plenty of air.
2. Fill the bale enclosure by alternating 2- to 3-inch layers of loose straw with 1- to 6-inch layers of green plant wastes. Make thinner layers of moist materials like grass clippings that might mat together, and thicker layers of loose, open ingredients such as tomato plants or pea vines. Sprinkle a layer of soil over each green layer.
3. Let compost happen. Eliot says he prefers to let his compost sit for about 1½ years before he uses it. The straw bales will hold together for at least 2 years. Then you can use them as ingredients in your next heap, with fresh, new bales for the enclosure.

BREATHE NEW LIFE INTO YOUR COMPOST PILE

You can get compost more quickly if you give your pile some gas—specifically that clear, breathable gas called oxygen. Air in your compost pile makes the ingredients break down faster, so you have finished compost for your garden sooner.

Adding air, by turning or using other ventilation techniques, helps when too many wet ingredients mat down and keep air from circulating through the pile. Too much air, however, can dry out a pile, so you need to be sure to add moisture even when you're turning a pile that's properly moist.

If turning your compost by moving the entire pile to a new spot seems like too much work, don't despair.

Basic Backyard Compost

Making your own compost is as easy as pie with this proven recipe from Cyane Gresham, compost specialist at the Rodale Institute Experimental Farm in Berks County, Pennsylvania. Cyane's recipe is based on her 10 years of research to identify the very best composting methods for home gardeners.

Ingredients and Supplies

1 part fresh green materials

1 part dried brown materials

1 part black materials

Directions

1. Build your pile at least 4 feet square and 4 feet high, if possible. When you make your pile this large, temperatures can quickly build up in the center to over 100°F. This rapid warm-up allows heat-loving microorganisms to rapidly turn the ingredients into finished compost.
2. Mix together the ingredients as you go and add enough water to make all the ingredients thoroughly moistened but not soggy. "Don't worry about the exact proportions," Cyane explains. "The composting process is very forgiving, and all organic matter will eventually decompose." The closer you can get to equal proportions of greens, browns, and blacks, the faster you'll get finished compost. But even if you made a pile entirely of greens, or entirely of browns, it would eventually turn into good compost. It will just probably take longer than when you mix the 3 kinds of materials together.
3. You can turn or stir the pile with a garden fork every few weeks if you want to really speed up the process, Cyane says, or you can just let it sit. Either way, make sure that the pile stays moist. If you just let it sit, "it should break down very nicely in a couple of months as long as the weather is warm." (Turning a compost pile "fluffs it up" and introduces more oxygen so that the microorganisms can multiply faster.)

Yield: 2 cubic feet of finished compost

COMPOST CHOICES

The "greens" you choose for your compost pile can include any fresh moist organic matter, like grass clippings, weeds, and kitchen scraps. Greens provide necessary nitrogen and moisture to the pile. The "browns" are older, drier, tougher materials like straw, cornstalks, sawdust, fall leaves, and dead plants. You need the browns to keep the pile loose so that air can circulate. The "blacks" can be either garden soil, manure, or chunky incompletely decomposed material from a previous compost pile. "The blacks are the great equalizer in the pile," Cyane Gresham explains. "They absorb and hold moisture, and they also introduce the microorganisms that break down the browns and greens."

Loose-Leaf Compost

If rich, soil-building compost fell from the sky every fall, there's no question that you'd gather up some for your garden, right? So why would you even think of disposing of the wealth of free, nutrient-rich leaves that fall from your trees each year?

"Homeowners should never throw away their fall leaves," says *Organic Gardening* magazine's research editor Cheryl Long. "Tree roots draw minerals from deep in the soil in order to grow leaves and branches. If you throw away leaves instead of recycling them, you are literally making your soil poorer and poorer every year." Fortunately leaves are very easy to compost, very good for your gardens, and often available in large quantities.

Ingredients and Supplies

Fall leaves

Lawn mower, string trimmer, or chipper/shredder

Directions

1. Shred your leaves. The benefits of shredding the leaves are threefold, Cheryl explains: "Shredding makes the volume of leaves much smaller and easier to handle. The shredded leaves are less prone to blowing away. And they decompose faster." Don't despair if you don't have a shredder—you can chop up leaves with your lawn mower. Or put the leaves in a trash can and then use a string trimmer to chop them up. Wear goggles and a dust mask with any of these methods to protect yourself from flying dust and debris.
2. Add the shredded leaves to your compost pile and mix with your other ingredients.

Variation: If you don't have time to shred your leaves, you can still compost them over the winter and add them to your gardens next spring. "All you have to do is pile 'em up, wet 'em down, and let 'em sit," Cheryl says. "If I don't have time to shred my leaves, I just rake them into a pile and put a ring of welded wire fencing around it to keep the leaves from blowing around. Putting them in big plastic trash bags works fine, too."

You can even rescue bags of leaves destined for curbside collection and turn them into compost, Cheryl says. Just poke some holes in the bags to let air and water in and out, then wet the leaves thoroughly. Open the tops of the bags so rain can get in, and let the leaves sit for a few months or more. Like turning a compost pile, occasionally shaking the bags will help add some air to the mix.

"If I have time, I also mix a few shovelfuls of good garden soil into each pile or bag," Cheryl says, ' "The soil inoculates the leaves with plenty of the microorganisms and earthworms that help turn them into compost."

When your leaves reach that dark, crumbly state that's called leaf mold, you can use it as a weed-blocking, moisture-conserving mulch. Or mix the leaf mold into your garden beds

to improve the soil. Either way, you'll be feeding the soil, the earthworms, and your crops with those treasures from the trees. Leaf mold also makes the perfect ingredient to add to grass clippings over the summer months. "Large amounts of fresh grass clippings alone tend to mat together and don't compost well," Cheryl explains, "If you mix in some leaf mold with the clippings, the pile will cook much better."

Halloween Leaf Compost

Transform all those brilliant red and yellow fall leaves into black gold for your garden with this recipe from veteran gardener George Weigel, garden columnist for the *Patriot-News* in Harrisburg, Pennsylvania. George's recipe includes grass clippings, which are high in nitrogen, an ingredient that speeds up the composting of the leaves.

Ingredients and Supplies

Compost bin

4 buckets fall leaves (preferably shredded)

2 buckets grass clippings, spent garden plants, or kitchen scraps

1 bucket garden soil

Sprinkling of lime or wood ashes (if available)

Directions

1. Dump the ingredients together and mix.
2. Moisten everything well as you mix.
3. Repeat with more layers until you run out of materials, bin space, or energy.

Yield: 3 buckets of finished compost

Note: Mix the finished compost into your beds. George recommends mixing in the compost about 2 weeks before planting.

Just Add Air

The tiny critters that turn your kitchen scraps and yard wastes into compost do their best work when they get plenty of oxygen. Thus, a well-aerated compost pile breaks down much more quickly than one in which the microorganisms are practically gasping for breath. The good news is, you don't have to turn your compost to keep its population of busy microorganisms breathing freely. Instead, do a little advance planning and build in a ventilation system when you build your pile.

Ingredients and Supplies

Several cornstalks, saplings, or sunflower stalks, each 4–5 feet long

String or twine

Directions

1. Use string or twine to tie the stalks or saplings into a bundle that is 5 to 6 inches in diameter.
2. Build your compost pile around the bundled stalks, so that the bundle becomes a "chimney" sticking up from the middle of the pile. Air will travel through the hollow stalks and in the spaces between them into the center of your pile.

Variation: Lay 4- to 5-foot-long perforated plastic pipes horizontally at different layers as you build your compost pile. These will also let air into the middle of the pile. As lower layers decompose, pull out the pipes at the bottom of the pile and lay them across the top before adding more ingredients.

Chicken and Chips Compost

It's a perfect compost combo—rich chicken manure mixed with wood chips or sawdust. Noted garden experts and authors Doc and Katy Abraham of Naples, New York, explain that both chicken manure and wood chips can burn plants when used alone, but when you mix the two and compost them together, you can produce a safe and effective soil amendment.

Ingredients and Supplies

1 part chicken manure

1 part wood chips or sawdust

Directions

1. Mix the 2 ingredients together thoroughly and water well.
2. Add them to your existing compost pile, or build a separate pile with them, if you prefer.
3. Let them compost for 6 months or even a year to give the wood wastes plenty of time to break down.
4. Turn the pile occasionally with a garden fork, and add water as needed to keep the material moist. (Or, if the weather is very wet, cover the pile with plastic to keep it from getting too soggy.)

Yield: 1 part of finished compost

Note: It's easy for gardeners to get wood chips or sawdust from tree-trimming companies or local sawmills, say Doc and Katy. "But when wood chips are stored in big piles, they can develop what's called sour mulch syndrome, which produces acetic acid, alcohols, and foul-smelling hydrogen sulfide," Doc explains. These compounds in sour wood mulch can damage plants. But you can prevent or cure sour mulch by combining the chips with chicken manure, which is extremely rich in nitrogen and other nutrients (so rich, in fact, that when used full strength it can damage tender seedlings). That chicken manure's nitrogen is exactly what's needed to balance the low nitrogen content of the wood chips. When the manure is mixed together with chips or sawdust and composted, the wood decomposes without producing any sour by-products, and the result is an excellent compost.

Rabbit-Powered Compost Pile

They're cute, they're cuddly, they're composting machines! More than just adorable pals, rabbits are the perfect backyard livestock, says organic gardener K. B. Laugheed of Fortville, Indiana. K. B.'s recipe for top-quality compost starts with high-nitrogen, nonsmelly rabbit manure—it keeps her compost heap hopping! K. B. says her bunnies are every bit as easy-care as the compost pile beneath their cage, and they help her process some compost ingredients, too: "The rabbits never need to be bathed, groomed, or taken for a walk," she says. "And they happily munch on your old lettuce, bruised apples, celery tips, and carrot scrapings."

Ingredients and Supplies

1 or 2 rabbits

Raised hutch with wire bottom

Kitchen scraps and yard wastes

Directions

1. Lay 8 to 10 inches of kitchen scraps and yard wastes under the rabbits' hutch.
2. Let the rabbits do their thing. As more kitchen scraps and yard wastes become available, add them to the pile.
3. Add water, as needed, to keep the pile moist. In dry climates, dig a hole under the hutch to hold the pile so that it doesn't dry out quickly.
4. About once a year, rake out the finished compost and start again with a fresh base of yard wastes.

Composting by the Numbers

Knowing that the ideal ratio of carbon to nitrogen in your compost pile is about 30:1 isn't too helpful, unless you also know how to reach that ratio. But if you really want to crank up your compost pile and get it rotting hot and fast, that 30:1 ratio is a good goal to aim for. It provides a balanced "diet" that lets the microorganisms in your pile thrive.

Eric Evans, director of the Woods End Research Laboratory in Mt. Vernon, Maine, offers a few tips to help homeowners make the most of the carbon-to-nitrogen ratio. "The biggest factor in the carbon-to-nitrogen ratio is how much water is present," Eric says. "Dry materials are generally in the range of 40 to 50 percent carbon, and sloppy, wet materials are generally 10 to 20 percent carbon." So the more dry ingredients you have, the quicker you'll reach the 30:1 ratio.

Ingredients and Supplies

Pencil and paper or a calculator

Directions

1. Calculate your pile's total carbon value by multiplying the percentage of carbon of each ingredient by the number of parts (by weight) of that ingredient and then adding up the carbon totals for all the ingredients. (See "Math for Composters" below to see how to do the calculations.)
2. Do the same for the nitrogen.
3. Divide the carbon value by the nitrogen value to get the carbon-to-nitrogen ratio. If it's between 25:1 and 35:1, your pile should compost beautifully. If the ratio is higher or lower than that, adjust the proportions of ingredients to bring it into the range of 25 to 35 parts carbon for each 1 part nitrogen.

MATH FOR COMPOSTERS

Here's an example of how the carbon-to-nitrogen (C:N) ratio works when you apply the formula to real-life amounts of real-life compost ingredients:

Starting with 50 pounds of non legume hay (about 1 bale), 10 pounds of kitchen scraps, and 2 pounds of coffee grounds:

Not Your Backyard Compost

Homemade compost differs from commercial compost products in several key ways:

- Commercial compost piles are larger (commonly 8 feet tall and 16 feet wide, versus the 4 x 4-foot backyard compost pile). The size of commercial compost piles makes them difficult to mix and maintain, resulting in inconsistent quality.
- Many commercial composts are based around a single material, such as manure. (Homemade compost usually contains a mix of garden wastes, grass clippings, kitchen scraps, and leaves.) A single ingredient typically doesn't compost as well as a mix of materials. Commercial-compost makers don't always add other materials because of the extra time and cost involved.

Experts predict that we'll see more dry or dehydrated manure products marketed as compost. Many of these products claim to be fully composted, but aren't. And if you apply them at the same rate as other composts, they could burn plants because of their higher nitrogen content. If the label tells you that the product contains dehydrated manure, use it at a lower rate than mature compost.

50 lbs. hay x 40% C = 20 lbs. C

10 lbs. kitchen scraps x 10% C = 1 lb. C

2 lbs. coffee grounds x 25% C = 0.5 lb. C

20 + 1 + 0.5 = 21.5 total carbon value

50 lbs. hay x 1% N = 0.5 lb. N

10 lbs. kitchen scraps x 1 % N = 0.1 lb. N

2 lbs. coffee grounds x 1 % N = 0.02 lb. N

0.5 + 0.1 + 0.02 = 0.62 total nitrogen value

21.5 : 0.62 = 34.7 parts carbon to 1 part nitrogen

Note: "The more dissimilar the materials are in terms of moisture, the bigger the error if you measure by volume and not weight," Eric adds. Even if you're unlikely to weigh every ingredient you add to your heap, this formula will give you an idea how to adjust the proportions of materials in your pile to get finished compost more quickly.

Fast, Easy, Pest-Proof Compost in a Drum

Tumbler or drum composters make composting a breeze. They provide easy turning, super-fast compost, and no pest problems. Instead of a bin that sits on the ground, drum composters feature a large, barrel-shaped container mounted in a frame that lets you easily aerate the compost by spinning the drum. Since the tumbler is completely enclosed to keep the compost in when it spins, it's perfect for keeping foraging animals out. Drum composting works best when you shred bulky materials before you put them in the tumbler. Mike Peck, president of the PBM Group, Inc., marketers of the ComposTumbler, one of the original drum composters, offers six different recipes that work well in a drum composter.

Ingredients and Supplies

Recipe # 1

12 parts fresh grass clippings and/or kitchen scraps

3 parts sawdust

Recipe #2

9 parts fresh grass clippings

3 parts kitchen scraps

3 parts straw

Recipe #3

9 parts fall leaves, shredded

3 parts dehydrated cow manure

3 parts fresh weeds

Recipe #4

9 parts fresh grass clippings

3 parts kitchen scraps

3 parts newspaper, wet and shredded

Recipe #5

7 parts fresh or dehydrated horse manure

3 parts fall leaves, shredded

3 parts sawdust

Recipe #6

10 bushels fall leaves, shredded

2½ pounds blood meal or alfalfa meal

Directions

1. Choose your recipe and assemble your ingredients. Mike says it's best to moisten dry materials before you load them into the drum.
2. As you're loading, close the door and turn the drum several times to mix the materials.
3. Once the composter is loaded, turn it slowly once a day, and it will soon heat up to over 120°F.
4. Check the moisture level every few days and add water if needed. "The material should always be damp, like a wrung-out sponge, but not soggy," Mike says. Tumbled compost will be ready to use in as little as 2 weeks, as soon as the core temperature is no higher than the outdoor temperature during a cool part of the day. (Garden centers and garden supply catalogs sell special thermometers for measuring compost temperature, or you can just stick your hand in and make an educated guess.)

Note: Compared to other composting techniques, drum composting offers the big advantage of producing a batch of finished compost very quickly. That's because it provides the ideal conditions for fast decomposition—even moisture levels, plenty of air, and finely shredded materials. But you can use these recipes to make quick compost in a regular bin, too, because they've been calculated to have the perfect ratio of carbon to nitrogen for rapid microbial growth and decomposition. Just be sure to keep things moist and turn the pile often.

Commercial Compost

Homemade compost is the best thing you can use to feed your plants and improve your soil. But even if you make your own, there may be times when you don't have enough of it to go around. That's when commercial compost comes in handy.

Product Inequality

Your local municipal compost site or garden center is certainly an option when it comes to loading up with bulk or bagged compost. But before you do, be forewarned: Not all commercial compost

Continued →

is created equal. Commercial composts are highly variable in organic matter and nutrient content. Some can even harm your soil and plants. Here's how to tell the difference between safe-to-use commercial composts and the stuff you should pass on.

Municipal Compost

With landfill space decreasing and waste disposal costs rising, more communities are becoming involved in large-scale composting. In 1990, more than 1,000 municipal composting sites were operating in the United States. And new legislative limits on waste disposal and public demand for environmentally safe waste handling are sure to lead to more of these operations.

Municipal compost operations range from small leaf-composting facilities to huge systems capable of turning 800 tons of waste per day into compost. Most use mechanized turners and forced-air methods to break down the large volume of materials as fast as possible. A few are fully enclosed, automated "in-vessel" systems that take in refuse at one end and sort, grind, mix, moisten, and aerate the material as it proceeds to the other end, where it emerges as finished compost.

Many municipal compost sites offer their product to local residents at little or no cost. Even if you must pay a small fee (common if you're not a resident), you'll still probably save compared to the cost of bagged compost, which sometimes reflects the cost of transportation.

To locate a municipal composting site near you, check township or city government listings in your phone book or online. Contact the office that manages solid waste. Most states also maintain a list of operating or planned compost facilities.

(Just remember that when you visit a municipal compost site, the compost won't be bagged—meaning you'll need containers or a pick-up truck in which to haul it.)

USING MUNICIPAL COMPOST

Because the quality of compost from municipal operations can vary considerably, you should keep the following tips for using municipal compost in mind.

- Never use municipal sludge or compost that contains sludge. Sludge (sometimes called "biosolids") may contain toxic heavy metals, such as cadmium, nickel, and copper, which can build up in soil.
- Use municipal compost on ornamental beds—not for edible plants. Municipal compost is made from yard wastes. And some of that plant debris probably was treated with herbicides, fungicides, or pesticides.
- Gauge the quality of the compost before you load up. Some piles will be more finished than others. Choose compost that has a uniform dark brown color and sweet, earthy odor—no hint of ammonia or sourness. It shouldn't contain visible wood chips, pine needles, or other materials that still need to decompose.

Mushroom Compost

If you live near a commercial mushroom grower, you may be able to buy mushroom compost—the medium used to grow mushrooms. Mushroom compost (also called "mushroom soil") is a blend of one-third horse manure, one-third spoiled hay, and one-third ground corncobs. With a 1.4-1-1 NPK value and a near-neutral pH, mushroom compost makes an excellent soil amendment.

A bulk load of mushroom compost (about 16 tons) costs about $100—delivered. (Most places will deliver or fill a pickup truck with mushroom soil for just $5 to $10.)

Make sure you get *organic* mushroom compost, however. Organic growers use steam to kill weed seeds and competing fungi and molds—other mushroom composts may be chemically treated. One supplier of organic mushroom compost is Hawk Valley Farm in Kempton, Pennsylvania.

Eastern Pennsylvania is the "mushroom capital of the world," but mushroom growers are scattered throughout other regions, too. Check with your local Cooperative Extension office for the names of nearby growers in your area.

Bagged Compost

If you're willing to pay a bit more, you can purchase commercial compost by the bag at your local garden center or home-improvement store. But be aware: Buying compost isn't as simple as looking for the best brand. Most commercial composts are produced and sold locally—you won't find the same products in South Dakota and Tennessee, or even in Nashville and Memphis.

The quality of commercial composts varies because they are usually made from whatever local waste materials are available at that time. For example, one batch might be made with low-salt manure and the next with high-salt manure. That means that unless the producer monitors each batch carefully, a brand that tests at the top of the class one month could flunk the next time around.

Organic Gardening magazine and Woods End Research Laboratory in Mount Vernon, Maine, tested 30 brands of bagged compost and found the following product problems:

- **More than half of the brands tested were too old or diluted with soil,** resulting in a low organic-matter content. If the level of organic matter is too low, the compost won't improve the soil as well as a better-quality product would. (High-quality, finished compost contains 30 to 60 percent organic matter.)
- **Nearly half of the samples tested had a pH outside the preferred 6.5 to 7.5 pH range.** For optimum growth of most plants, you want a near-neutral soil pH. Nine of the samples tested too high (as alkaline as 8.3 pH), and four of them tested too low (as acidic as 4.5).
- **A quarter of the samples contained too much salt.** If compost production isn't managed properly, or if a large

amount of chicken manure is used, salts can accumulate to a level high enough to injure plants—especially seedlings.

- **A quarter of the samples were sticky and wet.** These compost products would have been difficult, if not impossible, to spread.

BUYING QUALITY COMPOST

Fortunately, a simple look and smell are all you need to do to find a good-quality product. If possible, ask your garden center or supplier to let you take home a few samples before you buy. Put the samples through your own round of testing, using the following criteria.

- **The texture should be loose and granular**, with little or no recognizable bark or wood. If the compost isn't loose enough for you to spread and work it easily into your garden beds, don't buy it.
- **The color should be dark brown or black-brown.** Avoid products that are light in color. They probably contain too little organic matter and too much soil. It's easiest to tell the true product color if you let the compost sample dry out.
- **The compost should be moist, not dry or soggy.** In the soil, compost can hold up to 2½ times its weight in water. But in bagged products, excess water makes the compost difficult to spread. (Plus, you'll be paying for water, not compost.) Simply lifting a bag of compost will give you a good idea of its moisture content. If it feels like a big glob, the compost probably is too wet. If it feels loose, it's probably drier.
- **Mature compost has a pleasant, earthy smell.** If you find an earthy, woodsy odor, you've probably struck "black gold"—a mature, good-quality compost. Avoid composts with a strong or unpleasant smell, indicating immature compost that could damage plants. (*Note*: Some good-quality bagged composts have a slight musty or barnyard odor when first opened. That's because the plastic bags restrict the oxygen supply to the organisms that release the earthy odor. After a day or two, the compost should acquire that earthy aroma.)
- **Mature compost contains 30 to 60 percent organic matter.** To test the organic-matter content of any compost (commercial or homemade), spread some out on a thin layer of newspaper and let it air-dry for about a week. Then measure exactly 1 cup of the dried compost and weigh it. If it weighs between 4 and 6 ounces, it contains the desired amount of organic matter. If it weighs less than 4 ounces, it's probably immature. If it weighs more than 6 ounces, it's probably old or diluted with soil—so you shouldn't use it.

Some stores won't allow you to sample or inspect before you buy. If you buy a bag and find that it's not up to these standards, take it back and ask for a refund or dump it onto your home pile to dilute and fully compost it.

Another option is to look for bulk compost, sold at some garden centers. You'll not only be able to see what you're buying but also save some money. Many bulk composts are cheaper than bagged products: 1 cubic yard of bulk compost (the equivalent of twenty-five 40-pound bags) usually costs less than $30, while the good-quality bagged composts sell for $2 to $4 per 40-pound bag. Another advantage of bulk compost is that the garden center might be willing to deliver it right to your garden. (If they don't deliver door-to-garden, use your pick-up truck—or a neighbor's—to pick up your compost.)

Using Compost

Deborah L. Martin and Grace Gershuny

Your compost is finished. After carefully following the recommended steps for turning the year's bounty of organic materials into rich, mellow humus, you want to be certain that it's used to best advantage—that it benefits your soil most and helps to ensure a natural abundance and health in your coming crops.

It is not possible to stress too heavily the "soil bank account" theory of fertilizing. The real purpose of the organic method is to build permanent fertility into the soil by adding to its natural rock mineral reserves and to its humus content. Practically all the natural fertilizers are carriers of insoluble plant food. They start working quickly, but they don't drop their load of food all at once, as does a soluble fertilizer. An insoluble fertilizer will work for you for months and years.

So you can see that, as an organic gardener or farmer, you are adding fertilizer not only to supply immediate plant food needs, but also to build up the reserves that future crops will draw upon.

When to Apply Compost

The principal factor in determining when to apply compost is its condition. If it is half finished, or noticeably fibrous, it could well be applied in October or November. By spring it will have completed its decomposition in the soil itself and will be ready to supply growth nutrients to the earliest plantings made. Otherwise, for general soil enrichment, the ideal time for applying compost is a month or so before planting. The closer to planting time it is incorporated, the more it should be ground up or worked over thoroughly with a hoe to finely shred it. The special tools and equipment will come in handy when you wish to add compost to your soil close to planting time.

If your compost is ready in the fall and is not intended to be used until the spring, keep it in a protected place. If it is kept for a long period during the summer, water the finished compost from time to time.

Continued ➔

For organic farmers and gardeners, it's not a bad idea to make applications of compost either in the fall or winter or in the early spring. The big advantage here is that application at such a time helps to equalize the work load. Usually this time of year is the least crowded with busy schedules, and the farmer or gardener can devote more time to doing a good job without interfering with the rest of the crop program. Also, there is less chance of damaging the soil or of injuring crops.

Just before you first work the soil in spring is a particularly good time to apply fertilizer. Then when the soil preparation is done, the fresh organic matter can be worked down into the soil to supply food for the organisms that give life to the spring soil. They become active and start to grow at about freezing temperatures. However, soil temperatures must rise to 50°F (10°C) before they really take on the dynamic action that characterizes a living organic soil. In early spring, the temperature is just about to rise to the level where the vital soil organisms can make use of it.

In summer, plants take more nutrients from the soil than they do in any other season. But perhaps you didn't realize that in summer the soil has more nutrients available to give to plants than at any other time of the year. During the summer the increased activity of bacteria and other soil microorganisms is primarily responsible for the abundance of plant food. These same microorganisms are one of the primary forces that act on organic and natural rock fertilizers to make them available to plants. The beauty of this system is that microbes are releasing nutrients to plants most quickly at just the time when plants are growing most rapidly.

Summer can be a fine time to apply compost and the natural rock fertilizers—rock and colloidal phosphate, greensand, granite dust, and diabase dust. Organic fertilizers of all types are needed even more in the summer, because they hold moisture in the soil and stimulate the bacterial activity that takes place during the warm months. However, don't count on these slow-release materials to help growing crops that suffer from deficiencies. They will not become available until the microbes have had a chance to work on them for a while. The nutrients you add in the summer will greatly benefit your plants next year and the year after.

General Rules for Applying Compost

Apply at least ½ inch to 3 inches of well-finished compost over your garden each year. There is little if any danger of burning due to overuse, as is the case with chemical fertilizers. You can apply compost either once or twice a year. The amount would depend, of course, on the fertility of your soil and on what and how much has been grown in it.

For most applications, it is important that compost be well finished—that is, aged long enough so that the decomposition process has stabilized. Unfinished compost has been found to retard germination and growth of certain plants. Some plants, such as corn and squash, seem to thrive on partly finished compost, however. In general, be most careful when applying compost shortly before planting or in seeding mixes. Fall soil preparation and mulching applications are less critical.

If you want to be certain that your compost is aged well enough, you can perform a germination test. Soak a few seeds, such as lettuce or radish, in a tea made with your compost, and soak an equal number from the same packet in distilled water. Lay each batch on a paper towel, and keep them warm and moist for a few days, until they start to sprout. If the distilled-water-treated seeds germinate better, you know you must let your compost age longer.

When applying either half-finished or finished compost to your soil, turn over the soil thoroughly and mix the compost in with the top 4 inches of soil. If you have a rotary tiller, you can simply spread the compost on the soil surface and go over it a few times to work it in.

To improve the structure and fertility of poor soil quickly, give it a thorough compost treatment in the fall. Spade it 12 to 18 inches deep, and mix in all the half-rotted compost you have. Then leave the surface rough and cloddy so that the freezing and thawing of winter will mellow it (or plant a green manure crop that will add more fertility when it is dug or tilled under in the spring).

Putting compost down deep in the soil will also give your plants built-in protection against drought. Having humus down in the lower levels of your soil means that moisture will be held there where plant roots can get all they need in dry weather.

Also, this moisture will prevent the plants from starving during drought, since their roots can pick up food only when it is in liquid form.

The Vegetable Garden

Your vegetable garden will thrive if you give it liberal amounts of compost. Dig it in during the fall, bury it in trenches, put it in the furrows when you plant and in the holes when transplanting seedlings. When the plants begin to grow rapidly, mix compost with equal amounts of soil and use it as a topdressing; or mulch the plants heavily with partially rotted compost or with such raw compost materials as hay, straw, sawdust, grass clippings, or shredded leaves.

There is one rule to remember when mulching: The finer the material, the thinner the layer you will need. Remember that compost used at planting time should be well finished, especially for potatoes, which are prone to become scabby when in contact with incompletely decomposed manure. You may safely use partially finished compost only on heavy feeders like corn and squash.

For sowing seeds indoors or in a cold frame, put your compost through a ½-inch sieve, then shred it with a hoe or even roll it with a rolling pin to make it very fine. Then mix it

with equal amounts of sand and soil. The ideal seeding mixture is fine textured and crumbly and tends to fall apart after being squeezed in your hand.

The Flower Garden

Finely screened compost is excellent to put around all growing flowers. Apply it alone as an inch-thick mulch to control weeds and conserve moisture, or topdress it mixed with soil. In the spring, you can loosen the top few inches of soil in your annual and perennial beds and work into it an equal quantity of compost. And use compost generously when sowing flower seeds.

Compost watering is an excellent way to give your flowers supplementary feeding during their growing season. Put a generous amount of compost in a burlap sack or other permeable container, place it in a watering can, add water, and sprinkle liberally around the plants. The can may be refilled with water several times before the compost loses its potency.

Another advantage for flower growers is that plenty of compost has been found to keep the moisture level of the flower bed too high for ants.

Your Lawn

To build a lawn that stays green all summer, has no crabgrass, and rarely needs watering, use compost liberally when making and maintaining it. Your goal is to produce a thick sod with roots that go down 6 inches, not a thin, weed-infested mat lying on a layer of infertile subsoil.

In building a new lawn, work in copious amounts of compost to a depth of at least 6 inches. If your soil is either sandy or clayey (rather than a good loam), you'll need at least a 2-inch depth of compost, mixed in thoroughly, to build it up. For northern gardeners, the best time to make a new lawn is in the fall. But if you want to get started in the spring, dig in your compost and plant annual or perennial ryegrass, which will look quite neat all summer. Then dig this green manure in at the end of summer, and make your permanent lawn when cool weather comes. Southern gardeners might be better off starting in the spring with a ryegrass cover and then over-seeding with a lawn mixture the following spring.

To renovate an old, patchy lawn, dig up the bare spots about 2 inches deep, work in plenty of finished compost, tamp and rake well, and sow your seed after soaking the patches well.

Feed your lawn regularly every spring. An excellent practice is to use a spike-toothed aerator, then spread a mixture of fine finished compost and bonemeal. Rake this into the holes made by the aerator. You can use a fairly thick covering of compost—just not so thick it covers the grass. This will feed your lawn efficiently and keep it sending down a dense mass of roots that laugh at drought.

Trees and Shrubs

Despite the attention that has been given to backfilling mixtures for the planting holes of trees and shrubs, this is one place where compost should not, as a rule, be used. Evaluations of trees planted in holes backfilled with amended materials show that this practice encourages root growth only in the original planting hole—roots don't extend out into the surrounding soil—and such plants are susceptible to waterlogging, wind throw, disease, and insect problems.

A better use of your compost for feeding newly planted trees and shrubs is topdressing the soil area surrounding the plant and watering the compost in. Small "plugs" of compost may also be augered in around the drip line; manure tea feedings are also beneficial.

Established shrubs should be fed yearly by having ½ bushel of compost worked into the surface soil, then mulched.

The "ring" method is best for feeding trees: Start about 2 feet from the trunk, and cultivate the soil shallowly to 1 foot beyond the drip line of the branches. Rake 1 or 2 inches of compost into the top 2 inches of soil. Another way to feed established trees is to apply liquid compost, beginning around the base of the trunk and working out toward the drip line.

When hilling up the soil around your rose bushes for winter protection, mix plenty of compost with it—they'll get a better start next spring.

Fruit Trees

The ring method is ideal for fruit trees, too. You can work in as much as 3 or 4 inches of compost, then apply a heavy mulch that will continue to feed the trees as they rot. Some gardeners merely pile organic materials as deep as 2 feet around their fruit

Continued →

trees, adding more material as the covering decomposes. You can even add earthworms to speed the transformation to humus. Berry plants may be treated the same way, with lower mulches, of course, for low-growing varieties.

Another good trick for pepping up old fruit trees is to auger holes a foot apart in the soil all around the tree, and pack these with compost.

Houseplants

Lots of humus means extra-good moisture retention and air circulation in houseplant soil. A good potting mixture is composed of equal parts of loam, sand, and compost, the last put through a ¼-inch mesh. Leaf mold compost makes a fine, loose soil, while for acid-loving plants like azaleas, compost made from pine needles or oak leaves is best. Feed your houseplants every 2 weeks during their growing season with compost tea, made by suspending a cheesecloth bag of compost in water and using the liquid when it is a weak tea color. In general, compost can be added to potting mixtures as one-fourth of the total.

To rejuvenate the soil in window boxes, tubs, and indoor plant boxes, scratch an inch or so of compost into the surface twice a year. Occasional light topdressings of compost are also excellent for the soil in greenhouse benches. All of these will benefit from regular feeding with compost tea.

Soil-Compost Mixture for Starting Seedlings

You can help to ensure good germination by adding compost to seed-starting flats and beds. Make a mixture of 2 parts good garden loam; 1 part fine, sharp sand; and 1 part compost. Mix well and put 8 inches of the mixture into the hotbed, cold frame, or flat. It's a good idea to let this growing medium age for several months before seeding, especially if you are not sure that your compost has fully stabilized. Sift the soil mixture through a ¼-inch mesh screen to provide a fine-textured bed for planting. When screening the mixture, place coarse screenings in the bottom of the flats to provide better drainage.

This mixture provides adequate nourishment for young plants; you don't need to add manure or other organic fertilizers high in nitrogen. Used too soon, these fertilizers can cause the young plants to grow too rapidly, unbalancing their natural growth.

When starting plants in flats, some gardeners prefer to place a layer of sphagnum moss in the bottom quarter to half of the flat. Then after the seed has been placed in the rows, finely screened compost is sifted on top of them. When the seedlings are ready for transplanting to another flat, fill the flat with 1 part compost, 1 part sand, and 2 parts leaf mold.

Starter Solution for Plants

Starter solutions made from compost or manure can be a big help in the growing of vegetable plants. The home gardener as well as the commercial grower can benefit from the rapid and unchecked growth of young plants if the plants have reached a sufficiently advanced stage of growth and if the solution is used before they are moved to the field from the greenhouse, hotbed, or cold frame. Greenhouse operators have long made use of this method to bring their crops to a rapid and profitable production. Earlier yields have also been reported in the field.

The main benefit received from these solutions is that of providing the plant with immediately available plant food. This stimulates leaf and root growth, giving the plant a quick pickup after transplanting. These solutions are used especially on young lettuce, tomatoes, celery, peppers, melons, eggplant, cabbage, cauliflower, and all kinds of transplanted plants.

How to Use Compost Tea

The juices of compost can be the best part. Often, some of the valuable nutrients in compost are dissolved in water quite readily, and in solution these nutrients can be quickly distributed to needy plant roots.

Since plants take up nutrients along with water, the use of compost tea makes quite a bit of sense, particularly during dry periods when plants are starved for both food and water.

Many problem plants and trees can be nursed back to health by treating them with compost tea. You can use it on bare spots on your lawn, on trees that have just been transplanted, and on indoor plants that need perking up. You can even use it on vegetables in the spring to try to make them mature earlier. Compost tea is especially effective in greenhouses, where finest soil conditions are needed for best results.

It is really no trouble to make compost tea on a small scale. For treating houseplants or small outdoor areas, all you have to do is place a burlap or cloth bag filled with finished compost in your watering can and add water. Agitate it for a couple of minutes, or let it sit for a while, then pour. Nothing could be easier than that. The compost can be used several times, as one watering will not wash out all its soluble nutrients. The remaining compost is actually almost as good as new and should be dug into the soil or used as mulch. It takes the action of soil bacteria and plant roots to extract the major value from compost.

Developing a continuous system for making compost tea for the home grounds requires a little more ingenuity and mechanical skill. One method is to attach a hose connection and an outlet pipe to a plastic bucket with a lid that will stand up under normal water pressure. The type of 5-gallon plastic pail in which primer paint, drywall compound, and a variety of commercial food products are sold can be used for this project. Create a water intake near the bottom of the bucket by drilling a hole just large enough to insert a garden hose replacement coupling. Use epoxy to attach the coupling to the bucket and to seal the edges of the hole. Make an exit for your compost tea near the top of the bucket, opposite the water intake. The water has to circulate up and through the compost before it can get out of the bucket. Epoxy a piece of PVC pipe into the exit hole to create a spout to which a sprinkler head may be attached. A second hose connection can also be used in the exit hole, allowing the bucket to remain stationary while compost tea is sprayed through a hose coming from the exit.

The operation of this compost watering can is simple. You attach the water supply to the intake connection, and the hose or sprinkling device to the exit connection. The bucket may be carried to different parts of your garden, and one charging of compost lasts for about 15 minutes of watering. A screen placed over the exit hole on the inside of the can prevents solids from escaping and clogging the sprinkling heads.

Your Seasonal Guide to Composting

Now you know the complete story about compost: how it helps your soil; the ingredients you need to make it; different methods you can use to build a pile; and how to apply it. So to help you along in your compost-making endeavors, we've put together this month-by-month calendar, which will guide you through what to do when. (Believe it or not, making compost is really a year-round project.)

JANUARY

Consider starting a worm composting bucket or **bin** indoors, using newspapers as bedding material and kitchen scraps for food. Order your redworms through a garden-supply catalog.

FEBRUARY

Plan your **composting strategy**. Decide whether you want to buy a commercial bin, build your own, or just have a free-form pile. Find a shady spot on your property to place or build the bin or to build your free-form pile. Look for nearby sources of raw materials, such as pine needles or seaweed (depending on where you live).

MARCH

Find a source for finished compost (just in case your needs are greater than your means). Many **counties** and **municipalities** compost leaves and yard wastes for residents' use.

APRIL

Clean out your perennial and vegetable beds, and **add** the **winter mulch** that hadn't decomposed to your compost pile. Get those spring weeds out before they set seed and put them in your pile as well. **Dig finished compost** into your vegetable beds before planting. And **side-dress** your **perennials** with whatever compost you have left. If you have a worm bin, you can move it outside to a shady spot (but keep it covered).

MAY

With the garden in full swing, you should have plenty of raw materials (such as **spent plants**, vegetable scraps, and weeds) to add to your compost pile.

- Keep adding ingredients to your pile until it's 3 to 4 feet high, and **turn** the pile **frequently** to keep it cooking.
- When your pile gets to be a good size (a 3- to 4-foot square), **start another**.
- If heavy rains are predicted, **throw a tarp** over your compost so it doesn't get sopping wet.
- Convince your grass-bagging neighbors to call you after they mow (but **leave** your own **clippings** on the lawn to benefit the soil)—and add the clippings to your pile (as long as your neighbors don't treat their lawns with chemicals).

JUNE

If you started a compost pile back in March or April, you might have some finished compost by now.

- **Screen out** the large pieces that haven't decomposed and put them in your working pile.
- **Check the pH** of the finished compost.
- As for the unfinished stuff, turn, turn, turn.
- Also **take its temperature**. A hot (150° to 160°F) pile will be more likely to kill diseases and seeds. If it isn't as hot as you'd like it to be, **add high-nitrogen materials**, like grass clippings or vegetable peelings.

Continued ➔

JULY

Keep your compost moist (but not wet) during the hot midsummer days. You can **trap rainwater** by making a shallow depression on top. If your pile gets very dry, rebuild it, giving each 6- to 8-inch layer a **good sprinkling**.

AUGUST

You know the routine. Build the pile; turn the pile. Keep it moist; keep it hot. **Renew the soil** between plantings by digging in finished compost. There's no such thing as too much compost.

Take photos of your compost pile and of the lush gardens that are reaping the benefits of your homemade compost.

SEPTEMBER

Spread a thin layer of compost on your lawn to keep the soil alive and healthy. As you clean out your vegetable and perennial beds and **compost** the old **stalks and stems**, remember to dispose of diseased plants and weeds that have gone to seed elsewhere.

OCTOBER

Leaves are falling!

- First, run over them with your **lawn mower**. Then you can use them on your vegetable and perennial beds, pile them in your compost bin, or bag them to mix with next summer's high-nitrogen greens. One way or the other, use your leaves.
- It's also time to clean out your worm bin. **Remove** most of the finished compost and most of **the worms**. The compost (castings) makes a high nitrogen soil additive.
- **Share extra worms** with your friends, then move your worm bin indoors for the winter.

NOVEMBER

Continue to compost your **kitchen scraps** by toting them out to your compost pile, or by feeding them to your worms if you have a worm bin.

DECEMBER

Feed the worms! Remember to make use of your Christmas greens by laying them over your perennials. Pine needles or shredded leaves also make good materials for a winter mulch, which helps to insulate the soil and protect your plants from frost heaving.

Composting Glossary

Aeration. The exchange of air in the pore spaces of the soil with air in the atmosphere. Good aeration is necessary for healthy plant growth.

Aerobic. Describes organisms living or occurring only when oxygen is present.

Anaerobic. Describes organisms living or occurring when oxygen is absent.

C:N ratio. The proportion of bulky, dry, high-carbon materials to dense, moist, high-nitrogen materials. The ideal C:N ratio for stimulating compost organisms is 25:1 to 30:1; finished compost's C:N ratio is about 10:1.

Clay soil. Soil made up of very fine particles. Holds water and nutrients but does not drain well and can be hard to work. When dry, can become clumpy.

Cold pile. A compost pile that receives little or no turning, allowing some anaerobic decomposition to occur; composting continues at cooler temperatures over a longer period of time.

Compost. Decomposed and partially decomposed organic matter that's dark and crumbly. Used as an amendment, compost increases the water-holding capacity and drainage of the soil, and is an excellent nutrient source of microorganisms, which later release nutrients to your plants.

Decomposer. Organisms, usually soil bacteria, that derive nourishment by breaking down the remains or wastes of other living organisms into simple organic compounds.

Fertilizer. A natural or manufactured material added to the soil that supplies one or more of the major nutrients—nitrogen, phosphorus, and potassium—to growing plants.

Hot pile. A compost pile that's turned or otherwise aerated frequently, creating high temperatures and finished compost in a relatively short time.

Humus. A dark-colored, stable form of organic matter that remains after most of the plant and animal residues in it have decomposed.

Loam. The best texture for soil to have; it contains a balance of fine clay, medium-sized silt, and coarse sand particles. Loam is easily tilled and retains moisture and nutrients effectively.

Micronutrient. A nutrient plants need in very small quantities. Micronutrients include copper, chlorine, zinc, iron, manganese, boron, and molybdenum.

Organic matter. An organic soil substance that contains valuable nutrients. Can include kitchen or garden wastes, insects, sawdust, or any number of other compostable organic materials.

pH. A measure of how acid or alkaline a substance is. The pH scale ranges from 1.0 to 14.0, with 7.0 indicating neutrality, below 7.0 acidity, and above 7.0 alkalinity. The pH of your soil has a great effect on which nutrients are available to your plants.

Sandy soil. Soil that contains more than 70 percent sand and less than 15 percent clay. Sandy soil is generally easy to work with and well drained, but it has few nutrients and poor water-holding ability.

Sheet composting. A method of spreading undecomposed organic materials over the soil's surface, then working them into the soil to decompose, rather than piling them and spreading the resulting compost.

Side-dress. To apply solid (as opposed to liquid) fertilizer alongside annual plants during the growing season.

Silt. Refers to a soil particle of moderate size—larger than clay but not as large as sand.

Soil amendment. A material added to the soil to make it more productive by improving its structure, drainage, or aeration. An amendment such as compost can also be used to enhance microbial activity.

Soil structure. The physical arrangement of soil particles and interconnected pore spaces. Soil structure can be improved by adding organic matter.

Soil test kit. A set of instructions and a soil bag available through your state's Cooperative Extension Service. Test results indicate soil pH and specify which amendments you should add to your soil.

Top-dress. To apply compost or fertilizer evenly over a bed of growing plants.

Fern Marshall Bradley

The notion that a tool is nothing more than a device for doing work stops at the garden gate. Anyone who has worked soil with a well-balanced fork or rake or sliced weeds effortlessly with a skillfully sharpened hoe knows that a high-quality tool not only gets the job done but also adds pleasure to the doing. Little wonder that gardeners come to think of their most effective tools as friends.

In this section, several of our experts describe the tools that they have found to be most efficient and explain why. In addition, there are tips to help you in your own search for the "perfect" tool repertoire. You'll learn how to choose and use tools, how to take care of them, and even how to improve them. You may even be inspired to come up with a new garden use for a common household item. The possibilities are endless!

Improving Tools

The tool that's sold in the local hardware store isn't always just what you need to do your best work. There's immense satisfaction in learning how to modify a tool to do its job more efficiently. Try the following expert tips for improving on standard tools, and see if they don't help lighten those gardening chores.

HACK YOUR HOE IN HALF

There's a whole slew of new, lightweight, efficient hoes on the market these days. "I'm a big fan of the Dutch scuffle hoe," says Phil Colson, the garden center manager at Highland Hardware in Georgia. "It's light and has a long handle, and the blade lays flat to the ground, so you just push and pull it back and forth through the soil to cultivate or cut weeds. Ergonomically, anything that works by pushing and pulling has a distinct advantage over the old design."

Too bad the new hoes are so expensive—and in most areas, difficult to find at the local hardware store. If you can't find (or afford) these new hoes, you can always modify a conventional hoe to act like a scuffle hoe. The conversion couldn't be simpler. Using a hacksaw, cut the hoe's blade in half from left to right. Then file the cut edge to restore the bevel at the outside bottom edge. (For directions on filing tool edges, see "Sharp Tools Save Time and Energy.") Use a hammer to bend the blade inward slightly to give it a better angle for chopping weeds. "That's all there is to it," says Colson. "You'll have a hoe that's easier to use and that does a much better job of cultivating and weeding."

COLORFUL TOOLS ARE HARD TO LOSE

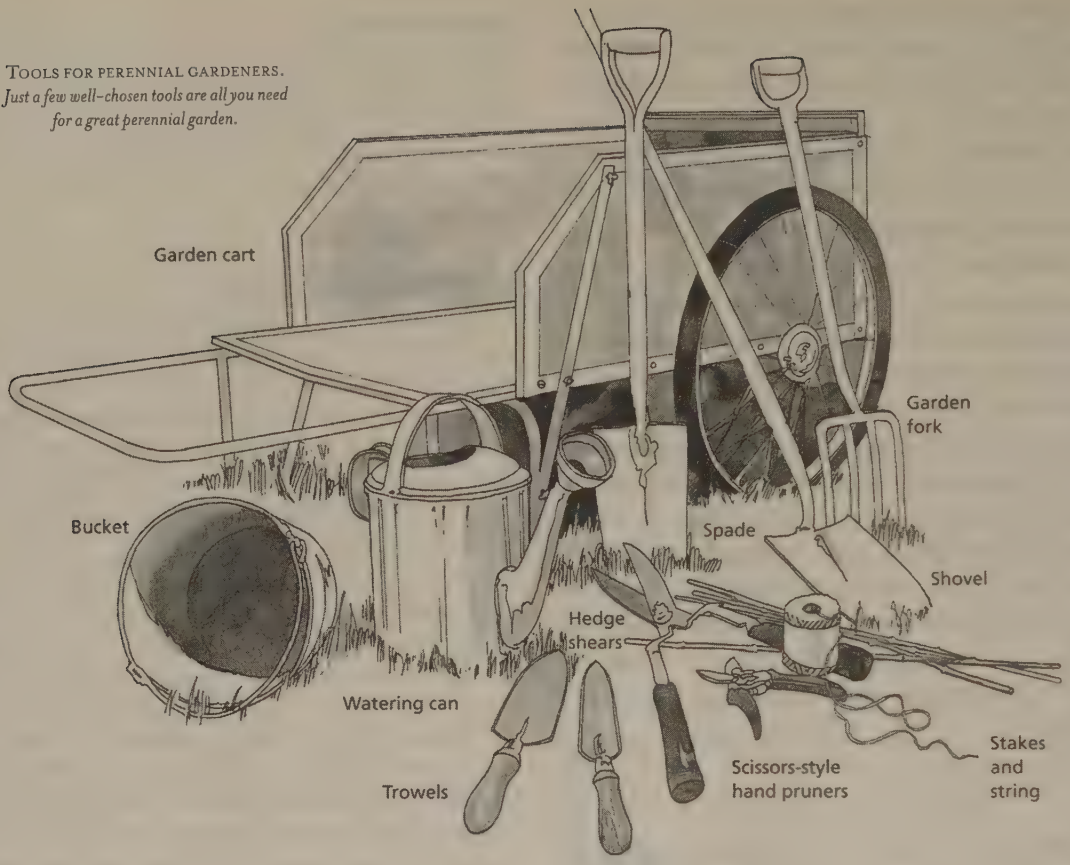
You know how it is. You could swear you put that darn tool down *right there*, but somehow it walked off on its own, and you can't find it anywhere. Then, after three days of rain, you find your favorite hoe on the ground, soaking wet and sporting little orange circles of rust-to-be. Susan Sides, a North Carolina garden writer, offers this sensible solution: Paint your tool handles bright red or some other attention-getting color. "It's almost impossible to lose a tool that's painted some loud color," says Sides. It is also a not-so-subtle reminder to friends who tend to borrow tools and forget to bring them back—they'll think twice about hanging onto your hot-pink hoe or glowing yellow shovel!

TAKE TIME TO HANDLE THE HANDLES

It pays to take a few minutes to work out with a new wooden-handled tool, says Phil Colson, the garden center manager at Highland Hardware in Georgia. "The first thing I do when I bring a new tool home is sand the handle smooth," says Colson. "Then I close my eyes and start feeling the surface. Instead of looking at it with my eyes, I look at it with my hands, because they're the ones that'll be grabbing it."

Use a rasp to round off any sharp edges, corners, or other places that don't feel comfortable, says Colson. Then give your

Continued ➔



TOOLS FOR PERENNIAL GARDENERS. *Just a few well-chosen tools are all you need for a great perennial garden.*

hands another "look" at the handle. When the feel is just right, give the entire handle a final sanding with fine-grit sandpaper.

Then, instead of using boiled linseed oil (the usual recommendation), Colson advises that you rub tung oil into the wood. "The trouble with boiled linseed oil is that it takes forever to dry, and it's always evaporating," says Colson. And you have to keep putting more on. Tung oil, though, penetrates and sets up overnight, and it seals the wood to keep out moisture. "To my mind," claims Colson, "it's a better way to go."

Maintaining Your Tools

Tool maintenance just isn't as much fun as using the tools in the garden. But with the size of the investment they represent, it's time well-spent. Here is advice from the experts on how to keep your tools in tip-top shape.

SHARP TOOLS SAVE TIME AND ENERGY

To give yourself an edge in the garden, grab a file and put an edge on your garden tools. "You won't believe how much easier a sharpened spade or shovel cuts through dirt," says Susan Sides, a North Carolina garden writer. "And the same holds true for almost any other garden tool with a blade. You'll save yourself a ton of work if you sharpen your digging and weeding tools and touch them up occasionally when you're out working with them in the garden."

Here are three tips for quick and easy sharpening:

1. Sharpen single-beveled tools such as spades, shovels, and traditional hoes on the beveled side only. Never sharpen the flat side.
2. Use a file that matches the contour of the surface—for instance, a flat file for a flat-faced garden spade and a half-round file for a curved shovel.
3. Sharpen the blade at whatever angle will serve you best. Generally, that means following the same angle as the original bevel. But remember that sharpening at a shallow angle gives you a sharper edge—a good choice for weed-slicing tools. Sharpening at a steeper angle produces a longer-lasting edge that's good for digging.

To sharpen, push the file forward and across the tool's blade, pressing down hard and using the file's full length on each stroke. Lift the file up off the blade on the back stroke. Keep filing until you can feel a slight burr—a barely detectable buildup of metal—along the full width of the blade's opposite side. Finish the edge by running your file lightly across the burr to remove it.

How often should you *resharpen* a tool? As often as it takes to keep the tool useful and efficient. "When I feel that the work has slowed down," says Sides, "I'll try scraping any mud buildup off the blade. Sometimes that cleaning makes the difference. If not, I'll clean the blade with an oily rag and give it a few swipes with the file to take the dullness off."

STRAIGHTEN THOSE TINES

If you use a standard triangular-tined digging fork, known in most regions as a potato fork, you know that the tines tend to bend occasionally—or more than occasionally, depending on how hard the ground is (and how old the fork is). Straightening the tines can be a real bother. "But a piece of pipe makes the job really easy," says Phil Colson, the garden center manager at Highland Hardware in Georgia.

To make a tine straightener, just drive a 3-foot length of 1-inch-diameter galvanized pipe into the ground near the place where you store your tools, leaving about 1 foot of the pipe above ground. "When you're finished using your fork and you notice a tine is bent, just stick it down into the pipe and bend it back the way it's supposed to be," says Colson.

AN "A-MAIZING" TOOL CLEANER

Garden tools have a way of repeatedly caking up with dirt and mud, and your work really slows if you don't take time to clean the stuff off. What to use? "A dry corncob makes a great in-the-garden tool cleaner," says Susan Sides, a North Carolina garden writer. "The rough surface gets all of the soil off fast, and when you're done with the corncob, you can just throw it in the compost pile."

QUICK TIPS FOR SPRING STARTUPS

Ah, spring at last, and there's work to do. You get out the old mower or tiller, yank on the starter rope—nothing. A few more useless yanks later, and you're ready to call it quits. But first, try these tips from Mike Ferrara, a senior editor for *Organic Gardening* magazine:

1. Replace any old fuel in the tank with new, fresh gas.
2. Buy and install a new spark plug.
3. Change the oil—old oil can gum up the works. Also, if it's a cool day, set the machine in the sun to warm and "thin" the oil.
4. Disconnect the spark plug and check the machine's working parts—such as tiller tines and mower blades—for tangled vegetation, twine, or the like. Clear away any obstructions, and reconnect the spark plug.

"Nine times out of ten, doing just those four things will get a sluggish engine up and going," says Ferrara.

PREVENT SPRAYER CLOGS WITH PANTY HOSE

Spraying is enough of a chore without being stalled by a clogged nozzle. Especially if you're spraying compost or manure tea, particles clogging the nozzle can be a real problem. Michael Maltas, the garden director of the organic showpiece garden for Fetzer Vineyards in California, suggests this cheap and effective spray strainer: "Take a pair of discarded panty hose and turn one leg inside the other to form one double-thick leg. Let the toe dangle into the spray tank, and stretch the top of the hose over the opening of your sprayer tank, securing it with a rubber band. When you pour your spray into the [panty hose] strainer, the nozzle-clogging particles will be trapped." Before spraying, remove and discard the used strainer—particles and all—or rinse it out for future use.

Clues for Saving Cash

Gardeners tend to be an ingenious group, especially when it comes to saving time and money. And they're always on the lookout for ways to ease the strain on those aching backs. We asked the experts for some of their favorite tips and techniques for stretching a dollar (and not stretching a muscle!).

TIPS FOR TROUBLE-FREE RENTALS

Renting can be the best option for tools and power equipment that you need only once or twice a year, suggests Mike Ferrara. "Chipper/shredders, heavy-duty tillers, lawn aerators, dethatchers, sod cutters, lawn rollers, stump grinders, fertilizer spreaders, and chain saws are all examples of equipment that many people don't need full-time but that are awfully useful when you do need them," says Ferrara. Some tips to keep in mind:

Most tools are rented by the day or half-day. If you think you'll need it for only a couple of hours, ask friends or neighbors if they're interested in using the tool and sharing the rental fee with you.

Try out the tool before you take it home. In the case of power equipment, start the engine, and run the machine just as if you were using it. And be sure you know how to stop it, too.

Consider hiring instead. Before you rent, check around to see if someone can do the job for you for less money. Sometimes it's actually cheaper to hire a professional with his or her own equipment than it is to do it yourself with a rental.

Shop around. The price, terms, and condition of tools can vary widely among rental stores.

Return the equipment on time. Some rental yards charge stiff penalty fees for late returns; others just call the sheriff.

PAD YOUR KNEES TO SAVE YOUR BACK

Slip-on knee pads and cushioned mats are sold at garden centers as "ground softeners" for gardener's knees. "But what knee pads really do is save your back," says Phil Colson, the garden center manager at Highland Hardware in Georgia. "Most people," he observes, "hate to get down on their knees because it's uncomfortable and often the ground is wet or muddy. So they end up bending over the whole time they're weeding or whatever, and pretty soon they've got back problems."

Continued →

Padded Handles Protect Hands

No matter whether it's a trowel or a tiller—the longer you use it, the harder and more unforgiving its handle seems to get. Even gloved hands become sore and cramped.

The solution? "I use pipe insulation to make the handles on my tools softer and easier to grab," says Matthew Cheever, the owner of Evergreen, a landscape design and maintenance company in Wisconsin. Cheever says the foam cushions help him avoid blisters when using trowels, shovels, and rakes, and they allow him to use a tiller for hours at a time "without getting white-finger disease from all the vibration."

Plastic-foam pipe insulation is sold in 3-foot lengths and in most common pipe diameters at hardware and discount stores. The cushioned sleeves are slit along one side. To pad a tool handle, just cut the insulation to length, slip the insulation over the handle, and wrap duct tape or electrical tape around each end to hold it in place.

Fall Care for Hand Tools

Assembling a collection of good-quality gardening tools is not an inexpensive endeavor. Protect your investment by taking care of your tools and storing them properly for winter. Come spring, you'll be glad you did!

Check handles for cracks and chips. Sand chipped handles and rub tung oil into the wood to make it smooth again. If a handle is cracked or broken, replace it.

Clean off the mud. This is something you should *always* do before putting any tool away; it will prevent rust spots. Clean the metal with a piece of burlap, steel wool, or a wire brush, or dip it a few times in a bucket of sand to scour the metal clean.

Sharpen your tools. If you put a tool away with a dull blade, it will still be dull and hard-to-use when you go to use it in the spring. Take the time to learn how to sharpen your own tools, or take them to a professional before storing them for the season.

Oil your tools. Coat metal parts of tools with a light coat of oil, and hang the tools in a dry place to protect them from rust.

Quick Tip

One Way to Help a Hoe

Using a power grinder, etch a series of ⅝-inch-long, 1/32-inch-deep grooves along the inside bottom edge of your hoe's blade. Space the grooves about ½ inch apart, and slant them away from the blade's center at an angle of 20 degrees. According to the design's developers at I-Tech in Davis, California, when you sharpen the back side of the hoe's blade (just as you would a standard hoe), the grooves produce a serrated edge that reduces drag and cuts weeds more easily.

Can't find the special cushions at your hardware or garden store? Look for slip-on knee pads at sporting goods stores. Or make your own garden kneeling mat by filling an old hot water bottle with sand or sawdust.

KITCHEN KNIVES CUT GARDEN CHORES

Want a handy, inexpensive, multipurpose, nearly indestructible garden tool? Then shop around for old kitchen knives at flea markets, suggests Susan Sides, a North Carolina garden writer. "I have several old knives that I keep out in the garden all the time," says Sides. "I just stick them on fence posts where I can find them and where the kids can't get them. The knives don't rust because they're stainless steel—and they don't get lost as soon as you put them down, the way a pocketknife does."

Sides uses different knives for different chores, including weeding, harvesting, cutting off seed heads, and snipping twine. "I have one knife with a blade that's 2 inches wide and about 7 inches long that I use as a sort of mini-machete," she says. Smaller-bladed types, like a little butter knife, are great for pricking out seedlings for transplanting.

PICK UP A PICKLE BUCKET

"I couldn't garden without a 5-gallon bucket!" declares Virginia Blakelock, the past president of the Hobby Greenhouse Association. Blakelock loads her garden cart with buckets full of mulch, then pulls the cart to where she's working. She finds it's easy to carry a bucket of mulch into the perennial bed and spread the mulch just where she wants it. She also uses the buckets to mix up 5-gallon batches of liquid fertilizer such as fish emulsion.

Driveway sealer and other home-maintenance products are often packed in 5-gallon plastic buckets. You can also find the buckets at restaurants or luncheonettes—wherever pickles are served—often free for the asking. Clean your buckets thoroughly before relegating them to the garden.

Favorite Tools

What tools are the best? Everyone has their own special favorites. We asked our experts for their top picks in tools: Here are their answers.

WHEEL HOES FOR REAL POWER

The classic wheel hoe (a tool with long handles, a single front wheel, and a tool bar attachment behind) is generally considered strictly a weeding tool. But modern updates of the traditional high-wheel design have created a much more efficient, versatile tool, says Stewart Hoyt, a Vermont market gardener. "The wheel is smaller, and there are stirrup-style oscillating-hoe attachments in varying widths that cut just below the surface," says Hoyt.

"I'm interested in ways of working the soil as shallowly as possible," Hoyt says. "I don't see any point in destroying the good work of the worms and the frost and such. I just want to be able to incorporate a cover crop and compost into the top 1½ inches of soil. A wheel hoe does a good job of that and cuts up weeds nicely, too."

SUSAN SIDES'S FAVORITE TOOLS

During her many years as head gardener at the Mother Earth News Eco-Village, Susan Sides, a North Carolina garden writer, refined her choices of tools. Her list of favorites is sheer simplicity: a Smith & Hawken garden spade, digging fork, and trowel, and a good-quality stirrup hoe.

Sides uses the first three "because they're really well-made." As for a good stirrup hoe, she advises that you get one that pivots from the end of the handle, with a stirrup blade that bows downward toward the soil. "And that's really all I need," says Sides. "Give me a spade, a fork, a stirrup hoe, and a trowel, and I can do almost anything."

Easy Machine Maintenance

Here are some things you should keep in mind as you winterize your machinery:

1. Clean off all dust, dirt, matted grass, and excess grease.
2. Look for loose or missing screws, bolts, or nuts; replace if necessary.
3. Disconnect the spark plug wire, and check the blades or tines of your machine. If necessary, sharpen and oil the blades or tines before replacing them.
4. If your machine has a 4-cycle engine, change the oil.
5. Clean and oil the air filter, following the manufacturer's directions.
6. To clean out the fuel line, drain out all gasoline, and then run the engine until it stops.
7. Remove, clean, and replace the spark plug.

Buying Used Equipment

Buying a used tiller, mower, or chipper/ shredder can save you big money—or cost you big money. The first step to getting good equipment at a good price is to let dealers know that you're looking. Most name-brand power equipment dealers sell reconditioned models, but the bargains go fast. Talk to local dealers, tell them you're looking, and leave your name and phone number. Once you find a machine you are interested in, use this checklist to make sure you are getting a good deal:

Start the engine. Check to see that the engine starts easily.

Examine the spark plugs. Dark carbon deposits mean only that a tune-up is overdue. Oil-fouled plugs spell trouble.

Look at the crankcase oil. Dirty oil or a nearly empty crankcase suggests poor maintenance and serves as a warning of future repairs.

Watch for other signs of neglect. A dirty air cleaner, clogged cooling fins, or a rusty or oil-gummed throttle linkage are all signs that a machine has not been properly cared for.

If you're buying a tiller, watch out for oil leaks, low transmission oil level, unusual grinding noises, or bent or worn tines.

On chipper/shredders, look for loose welds, stress cracks, low oil, and excessive vibration when the engine is running.

For walk-behind mowers, check for rust, excessive vibrations, and faulty oil seals. Avoid mowers lacking an automatic no-operator shutoff control.

PHIL COLSON'S FAVORITE TOOLS

Few people are as knowledgeable—or as opinionated—about garden tools as Phil Colson. "I'm basically lazy," says Colson, "so my whole focus on tools is to find the most efficient implement for the job." Here are a few of his favorites:

English square-tined digging fork. "Nothing's better for separating and breaking up soil," he claims.

Floral shovel. "Most of my tools hang in the shed, but my floral shovel never gets hung because I'm always using it," says Colson. "It's about two-thirds the size of a regular shovel, with a blade about 8 inches across. You can't beat it for planting bulbs, digging, and transplanting."

Continued ➔

A Checklist of Basic Tools

While experienced gardeners are likely to have three times this many tools in the shed, this list will give you a basic idea of the tools you'll need to have to take care of a home landscape:

- Shovel
- Spading fork
- Leaf rake
- Bow rake
- Leather garden gloves
- Pruning shears
- Trowel
- Sprayer (even if it's just a hand-held, window cleaner type)
- Wheelbarrow

Different regions of the country also have their own specialized tools. In areas with heavy clay or rocky soil, for example, it sometimes takes a pick to break through the subsoil. In the Southwest, a tool called a caliche bar (also known as a crow bar) is used to poke holes in the concrete-like caliche soil.

Quick Tip

Coffee-Can Tool Caddy

Long-handled rakes, shovels, hoes, and such have a way of "sinking" into the soil as soon as you need them. Here's a simple way to keep them organized and upright while you're working.

Cut the top and bottom from a large metal can, and nail the can to a fence post, about 3 feet up the post. Now when you're done with a tool, just slip the long handle through the metal can ring to hold it in place. A single 5-pound coffee can is big enough to hold two or three long-handled implements.

Italian grape hoe. "An incredible digging tool for jobs like planting a tree," says Colson. "You use it like a pickax; just throw it in the ground, and rock it back. You can lift soil up with its wide blade, push dirt around, and trench with it."

Dutch scuffle hoe. "I like this one because you just push the blade over the soil to weed and cultivate. And it has a long handle that lets you reach without having to take a step," says Colson.

Conventional wheelbarrow. Unlike a garden cart, a wheelbarrow doesn't require a wide path or a lot of clearance; it dumps right, left, and forward; and it's a great leverage tool for picking up heavy objects. Just lean it on its side and work the bottom edge under whatever you're trying to lift, then use your body weight to rock the wheelbarrow back up. "I've lifted 300-pound boulders that way—by myself," says Colson.

Japanese folding pruning saw. "You can carry this little 8-inch saw around in your pocket and just flip it out like a jackknife when you need it," says Colson. "It cuts on the pull stroke, and it's really sharp. It'll go through a ¾-inch branch with one pull. I hardly ever use loppers any more."

Japanese grubbing knife. "Nothing's better for getting out tenacious weeds like crabgrass and slicing off dandelions, particularly in rocky soil," says Colson.

Mason's trowel. Colson suggests this as an alternative to a high-quality garden trowel, which can be expensive. A mason's trowel is "made for lifting cement, so it's really strong, but it doesn't cost much," he says.

Felco pruners. "They give you a good, clean cut, particularly on woody material," says Colson.

Hand Tools

Barbara W. Ellis

The Basics

The range of garden tools offered today is bewildering, even for expeerienced gardeners, and a trip to the tool section of the hardware store or garden center may completely confuse the beginner. The wise gardener will start small, beginning with the basic hand tools and adding more only after learning the full use of the tools he or she already has.

You can probably get by with a few basic tools—a fork or spade for digging, a garden rake for smoothing the soil and preparing beds, a hoe for cultivating and weeding, and a trowel for working closely around plants.

The first rule of tool buying is to avoid cheap tools at all costs. The $1 trowel at the discount store is stamped out of cheap sheet metal, poorly designed, and even more poorly constructed. Not only will it break in a short time, but it will annoy you while you use it because it won't do the job well. Do not buy cheap tools for children, either. Even children should have good tools, because they'll never learn to love gardening if the first tools they use do not work well.

The best wood for a shovel handle, as for all long-handled garden tools, is North American white ash, which is strong, light, and resilient. Hickory is stronger and is ideal for hammers and other short-handled tools. It is sometimes used for spades and forks, but is too heavy and inflexible to use for shovels and rakes. Examine the lines (rings) in the wood; they should run straight down the entire length of the handle, with no knots. Avoid

painted handles, which often hide cheap wood. Also watch out for handles that are painted to look like straight-grain ash.

The attachment of the metal part of the tool to its handle is important to durability, especially for shovels. Avoid shovels of open-socket construction. The scoops are die-cut from sheet metal, then wrapped around the handle and riveted, leaving a seam. Instead, buy a shovel with solid-socket or solid-strapped construction. These are forged from a single bar of steel and completely envelop the handle, thus protecting it and greatly adding strength.

KEEPING TOOLS IN SHAPE

After making a considerable investment in good quality hand tools, it is wise to spend some time to keep them in good shape.

ROUTINE CARE

At the end of each day of gardening, clean, dry, and put away all the hand tools you used. Keep a large plastic kitchen spoon handy to knock dirt off metal blades. Do not use a trowel or other metal tool, as you could damage the blades of both tools. A 5-gallon bucket of sharp builder's sand in the tool shed or garage is useful for cleaning tools. Dip the metal blade of each tool into the sand and plunge it up and down a few times to work off any clinging soil. Use a wire brush to remove any rust that may have formed.

CARING FOR HANDLES

Wooden handles and shafts of hand tools should be kept varnished and sanded to keep them resilient and good-looking. If you buy a good-quality tool secondhand, and it has a weather-beaten handle, refresh it with several coats of varnish, sanding between each coat. You can repair split handles temporarily with tape and glue, but replace broken handles as soon as possible.

SHARPENING

Sharp-bladed hand tools will perform efficiently and with ease only if they are kept sharp. Take the time to study the angle of the bevels on all your tools, then sharpen each as needed to keep the proper bevel. And, for tools that are especially difficult to sharpen, don't hesitate to take them to a known and trusted professional.

The edge of a hoe can regain its sharpness if you run it across a grinding wheel several times. Bevel the side of the blade opposite the handle, holding the hoe at a 35- to 40-degree angle to the wheel.

The edge of a shovel need not be especially sharp, but it should be kept smooth so that dirt will readily slide off the blade. Hammer out any curls with a ball-peen hammer, and smooth out nicks with a fairly fine metal-cutting file.

On pruners, the outside of the cutting blade should be kept as sharp as possible, maintaining a fairly steep angle (10 to 15 degrees) of file to edge. The cutting edge of loppers should be filed at a similar angle.

At the end of the season, polish all the metal parts of your hand tools with steel wool, oil them to prevent rust, and store them in a dry place. Lubricate all tools that have moving parts. This is also a good time to take tools to the sharpening shop, particularly those that are tricky to sharpen at home.

Hoes

There are probably more different kinds of hoes than any other garden tool. Avid gardeners become as atttached to favorite hoes as golfers do to putters, probably because their hoe is the tool they use most frequently. With a hoe, you can lay out rows, dig furrows, cultivate around plants to loosen the soil and kill weeds, create hills and raised beds, break up clods, and prepare bare spots in lawns for reseeding.

TYPES OF HOES

The standard American pattern hoe is a long-handled tool that allows you to work without too much bending. It has a broad and straight blade, a little larger than 6-by-4 inches. However, many gardeners prefer a nursery hoe, which has a shallower (2- to 3-inch) blade and is lighter to work with.

In many Third World countries, the eye hoe, with its large, heavy, and deep blade, is the standard tool for breaking new ground and digging holes and trenches, as well as for cultivating.

The oscillating hoe is a modern version of the Dutch hoe, both of which were designed to slice weeds just below the soil surface. It cuts both as it is being pushed and pulled along the ground. In modern variations, often called the "hula" or action hoe, the slicing blade moves back and forth slightly to position itself for cutting while being pulled or pushed.

An onion hoe has a thin blade 1½ inches high and 7 inches wide, and can be pulled easily along the row to cut weeds well below the soil surface. Some are short handled, for use while kneeling. The blade of the grub hoe is narrower and taller than that of the standard American pattern hoe, enabling it to work deeply in tight rows.

Very different is the Warren hoe, which has a pointed, arrowhead-like blade used for planting furrows quickly. It is also handy for digging down to bring up stubborn weeds. The scuffle or slicing hoe is used for easy weeding in beds and borders. Its blade may be pointed or flat. A variation is the swan-neck hoe, named for the curve of the neck going into the blade. Its configuration allows the user to maintain a straight back and good balance while working. It is good for weeding in tight spaces, since the handle is held close to the body. There is also a pinpoint weeder, which has a narrow loop on the end to take up single weeds in very tight spaces.

The Canterbury hoe has three tines instead of a solid blade, and is perfect for breaking up soil, gathering up weeds and brush, and for aerating the top 4 to 6 inches of soil in rows and around plants. The double hoe has a blade on one side, tines on the other.

Continued ➔

The grape hoe, sometimes called a hazel or adze hoe, is a large, strong tool used for weeding and general cultivation in vineyards.

SELECTING AND USING HOES

When choosing a hoe, remember that narrower blades transmit your arm power more efficiently to the tool head than wider blades. Unless you need the depth of the standard hoe blade, you will probably be better off using an onion hoe, which is lighter and easier to use. The hoe handle should be at least 54 inches long (the traditional Dutch hoe is 64 inches) so you can work without bending over and straining your lower back muscles. In general, when working with hoes, try to remain standing upright. Run the hoe blade below and parallel to the soil surface to loosen the soil or to cut the roots of weeds. Remember to sharpen your hoe so that it will cut through weeds, which is easier than using the tool to yank the weeds out of the soil.

The blade, shank, and handle socket should be made of one-piece forged steel, attached to the handle by solid-socket construction. The handle will then be relatively easy to replace in case it breaks.

Spades, Shovels, and Forks

The standard American long-handled shovel has many uses around the home grounds, but some experienced gardeners seldom use it in actual garden work. For while a shovel is the best tool for digging rounded planting holes, most digging jobs are best accomplished with a four-tine garden fork or a spade.

SPADES

A short-handled, square-end spade is one of the most valuable and versatile garden tools you will ever own. A spade has a flat, rather than scooped blade, with squared edges. The handle is generally shorter than a shovel handle, usually ranging from 28 to 32 inches. The angle between shaft and blade is shallow, and the handle usually has a D-shaped grip for fine control.

On a good quality spade, the grip is made of wood or metal-reinforced wood that is firmly attached to or part of the handle. A spade should also have a turned edge or footrest along the shoulders of the blade to protect your feet when you step on the tool.

With a spade, you can cut easily through sod and create straight edges in soil. Spades are used for digging planting holes, prying up rocks, diggging up strong roots, dividing perennnial clumps, cutting unwanted tree and shrub roots, tamping sod, hammering stakes, cutting cord, digging trenches, and moving perennials.

There are several spades deesigned for special purposes. One is the drain-tile spade, a narrow-bladed spade used for digging small trenches. It's also good for digging postholes and for transplanting in close quarters. A border spade has a short handle and a narrow blade and may be more comfortable for short people to use. The nurseryman's spade has a small, slightly curved blade especially designed for transplanting.

SHOVELS

Shovels are good for mixing cement, and for moving soil, gravel, and sand. In a pinch, you can use a shovel as a scuffle hoe to cut weeds just below the soil surface, as a garden edger, and as a posthole digger. It's a good tool for prying rocks and root clumps from the soil, although be careful not to strain the handle to the breaking point.

The standard American shovel has a handle about 48 inches long. The shovel handle should come to shoulder height or higher, to enable you to work most efficiently. Shovels should also have a turned edge or footrest along the shoulders of the blade to protect your feet when you step on the tool.

If you want to buy a shovel that will last a lifetime, ask a local building contractor for the most reliable source.

FORKS

A spading fork can cut into soil like a shovel or a spade, but usually does it more easily than solid-bladed tools can. A spading fork is handy for mixing materials into the soil, and for harvesting potatoes, carrots, and other root crops. The tines of the standard spading fork are broad and flat. Those of the English cultivating fork are thinner and square. The English version is better for cultivating and aerating the soil. Remember that forks are used to loosen soil, not to lift it.

Using Spades and Shovels Safely

When digging or lifting materials with either a spade or shovel, remember these guidelines to avoid unnecessary stress on your back.

- Push the blade vertically into the soil with your foot, using your body weight to force the blade down—don't jump onto the tool to force it into the earth.
- The angle between the blade and the handle is a design feature that helps the digging process. After you push the blade down, remain upright, and pull the handle (which will be tilting away from you) back, close to your body. This action will loosen the shovelful of soil, making it easier to lift.
- Use your arms to lift the tool, and if possible, support the weight of the full blade with your thigh.
- Move your feet and turn your entire body to face the spot where you will be depositing the soil, rather than twisting from the hips to move the tool.

The standard handle length for a spading fork is 28 inches. Very tall gardeners may prefer a 32-inch handle (it will be more expensive, but well worth it). Short gardeners, including children, should use a border fork, which is smaller in both handle and tine lengths. Border forks, like border spades, are also ideal for transplanting in tight spaces.

A pitchfork (three tines) and a straw fork (five or six tines) are used for picking up, turning, and scattering hay mulch, leaf mold, and light compost materials. They are also useful for spreading mulch and for cleaning up garden beds in spring.

Trowels and Cultivators

When working on hands and knees, your best friend is your garden trowel, actually a miniature version of a shovel. Use it for digging planting holes for small plants and bulbs, for transplanting seedlings, for leveling the ground, and even for digging up weeds in thickly planted beds and borders.

A well-designed trowel is efficient and comfortable to use, and does not bend or break when you exert pressure on it. Some trowels are made from forged steel and fitted with hardwood handles, but good ones are also available in unbreakable one-piece cast aluminum. When buying an aluminum trowel, look for one that includes a plastic sleeve over the handle. This will prevent your hands from blackening from contact with the aluminum.

Trowels come in a variety of blade widths and lengths. Choose one that feels comfortable in your hand. You can use a narrow-bladed trowel for planting fine seed. First use the trowel to open a small furrow, and then put seed in the trowel and let it slowly trickle out into the furrow.

A few other small tools are more suitable than a trowel for particular tasks. A hand fork is good for loosening the soil around plants and for preparing small areas for planting. A hand cultivator works well to cultivate shallowly around plants. And a daisy grubber, also called an asparagus fork, has a long shaft and forked blade which make it ideal for jabbing deep into the soil to rout out long-rooted weeds.

Rakes

The traditional metal bow garden rake, so named because its head is attached to the handle with two bows, providing spring action. Popular alternatives to the bow rake include the level-head or square-back rake, which is generally narrower with shorter teeth and a shorter handle, and the landscaper's rake, which is very wide and designed specifically to level out broad areas.

These rakes are essential tools for leveling ground, creating raised beds, killing emerging weeds, gathering up debris from rows, covering furrows, thinning seedlings, working materials shallowly into the soil, erasing footprints, and pushing around mulch. Bow rakes come in many widths, with long or short teeth that are widely or closely spaced. The handle should be long, 54 to 60 inches, and the head should be heavy enough to bite into the soil easily. Wide-spaced teeth are recommended for working in rocky soil.

LAWN OR LEAF RAKES

Also called fan rakes, these are good for gathering up leaves, grass, weeds, and other debris, and for dislodging thatch from the lawn. They come in different sizes; a 19-inch head seems to be close to standard.

Metal lawn rakes last longest and are the springiest, although many gardeners prefer the action and feel of bamboo tines, and some prefer plastic or rubber. Some lawn rakes have adjustable heads that can be made narrower for raking in tight spaces such as under shrubs or in garden beds.

Scythes and Sickles

A scythe is a traditional hand tool used for mowing grain crops or tall grass and weeds. The tool consists of a long curving blade attached at an angle to a curved handle called a snath. Two short grips, called nibs, project from the snath. A sickle has a shorter blade and handle than a scythe and is used primarily for cutting back tall weeds in hard-to-reach areas.

The mechanical reaper invented in 1831 and subsequent modern machinery have made the scythe nearly obsolete. However, gardeners may still find the scythe useful for mowing grass on very steep slopes or in rocky areas. Scythes, mostly Austrian-made, are still found in many hardware stores, especially in rural areas.

A cross between the scythe and sickle is the grass hook (common names for these tools often overlap), a modern instrument with a slightly curved detachable blade that can be fastened to either a long or a short shaft. Used with two hands, it is much lighter and easier to handle than a scythe, yet has a cutting blade longer than that of a sickle.

USING A SCYTHE

Using a scythe is a tricky process that requires some strength and endurance. To mow with a scythe, stand with your feet spread moderately apart, and hold one nib of the scythe in each hand. Sweep the tool in an arc from right to left in front of you, with the blade parallel to the ground, to cut a swath. Swing the tool back from left to right to prepare to cut the next swath. Allow your feet to take small steps as you work, in natural rhythm with the swinging blade.

Scythe blades must be sharpened frequently with a whetstone or grinding stone to work efficiently. (See "Maintaining Your Tools" on page 116 for sharpening guidelines.) Grass or weeds may be easier to mow when they are green and wet than if they are dry or dead.

USING A SICKLE

A sickle is useful wherever tall weeds must be chopped down—along fence rows, up against buildings, around trees,

Continued ➔

wherever other tools cannot reach. The curved steel blade, typically 18 to 26 inches long, is attached to a hardwood, steel, or aluminum alloy handle.

Cut weeds with a sickle by slicing with one hand in a sideways motion. Use a stick held in your other hand to hold back overhanging grass so that you can cut growth near the stem bases. If the grass is wet, you may want to hold the stick upright with one end touching the ground as a barrier between the sickle and your body, in case the sickle slips on the wet grass as you swing. As with the scythe, keep your sickle sharp at all times.

Pruning Tools

Any garden that has trees, shrubs, and hedges needs frequent snipping, trimming, cutting, chopping, and pruning. While these jobs can be arduous with the wrong tools, they are a pleasure when using proper tools that are in good condition.

PRUNING SHEARS

A pair of good quality pruning shears is essential for cutting small branches, shaping shrubs, deadheading plants, harvesting grapes, removing raspberry canes, and cutting back tree roots. Most models will cut hardwood branches of up to ½ inch in diameter.

There are two basic types of pruners: the anvil type, in which a straight, sharp blade closes down onto an anvil or plate; and the bypass type, in which a curved cutting blade passes by a so-called hook blade, acting like household scissors. Anvil pruners are often easier to use, requiring less hand pressure to make the cut. Bypass shears make a cleaner cut, can work in tighter spaces, and can cut flush against a tree trunk or branch instead of leaving a short stump as anvil pruners do.

Many models of both anvil and bypass pruners are available, including some that have narrow blades for light trimming and working with flowers. The Japanese ikebana-style clippers have small bypass blades and large loops to fit the hand and are popular for working with flowers.

Whatever type you select, it's easiest to make pruning cuts if you work with the tool's design to get the greatest possible leverage. Position a branch between the blades as close as possible to the pivot point (the place where the two blades are attached to one another) before starting to cut, for greatest efficiency.

OTHER PRUNERS

There are other types of pruners that will make your gardening chores easier.

Pole Pruners. These are useful for reaching high tree branches or getting into the base of a thickly grown shrub. Most pole pruners operate with a lever handle or a pulley and rope mechanism.

Lopping Shears. Also called lopppers, these are heavy-duty pruners with wood or metal handles 25 to 30 inches in length. Made of either anvil or bypass construction, most can cut branches up to 2 inches in diameter. Some include ratchets or gears to increase leverage, or use several pivot points like a bolt cutter.

Hedge Shears. These tools have long blades and relatively short hardwood handles. They can cut branches up to ¼ inch thick. Most good quality shears have ash or hickory handles, although some are of metal or fiberglass. Most also have a shock absorber near the pivot point to reduce stress to the user's arm joints and to prevent knuckles from banging together. They are designed for cutting the tender new growth of hedges, and are also useful for trimming tall, coarse grass.

Electric Clippers. Power hedge clippers make short work of many trimming jobs. Some models are cordless, operating more than a half hour with a single battery recharge, and some even have small gasoline engines. The clipper blades range from 16 to 30 inches long. The shorter ones are easier to handle, the longer ones capable of doing more work.

Electric clippers seldom if ever need sharpening, since the scissor-like action of the blades keeps them sharp through use. Moderately priced clippers are dependable for cutting branches up to ¼ inch thick and will last for many years with little attention.

SAWS

Pruning saws can cut through most branches that are too thick for pruning or lopping shears. The standard seven-point (seven teeth to the inch) model has a hardwood handle and a removable curved blade 9 to 15 inches long. It can fine-cut branches up to 3 inches in diameter. For larger limbs, use a four-point saw, curved or straight-edge, with a D-grip and both cutting and raker teeth (the latter to remove sawdust as cutting takes place).

Pole saws are useful for high limbs. Some are made in combination with pole pruners. Because of their thin blades, bow saws can cut through wood very quickly. They are difficult to use when you don't have a lot of space in which to maneuver. Double-edge saws can cut both coarsely and finely, but sometimes damage other limbs when used in close quarters.

WHAT TO LOOK FOR

The difference between an inferior and a good quality saw is often in the arrangement and beveling of the teeth. The teeth should be set—bent alternately to left and right—so that the cut is slightly wider than the saw blade. This will keep the blade from getting stuck. Cheaper saws have teeth arranged like those of a rip saw and are cross-filed, making the top of each tooth flat like a chisel. Good quality saws are bevel-filed, a more expensive process than cross-filing but one that produces sharper teeth.

Wheelbarrows and Garden Carts

A wheelbarrow or garden cart can be a lifesaver if you're faced with transporting various and sundry plants, tools, flats, hay

bales, compost, and other materials. Each type of garden conveyance has advantages and disadvantages; be sure to select one that meets your specific gardening needs.

The traditional garden wheelbarrow differs from a contractor's model, which is specifically designed for transporting cement. A garden wheelbarrow is made of wood and has removable straight sides, not the sloping metal sides of the contractor's wheelbarrow. Many variations of the garden wheelbarrow have apppeared over the years, including some with double wheels. Still, the basic design has been retained, and therein lies the major disadvantage of the wheelbarrow for garden work: the distribution of weight. Since the load lies well behind the axle and wheel, the user must share much of the load with arms, shoulders, and back.

The garden cart, on the other hand, is a large, spoke-wheeled cart that places the load directly above the axles and wheels, enabling you to move heavy loads with comparatively little effort. The large diameter bicycle-type wheels also contribute to ease of transport. They ride easily over rocks and ruts, and yet their thin tires create little friction for easy movement.

The garden cart's two wheels, placed on either side of the load, also stabilize the cart so you don't have to work to keep the load balanced and steady, as is necessary when pushing a wheelbarrow.

Another advantage of the garden cart is its large capacity. Your transplanting job will be much easier if you can load your tools, compost, and other supplies all on the flat bed of the garden cart, and wheel it easily in one trip from the tool shed to the vegetable garden.

The wheelbarrow, on the other hand, can maneuver into tight spaces where a large garden cart cannot go. It can be pushed between two rows of corn, or down a narrow path to the woodpile. But pushing most loaded wheelbarrows through soft earth is virtually impossible.

Two-wheel garden carts are bettter for most garden uses, but there are still times when a wheelbarrow is the right tool for the job. Many gardeners own both.

The classic garden cart, which comes in several sizes, has a metal-reinforced plywood body. The standard model has a nonremovable front panel, but many gardeners prefer a model with a removable front panel for easier dumping.

It is difficult to find a traditional wood garden wheelbarrow today, although they are still being made. If you buy a contractor's wheelbarrow, be sure to buy one of professional or industrial grade, not "homeowner's" or "promotional" grade. Many cheap wheelbarrows and garden carts are sold at discount and department stores every year, but most of these are litttle more than toys that will not stand up to serious garden work.

Power Tools

Barbara W. Ellis

Tillers

Rotary tillers can make short work of turning and churning garden soil, breaking new ground, cultivating, aerating, weeding, and mixing materials into the soil. The rotary tiller is a gasoline-powered machine equipped with steel blades that rotate on a central spindle. The two basic types are front-bladed and rear-bladed, terms that refer to the placement of the blades in relation to the engine. Front-bladed tillers are less expensive. The least expensive of these have no wheels at all, letting the tines themselves power the machine forward. The heaviest and most expensive tillers have rear tines and power-driven wheels, and are more comfortable to operate. Sizes range from 20-pound machines, used for cultivating in flower and vegetable beds, to the 375-pound giants designed for heavy ground moving.

Most tillers depend on four-cycle engines, running from 2 to 8 horsepower, and drive mechanisms in the form of gears, chains, or belts—all of which are about equally dependable.

If you plan to buy a tiller, learn about various models by actually using them in your garden. Borrow or rent before choosing a tiller to purchase. Remember that wheeled tillers are always easier to operate than those without wheels. Large wheels provide more maneuverability than small ones. Look for heavy, heat-treated carbon steel blades.

Some models offer optional attachments, including snow blades and throwers, log splitters, generators, shredders, blowers, sprayers, various cultivators, and even chain saws. The quality of these attachments varies widely. Garden tractors also offer tiller attachments.

CARE AND MAINTENANCE

How you operate and care for your tiller will go far in determining how long it will last and how well it will perform. The first rule is, Never try to make a tiller do more than it was designed to do. It cannot clear a meadow of rocks, turn under a field of cornstalks, or uproot a tree. When you are incorporating organic matter into the soil, work in several thin layers, one at a time, so that the tiller (and you) can work with ease. When you till new soil, don't expect to reach 8 or 9 inches in depth with a single pass. Learn the limits of your tiller and work with it—not against it.

Tiller maintenance is similar to caring for a four-cycle lawn mower. Keep the air filter clean, and change the oil every 25 hours or once a season, whichever comes first. Also check the seals of the drive system regularly, and keep debris out of the fins on the cylinder (which are meant to help cool the engine) and the grass screen over the fan. Never use gasoline that is more than two months old.

Continued →

Clean your tiller thoroughly before winter. Knock out any carbon that might be plugging the portholes in the exhaust system, change the oil and filter, drain the gasoline, run the engine until all the gasoline has left the carburetor, and remove the spark plug. Then roll it into a corner and throw a blanket over the machine until spring.

Shredders and Chippers

One of the favorite large power tools of organic gardeners is often a shredder or chipper. This machine, powered with gasoline or electricity, can reduce all those leaves, pruned branches, and plant debris to beautiful mulch or compost material. Some machines are designed specifically for shredding soft plant material, others for chipping thick branches, and some have separate chutes for both functions built into the same machine.

Shredders usually operate with a spinning drum fitted with fixed hammers or swinging flails that pulverize materials. Chippers typically slice branches with one or two knife blades mounted on a metal flywheel. Shredders are better at handling weeds and other soft plant material; chipppers will handle heavier, woody materials. Large 5-horsepower models can chip branches up to 3 inches in diameter. Small chippers (around 2 horsepower) can take branches up to about 1 inch.

Many of these machines have trouble handling leaves. It is difficult to feed dry leaves into the machine chute quickly enough to attain any degree of efficiency—and wet leaves often clog the machine. Plus, the leaves must be collected before they are fed into the shredder. There are now string-trimmer shredders made especially for leaves, but many gardeners still find it simpler and quicker to collect leaves using a rotary mower with a bagger attached.

Electric shredder/chippers are gaining quick acceptance among gardeners. Compared with gasoline-engine models, the electrics are smaller, easier to start, quieter, and require less maintenance. However, they must be operated where there is a power source, and there is a drop in voltage when long extension cords are used.

For small amounts of garden debris, a 1- to 3-horsepower model should suffice. For a large suburban or country lot, a 5- to 8-horsepower model will both shred and chip all the waste you can produce. Sometimes neighbors will pool their resources and buy a large machine to be used by all.

CARE AND MAINTENANCE

Safety is a prime concern when using these machines. Ear pads and safety goggles are mandatory, as is common sense in feeding in materials and removing clogs. Never put your hand inside a chipper/shredder without first—every time—unplugging it or removing the spark plug. Follow all the safety precautions of the manufacturer.

Electric shredder/chippers are virtually maintenance-free. Gasoline-powered machines must have soil and filter changes according to the manufacturer's instructions. You may use this machine year-round, but if you plan to store it for the winter, drain the gasoline as you would for a tiller. For both electric and gasoline-powered machines, be sure the hopper and discharge chute are cleared of all plant debris after each use.

Mowers

Until the end of World War II, the only lawn mower common in the United States was the push reel type, in which several revolving blades move against a single fixed blade, producing a neat trim. It did a fine job on small lawns, cutting evenly and quietly. For those with small, level lawns, the push reel is probably still the ideal lawn-cutting instrument. It is inexpensive, not difficult to push, nonpolluting, still produces a neat-looking lawn—and its gentle sound of metal kissing metal is music to the ears.

The popularity of the gasoline-powered rotary mower grew with the spread of large suburban lots in the postwar period. Lawns often were too large to be cut by hand. Power reel models were in favor for a while, but gradually lost out to the standard rotary mower, whose single blade revolves at a high rate of speed, literally ripping the tops off grass plants. It can easily handle rough terrain and knock down high weeds, while a reel mower cannot.

Rotary mowers have cutting widths ranging from 18 to 24 inches and can be adjusted to cut grass at different heights. Some are self-propelled, a valuable feature if your lawn is large or sloping. Electric starters are appreciated by people with physical limitations that might preclude yanking on a cord. (Newer models use an overhead valve system—OHV—which virtually guarantees starting on the first or second pull.) A bagger is a valuable option, since it can be used to collect leaves in the fall. However, if you cut your lawn frequently and depend on grass clippings for nitrogen to feed your lawn, it's best to leave clippings on the lawn, where they'll decompose and return nutrients to the soil. A mulching mower has a blade that blows finely cut pieces of grass back onto the lawn, thus building up the lawn's organic matter while obviating any raking or bagging of clippings.

Electric rotary mowers are quiet and easy to maintain, but working around the cord which supplies power to the mower is a constant annoyance. Still, many urban homeowners with small lawns prefer them over noisy and fumy gasoline-powered machines.

Gasoline-powered motors are either two or four cycle. The former, which is less common, is more efficient and likely to last longer than the latter. You must mix gas and oil each time you refuel a two-cycle engine. A four-cycle engine has a separate crankcase; you must check the oil level regularly and change the oil at least once a season. Insufficient oil is the number one cause of lawn mower trouble.

A 7-horsepower riding mower with a 25-inch deck can mow an acre of lawn in an hour. An 8-horsepower model with a 32-inch deck can mow 1½ acres of grass in the same amount of time. But if your lawn is larger than 1 ½ acres, consider acquiring a small lawn or garden tractor, which would also be useful for many other jobs around your property. These have engines in the 15 to 25 horsepower range and power take-off (PTO) capability to drive a number of optional attachments such as a log splitter, chipper, snow blower, or generator.

CARE AND MAINTENANCE

Routine care of your rotary mower will greatly improve both its performance and its life. Use the oil recommended by the manufacturer and change it according to schedule. Use fresh gasoline—never more than two months old—and be sure to get the kind recommended in the owner's manual. Generally, it's unleaded for four-cycle engines, leaded for two-cycle.

After every second or third use, clean out any debris that has lodged under the housing. Cut away any string that may have wrapped itself around blades or shaft. And be sure to disconnect the spark plug or pull the electric plug before you work under the housing—every time.

Keep the air filter clean during the mowing season, following the manual directions. Clean the spark plug several times during the season, carefully scraping the tip clean and adjusting the gap to manual specifications. A plug should last two or three years and should be discarded when it becomes corroded or deformed.

Before putting the mower away for the winter, remove both gas and oil, clean it thoroughly, and sharpen the blade.

Tool Tricks and Techniques

Roger Yepsen

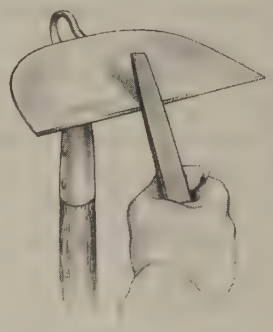
Every gardener starts out with a plot of ground, a shovel, and a few packets of seeds. And that's all you need, at the absolute minimum, to coax edibles and ornamentals from the yard. For most of us, however, the equipment tends to proliferate. Tools, sprayers, fencing, gadgets to scare away pests—all have the potential to make gardening easier and more productive. Some, like a good trowel or clever one-wheel cultivator, can be a pleasure to use as well.

Eventually, the well-equipped gardener may feel a bit overwhelmed by the need to clean and maintain and store this hardware. There can be a move toward simplicity, scaling back just a bit in order to get closer to the simple pleasures of collaborating with nature on a lovely day. It's a matter of balance between convenience and complexity—between time-saving equipment and finding the time to manage a garage full of stuff.

Hoe Honing

In the kitchen, you wouldn't waste your energy chopping up vegetables with a dull knife, but chances are the blade of your garden hoe hasn't gotten much attention lately. And yet if you want to efficiently deal with weeds, a sharp blade is important.

To put a keen edge on a hoe, use a mill file, a flat file with fine teeth that's available at hardware stores. Since you'll be turning your homely hoe into a weed weapon, you should wear work gloves and sharpen with care. Support the hoe, blade up, and go over the beveled edge of its blade, typically along the outer side. Hold the file at about a 45-degree angle, drawing it away from the handle as you slide it along the entire width of the blade. Repeat the stroke as needed.

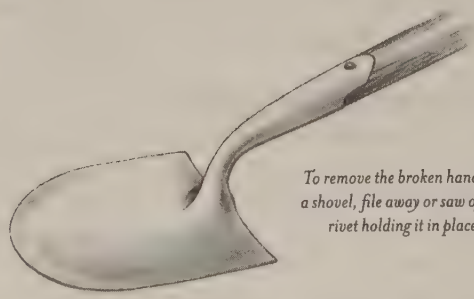


A hoe does have a blade, so it shouldn't be surprising to learn that it will be a better weapon against weeds if it's kept sharp.

Replace a Handle, Spare a Shovel

If a shovel or hoe has served you well, you may be reluctant to chuck it when the handle breaks. Chances are you'll be able to replace it.

To remove an old handle, either grind the rivet down with a mill file or saw it off with a hacksaw. Drive out the rivet by tapping with a punch or a large nail. Take the shovel or hoe head to a hardware store to find a handle that will fit. A bit of filing may be necessary; use a wood rasp with coarse teeth for this part of the job. Drive the handle into place by tapping its end with a hammer cushioned with a piece of scrap wood. Secure the handle by drilling a ⅛-inch-diameter pilot hole for a wood screw.



To remove the broken handle of a shovel, file away or saw off the rivet holding it in place.

The Long and Short of Shovels

Shovels come with short D-handles and long straight handles. Which is best? That depends on you, and what you intend to accomplish in the garden. You're apt to experience less back strain with a long handle. Yet while a short handle requires you

Continued ➔

to bend a good deal more, it will make more efficient use of your energy. You might want to buy one of each, reserving the short shovel for short bursts of relatively intense digging. Chances are you'll find yourself reaching for the longer one most of the time.

GARDEN TOOLS FOR WOMEN

There are female gardeners stronger and taller than some male gardeners, of course. But very generally speaking, women may find that they prefer lighter, smaller-scaled tools, as well as those that have advanced ergonomic designs to make the most of the user's strength. The advantages go beyond comfort. A properly sized tool is more efficient, will be less likely to trigger an injury, and can even give your body a superior workout.

The most obvious requirement is a pair of gloves for smaller hands, rather than settling for the usual one-size-fits-all jumbos. Several companies now market lines of tools especially for women, including trowels, pruning shears, a lightweight cordless drill for outdoor build-it projects, and a lightweight string trimmer. Women may want to look for a border spade rather than a standard shovel, because the blade is lighter and considerably smaller in area. There also are garden clogs and kneepads sized for smaller gardeners. Whatever the tool, it's a good idea to get a sense of how it feels in the hand when shopping, evaluating both weight and size.

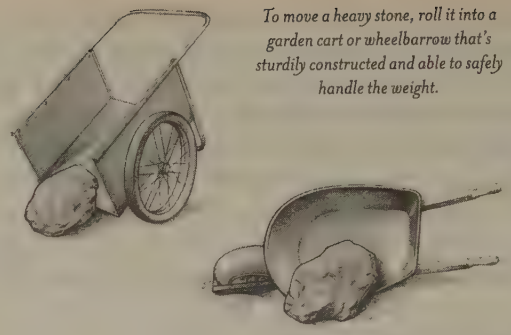
GARDEN TOOLS FOR KIDS

There's no better way to introduce children to chores than getting them involved in gardening. The work isn't exactly child's play, but it can be enjoyable on a lovely day and with reasonably defined tasks. And the kids can look forward to the payoff of a flavorful harvest in several weeks' time. To make sure they will really contribute and not just playact at gardening, it helps to equip them with specially made, specially sized equipment—watering can, brightly colored hand tools, shovel, rake, and hoe. There are kid-size wheelbarrows, and Troy-Bilt, the well-known garden equipment supplier, sells a serious-looking metal wagon with beefy tires and wooden sides. Don't forget little work gloves, as well as a sun hat of some kind.

Heavy Lifting with a Wheeled Friend

Don't test your back by lifting big rocks and bales of peat moss. Let a garden cart do it for you, with another person on hand. Approach the all-but-immovable object with a cart that has a removable front panel. Slide off the panel, and lift the handle of the cart to bring its front edge to the ground. Then roll or slide the payload into the cart while your helper leans on the cart handle to bring it upright.

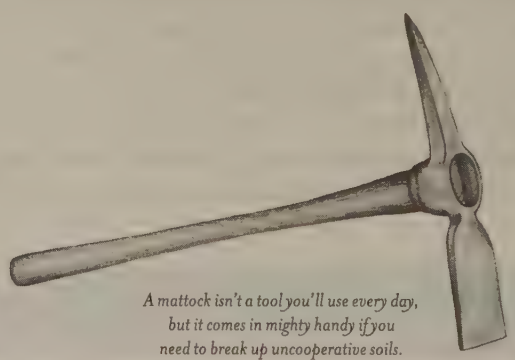
A version of this no-lift technique works with a wheelbarrow. Tilt the wheelbarrow on its side next to the object. Then push or roll the object into the tray while also pressing on the top edge of the tray, and have a helper assist you in righting the wheelbarrow.



To move a heavy stone, roll it into a garden cart or wheelbarrow that's sturdily constructed and able to safely handle the weight.

Hard-Packed Soil a Headache?

There are times when a shovel just won't cut it—won't cut into dense, clay-rich soil littered with stones, that is. For tough jobs, it's good to have a mattock on hand. There are a number of different versions, but a particularly useful one has a narrow blade on one end of the head and a pick on the other. Between the two, you can effectively loosen up any kind of soil to the point that it will be receptive to a shovel. As with swinging an axe (or a golf club, for that matter), you have to make certain that no one is anywhere near the arc of the tool as you swing it.



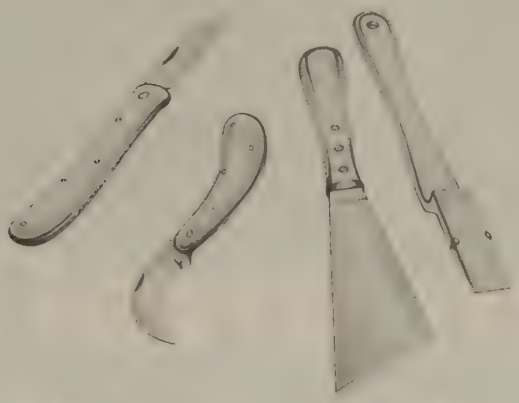
A mattock isn't a tool you'll use every day, but it comes in mighty handy if you need to break up uncooperative soils.

Knives for Gardeners

In the same way that you find yourself reaching for a certain knife in the kitchen, you may prefer a favorite tool when working in the garden and around the yard. Serious gardeners swear by their special-purpose knives, and there are beautifully crafted models that (for a price) have the look of family heirlooms in the making.

- It's fascinating (and free) to make new plants by taking cuttings and severing layered stems, and the right knife can be a big help. A propagation or grafting knife has a short, ultra-sharp blade for making clean cuts. You can buy a model with a fixed blade, or a folding blade that makes it unnecessary to have a sheath.
- A pruning knife is sturdily built to handle the task of cutting smaller branches, and some models have a distinctively curved blade.

- For lopping vegetables in larger plots, it helps to have a lettuce or vegetable harvesting knife. The shorter edge of the blade is used to sever plants at the stem, while the longer edge is handy for trimming leaves on cabbage as well as harvesting. A plastic-handled version will cost less than one with wood.
- To keep blades at their optimal sharpest, you can carry a lightweight set of mini-hones with you in the yard. Use them for knives and pruners as you go about your work.

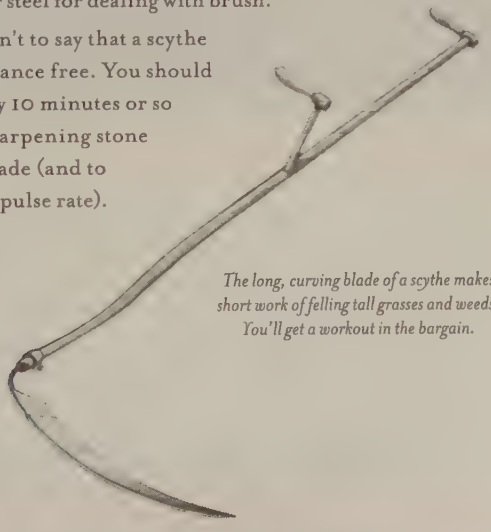


Special-purpose knives will make certain garden and orchard tasks go just a little more smoothly, especially if you regularly sharpen the knives with hones.

A Human-Powered Weed Whacker

For centuries, the scythe has been used to keep down brushy areas and also harvest crops. You operate it with a gently pivoting motion, feet planted securely and the upper body torqueing to and fro. It's a restful activity, and an ideal way to manage rank growth around the property, without the prep time and maintenance involved with operating a gas-powered string trimmer. They're available in beautifully curved wood, as well as in lightweight aluminum. You also can choose between blades suited for grasses and stouter steel for dealing with brush.

This isn't to say that a scythe is maintenance free. You should pause every 10 minutes or so to run a sharpening stone over the blade (and to lower your pulse rate).



The long, curving blade of a scythe makes short work of felling tall grasses and weeds. You'll get a workout in the bargain.

Over time, the blade will need to have its edge re-formed by peening with a special-purpose hammer and anvil, sold by the mail-order companies that deal in scythes.

One-Wheel Wonder

Imagine a cultivating tool that's somewhere between a plain old shovel and a fume-belching tiller, one that does its work efficiently but without a noisy engine. That's a fair description of a wheel hoe, a traditional device that you push like a little plow. They've been used for more than a century, and you sometimes can find them inexpensively at yard sales and auctions. If you're willing to spend a bit more, consider buying an updated version, with a pneumatic tire to make the rolling a bit easier and attachments including a variety of hoes, hillers, and cultivators.

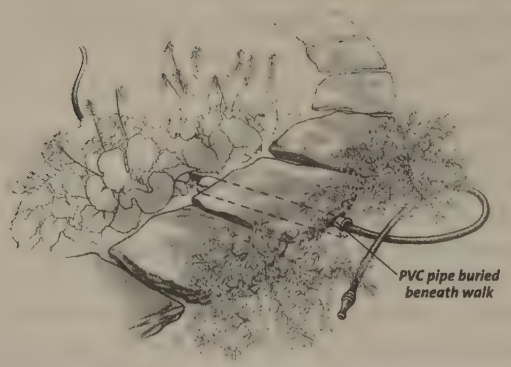
A wheel hoe makes efficient use of your energy, while sparing you the jarring, repetitive motions that can be involved with hoeing.

Hose-Taming Tricks

Garden hoses have a way of making trouble, sideswiping delicate plantings and getting underfoot. Here are a few ways of managing them.

- Put hose bumpers at the corners of beds, using either the commercial type that spins, the screw-in soil anchors sold for trellis wires, or large potted plants set a couple of inches into the ground.
- Get reel. Buy a hose reel, either freestanding or one intended to be mounted on a wall. There's even a model that uses the flow of the water to do the reeling for you.
- Bury hoses from the faucet at the house to individual gardens or beds.
- To avoid tripping on a hose across a walk, dig a tunnel under the walk (in an inconspicuous spot, if possible) and line it with a section of PVC pipe from the plumbing section of a home center or hardware store. It's easy to slip a hose through the plastic pipe.

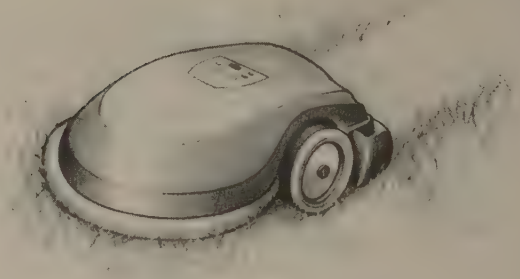
Continued ➔



By running a garden hose under a frequently used walk, you just might prevent a tripping accident. The hose can be pulled freely through a length of PVC pipe.

A Mindful Mower

The future is here—or at least it could be out on your lawn. The RoboMower, by Friendly Robotics, is a cute-looking automatic mower that quietly goes about taking care of that most tedious of outdoor tasks. It can operate for 3 hours on a battery charge, and it's kept from wandering off to neighboring lawns by a boundary wire that can be buried in the yard. A basic model sells for about $1,200. For a bit more, you can have a programmable RoboMower that will start mowing at a preset time and even chug on back to its docking station for recharging. And how do you keep a jealous homeowner from pirating your unattended mower? You can't, but the more-expensive model can be made to operate only when the correct four-digit code is input.



This sleek battery-operated robot mower will take over the job of trimming the lawn, freeing you up for other gardening and landscaping tasks.

SEEDS

Seeds and Seedlings

Jeff Cox

Seeds come in an amazing variety of forms and sizes; from the dustlike seeds of begonias to the hefty coconut. But all seeds have one quality in common: They are living links between generations of plants, carrying the vital genetic information that directs the growth and development of the next plant generation. Seeds are alive. They even carry on respiration—absorbing oxygen and giving off carbon dioxide.

As long as a seed is kept cool and dry, its life processes hum along on low. Most seeds remain viable for one to three years after they ripen on a plant. Some, such as parsnip seed, can't be counted on to sprout after more than one year, but others, like muskmelon seeds, can germinate after five years or more if storage conditions are favorable. In fact, certain seeds recovered from archaeological digs have sometimes proven to be viable after many hundreds of years.

Growing your own plants from seed can be one of the most satisfying and intriguing aspects of gardening. Almost all gardeners have grown vegetables from seed. But if you're interested in a challenge, you can start your own perennials, herbs, and even trees from seed.

Seed Germination

Moisture and warmth encourage seeds to germinate. When the seed absorbs water, its internal pressure rises, rupturing the seed coat. Growth hormones within the seed go into action, directing vital compounds to where they are needed and encouraging the growth of new tissue.

Continued ➔

All of these changes depend on temperature as well. Most garden seeds started indoors germinate best at a soil temperature of 75° to 90°F. Sprouting seeds also need air. A porous soil kept evenly moist (but not swampy) will provide enough air to support the germination process. Seeds often rot if they are submerged in water for days or if they are planted in completely waterlogged soil, so control the moisture.

After the germination process has been in action for several days (or, in some cases, for a week or more), the seed will change in ways that we can see. The root emerges and starts to grow, the stem grows longer, and then the cotyledons unfold. Once germination has begun, you can't reverse the process. If the sprouted seed continues to receive moisture, warmth, air, and light, it keeps growing. If not, it dies.

Most seeds have no specific light requirement for germination. However, some kinds of seeds need light to break dormancy and germinate, including many tiny seeds such as begonia, columbine, snapdragon, and petunia. Some larger seeds such as impatiens, spider flower, sweet alyssum, and dill are also best left uncovered. Sow light-sensitive seeds on the surface of fine, moist soil or seed-starting mix. Cover them loosely with clear plastic to retain moisture, or mist frequently.

A few types of seeds require darkness to germinate. For example, Madagascar periwinkle (*Catharanthus roseus*) will germinate far better if the flat is covered with black plastic or kept in a dark closet until seeds sprout.

Other seeds will germinate readily only if planted soon after they ripen. Angelica, hawthorn, and Solomon's-seal are three types of seed best sown soon after they are collected.

Check seed packet information to find out whether the seeds you want to raise have special germination requirements.

PRETREATING SEEDS

Some kinds of seeds require certain treatments before they'll start to germinate. No matter how ideal conditions are for germination, the seeds will remain dormant if pre-germination requirements have not been met. This characteristic, called innate dormancy, helps ensure survival in nature, because the seeds wait out the winter or the dry season before sprouting.

Certain seeds require a period of moist cold. This mechanism is common in plants native to climates with cold winters, especially perennials, trees, and shrubs. Other seeds have chemicals in their seed coats that must be soaked away before the seeds will germinate. Some seeds are slow to absorb enough water to start germination because of thick or impermeable seed coats. Plants native to areas with seasonal dry spells often have this type of dormancy. If you understand these dormancy mechanisms, you can work around them and coax the seeds to germinate.

Even seeds that don't have dormancy requirements may be slow to germinate. Appropriate pretreatment can significantly increase germination rate and reduce germination time.

Stratification. Some seeds must be exposed to cold for a certain period before they will break dormancy and germinate. Stratification simulates natural conditions when a seed overwinters in cold, moist ground.

Seeds of various perennials, including wild bleeding heart, gas plant, and cardinal flower, need a cold period. You can plant them outdoors in fall, or spring plant after giving them a cold treatment. Many woody plant seeds also require stratification, including birch, dogwood, false cypress, and spruce. Some tree and shrub seeds, including arborvitae, cotoneaster, and lilac, are double-dormant, which means they require a warm, moist period followed by a cold period to germinate. If planted outdoors in fall, these seeds may not germinate for two years.

Scarification. Some seeds, such as morning-glory, sweet pea, okra, baptisias, lupines, and others, have hard seed coats that inhibit water absorption. To make a hard-coated seed absorb water more readily, nick the seed coat. Be careful not to damage the embryo inside the seed. On large seeds, use a knife to cut a notch in the seed coat, or make several strokes with a sharp-edged file. If you have only a few seeds to treat, you can scrape the seed coats with a nail file. Or, you can scarify medium-sized or small seeds by rubbing them between two sheets of sandpaper. Yet another method involves putting a sheet of medium-grit sandpaper inside a cookie sheet or rectangular metal cake pan (one you don't mind getting scraped up), putting a layer of seeds on top of the sandpaper, and rubbing over them with a sanding block to wear down the seed coats.

After scarifying, soak seeds in lukewarm water for several hours before planting.

Presoaking. Even seeds that have thin seed coats can benefit from a soak in lukewarm water for several hours before planting. Large seeds such as peas, beans, and okra will germinate faster if soaked overnight first. Before planting, drain the seeds and dry them briefly on paper towels to make them easier to handle.

Presprouting. Presprouting takes seeds one step further than presoaking. It's a good way to handle such seeds as melons, squash, and their relatives, which need plenty of warmth for germination. Because sprouted seeds can tolerate cooler temperatures, you can concentrate your population of germinating seeds in one warm place and farm out the presprouted seedlings to cooler spots where they will receive plenty of light.

Presprouted seeds are fragile; handle them with great care. Be sure to plant them before their roots grow together and tangle. Plant sprouted seeds in individual containers of premoistened potting mix. Cover them gently but firmly with potting mix and treat them as you would any container-raised

seedling. Presprouted seeds may be planted directly in the garden, but it is better to keep them in containers until the roots become established.

Why Start Your Own?

Nancy Bubel

Security and adventure might be considered opposites in some situations, but the gardener who raises plants from seed can experience both. Security—that confidence in the future that springs from one's own ability, forethought, and preparation—and adventure—the soaring sense of "anything is possible" and "there are so many interesting things to try"—are well known to those who grow new varieties, experiment with new methods, and dabble in plant breeding and seed saving.

Skill in raising vegetable plants from seed is the very cornerstone of gardening independence. Choice of seeds and careful handling can bring you not only earlier harvests, but better vegetables. You can select varieties of food known to keep or process well so that the winter season, for which we gardeners are always planning, will be a time of abundance. Likewise, good eating will be yours all summer long from the selection of fresh vegetables you've planted for their superior quality.

Some varieties of vegetables and flowers can only be grown from seed.

The Reasons

I suspect that I'd continue to raise my own seedlings even without a good excuse, because I enjoy the process, but when I stop to think about it I realize that there are all kinds of good reasons for nurturing one's own plants from seed.

Earlier Harvests. You can get a much earlier start in the garden, and therefore put fresh food on the table sooner, when you've grown flats of cabbage, tomatoes, eggplant, and peppers indoors for setting out when the weather mellows. The sooner you can begin picking from your garden, the greater your yield for the year.

Greater Variety. Varieties of plants offered by commercial seedling vendors represent but a tiny fraction of the possibilities open to you as a gardener. Buying started plants severely limits your options for raising vegetables of special flavor, insect or disease resistance, or extra nutritional value. If, for example, you want to grow Juwarot or A+ Carrots (extra high in vitamin A) you'll have to start with seeds. Looking for special gourmet foods like globe artichokes, watercress, or Japanese melons? It's back to the seed catalogs. Peppers that are hot, but not too hot? Start your own Hungarian wax plants. Delicious, mild, sweet Golden Acre or Jersey Queen cabbage? You need to start those with seeds.

Stronger Seedlings. Seedlings you've grown yourself can be super seedlings. If you do all the right things at the right times, you'll have the best that can be grown, and you'll know that your plants have well-developed roots growing in good soil that hasn't been hyped with chemicals. You can even plant organically raised seeds to give your plants an extra start on excellence.

Buying the Best Seeds

Here are some tips to help you to get the most from your seed order:

- Send for several seed catalogs so you can compare offerings and prices.
- Keep seed catalogs for reference.
- Some companies offer small seed packets at reasonable prices. Seed mixtures give you a wide variety of plants from a single packet.
- Days to maturity is an average—the actual days in your area may be different.
- Hybrids may offer advantages such as early harvest or high yields but are usually more expensive. Open-pollinated cultivars may taste better and produce over a longer season, and they tend to be cheaper.
- Some seed is routinely treated with synthetic chemical fungicide. Specify untreated seed if you prefer it.
- Read descriptions and choose cultivars with qualities that are important to you.
- Certain catalogs specialize in plants suited to specific regions of the country.
- All-America Selections seeds grow and produce well over a wide range of conditions.

Healthier Seedlings. By raising your own plants, you minimize the chance of introducing soil-borne diseases to your garden. Club-root and yellows that affect cabbage, along with anthracnose, tobacco mosaic, and wilt, are some examples of plant diseases you may avoid importing if you grow your own. Of

Continued ➔

course, you must use uncontaminated soil, and, especially in the case of mosaic in pepper, eggplant, and tomato seedlings, avoid handling tobacco around the plants.

Cost Saving. You'll save money. Well, maybe. Certainly for the price of a dozen greenhouse tomato plants you can buy a small handful of seed packets, each of which will give you plants to share or to sell, or extra seeds to save for the following year. So many interesting plants can be grown from seed, though, that once you start raising seedlings you might find that you tend to put some of that saved money back into seeds of other kinds. But since you're likely to eat even better as a result, you may well consider that you're still far ahead.

Satisfaction. Creative satisfaction ought to count for something, too. From settling a well-chosen seedling in a pot of its own carefully prepared soil and watching it grow greener, sturdier, and leafier, to picking and eating the peppers, eggplant, or other nutritious food the mature plant finally bears, you've been involved all the way, and you can see that your skillful care has made a difference.

Enjoyment. At the very least, planting seeds indoors is a good cure for the winter doldrums—those bleak, cold days when February seems like a permanent condition and you feel you simply must do something to nudge the season into turning. Choose your earliest plantings judiciously, though. You don't want them to be past their prime when you set them out in the garden. Onions, chives, peppers, certain wildflowers and perennial plants, and houseplants like coleus and geraniums are good candidates for beginning the season.

First the Seeds

Nancy Bubel

You have in your hands an array of seed packets and perhaps a few jars of seeds you've saved yourself. You're anxious to plant, to get a start on the growing season that still seems far away. Take a minute now, if you will, to be aware of what the seed really is before committing it to the soil. Dry, flaky, hard, smooth, warted, ridged, powdery, or wispy, these distinctively shaped particles may look as lifeless as the February garden patch. Don't be deceived, though. Seeds don't spring to life when you plant them. Seeds are alive.

Often symbols of beginning, seeds are living guarantees of continuity between generations of plants. Inside even the most minute, dustlike grain of seed is a living plant. True, it's in embryonic form, possessing only the most rudimentary parts, but it lives, and it is not completely passive. At levels that we can't see, but laboratory scientists can measure, seeds carry on respiration. They absorb oxygen and give off carbon dioxide. They also absorb water from the air. Seeds need a certain minimum amount of moisture within their cells in order to make possible the metabolic processes by which they convert some of their stored carbohydrates into available food. Thus they maintain their spark of life—dim though it may be—until conditions are right for them to complete their destiny as germinated plants.

Begin by gathering your stored and bought seeds.

The Botanical Facts

By strict botanical definition, a seed is a ripened fertilized ovule containing an embryonic plant and a supply of stored food, all surrounded by a seed coat. In practice, though, gardeners use many seeds that are actually fruits (the mature ovary of a flower containing one or more seeds). A kernel of corn is really a seedlike fruit. Carrot, dill, and fennel seeds are, technically, dry, one-seeded fruits.

Seeds, then, are completely self-contained. Within the boundaries of the hard, dry coat that protects them, they possess enough food energy to carry them through their dormancy and into their first few days as seedlings. They have all the enzymes they'll need to convert this stored food into a form their tissues can use, and they carry within their cells the genetic information that directs what they will be and when and how.

Let's look at the bush bean as an example—not a typical seed, perhaps, but one in which it is easy to see the parts and their arrangement that are common to all seeds. The good old garden bush bean is the favorite of botanists for this purpose because its size and structure make it possible for us to see clearly how it is formed.

If you soak a bean seed in water for a few hours, the hard outer coat will slip off easily. The bulk of the bean that you now see is composed of the cotyledons, the two identical fleshy halves that comprise the "meat" of the seed. Cotyledons are rudimentary leaves. Unusually large and thick in the bean, they contain stored fat, carbohydrates, and protein. Both cotyledons are attached to a rudimentary stem, and they curve protectively over a tiny leafy bud. The root tip, at the other end of the seed, will elongate into the first root of the plant when the seed germinates. Any seed, no matter how tiny, wispy, or irregular, will possess these features: cotyledons (sometimes one, more often two), a brief stem, a leafy bud, and a root tip.

Most seed-bearing garden vegetable plants are dicots; that is, they possess two cotyledons. Beans, tomatoes, celery, cabbage, and other vegetable seedlings are dicots. When they germinate they send up two "wings." Monocots, with just a single cotyledon, are represented by the grass family (Gramineae), which includes corn, wheat, rye, and other cereal crops. These seeds send up the familiar, single grasslike spear of green.

Words to Know

Seed: A plant embryo and its supply of nutrients, often surrounded by a protective seed coat.

Seed germination: The beginning of growth of a seed.

Viable: Capable of germinating; alive.

Dormancy: A state of reduced biochemical activity that persists until certain conditions occur that trigger germination.

Seedling: A young plant grown from seed. Commonly, plants grown from seed are termed seedlings until they are first transplanted.

Cotyledon: The leaf (or leaves), present in the dormant seed, that is the first to unfold as a seed germinates. Cotyledons often look different than the leaves that follow them. In seeds such as beans, they contain stored nutrients. Also called seed leaves.

Endosperm: Specialized layer of tissue that surrounds the embryo.

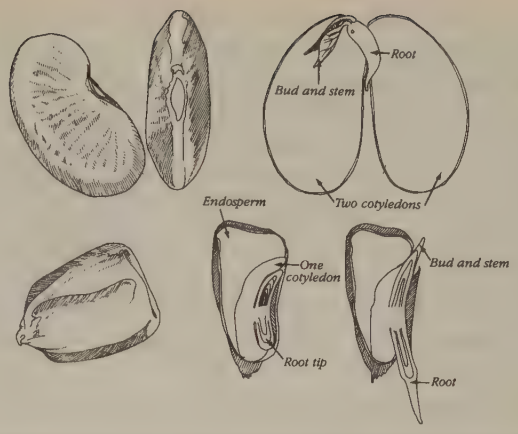
Scarification: Nicking or wearing down hard seed coats to encourage germination.

Stratification: Exposing seeds to a cool (35° to 40°F), moist period to break dormancy.

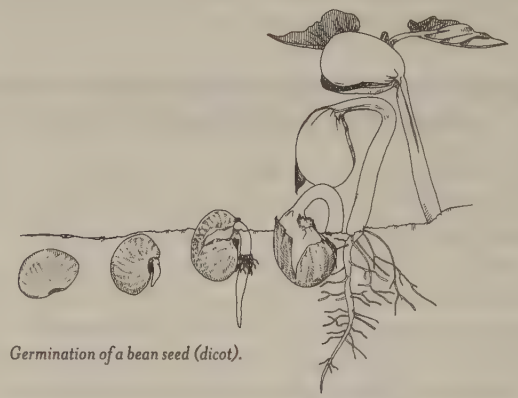
Damping-off: A disease caused by various fungi that results in seedling stems that shrivel and collapse at soil level.

In many seeds, some of which are important food crops in their own right, the stored food is not contained in the cotyledons, as in the bean, but in a layer called the endosperm, which surrounds the embryo. This part of the seed varies in different species. It may consist of starch, oil, protein, or waxy or horny matter, but whatever its form, its function remains the same—to nourish the seed from the time of its maturity on the parent plant until the beginning of the next growing season, when conditions will be favorable for its success as a plant in its own right. Often, of course, the tasty endosperm is what we're after when we raise the crop, as with buckwheat, corn, wheat, and rye.

Just to keep the record straight: Cotyledons of some plants may synthesize nourishment needed by the seed; others may both make and store food for the embryo. If you find that fact surprising, reflect that there is more—much more—that we don't yet know about seeds.



Cross sections of a bean seed, or dicot (top), and a corn seed, or monocot (bottom).



Germination of a bean seed (dicot).

Germination of a corn seed (monocot).

Dormancy

We're just beginning to appreciate, too, how much is still unknown about dormancy in seeds. If you've ever tried unsuccessfully to start a row of lettuce in midsummer heat, you have an idea of how a dormant seed behaves. It refuses to germinate, even if otherwise viable, when it lacks the right temperature, moisture, and oxygen supply that would ordinarily favor germination. Even though conditions might seem favorable for germination, such as those that occur in midsummer, they might not be right to induce germination in certain seeds.

Continued ➔

It can be annoying to miss a seeding date for a certain crop and be unable to plant it later in the summer; however, the ability of seeds to remain dormant, in varying degrees, has contributed to the survival of seed-bearing plants as we know them. Certainly a plant that needs 90 days of warm weather to mature will be doomed to failure if it sprouts as soon as it matures at the end of the summer, shortly after the first frost. Lettuce, likewise, has less chance of success under random conditions when sown in hot, dry soil than it does in the moist, cool surroundings that promote its quick growth. Dormancy, then, is a protective device, designed to assure the continuity of the species.

A seed may be dormant because its embryo is still immature, its seed coat is impermeable to water or to gases, its coat is too unyielding to permit embryo growth (although this is rare), or because of a metabolic block within the embryo. Often, more than one of these factors operates at the same time.

History of Seed-Bearing Plants

We know very little about the origin of seed-bearing plants. Charles Darwin called it an "abominable mystery." Spore-bearing plants, like ferns, existed first, followed by gymnosperms, like the evergreens, which shed their seeds unencased. Discoveries in West Virginia of early seeds encased in cupules—incompletely fused seed coats—have pushed the date of known true seeds back to 360 million years ago. Angiosperms, flowering plants in which the seeds (encased in an ovary) are more fully protected, appeared during the Cretaceous period (roughly 100 million years ago). Eventually they dominated the more primitive spore-bearing forms of green life, probably partly because the well-developed seed embryo, clinging to the parent plant until thoroughly mature, had the edge over the naked, randomly shed seed.

Although we still know so little, we know enough of the internal workings of the seed to stand in awe at its variety, its toughness, and its practical simplicity.

Breaking Dormancy

As a gardener, it is often in your interest to try to break dormancy in certain kinds of seed. Since you intend to give the plant special care and optimum conditions, you can often do this and get away with it. For example, if you are anxious to raise a fine bed of lettuce to eat with your midsummer tomatoes—a real mark of gardening expertise—how do you give your lettuce seeds the message that it's all right for them to sprout?

Studies of seeds in research laboratories have furnished valuable clues to the interruption of dormancy. The period is relative, not absolute. In fact, there seems to be general agreement among a number of scientists who have studied this phenomenon that the whole question of seed dormancy must be considered a matter of balance between the growth-promoting and growth-inhibiting substances that are found in all plants.

So how do you tip that balance in your favor? Here is what the experts have discovered.

Temperature. Chilling the seeds often breaks dormancy.

Light. Subjecting the seeds to light—even a dim continuous light or a sudden bright photoflash—will sometimes help, especially with lettuce. Germination depends on the total amount received. The dimmer the light, the longer the necessary exposure.

Red Light. Exposure of some seeds to red light (660 nanometers) promotes seed germination. Experiments with lettuce bear this out. However, far-red light (730 nanometers) has been found to inhibit seed germination. Practically speaking, this means that seeds that are difficult to germinate will often do better under fluorescent plant lights. Some seeds won't germinate when shaded by leaf cover, probably because the leaves filter out helpful rays while allowing the inhibiting far-red light to reach the seeds.

Dormancy is seldom a problem with vegetable seeds, except for some heat-sensitive seeds like lettuce and celery. Beans, mustard, and many other vegetable seeds never go dormant. Carrots and parsnips do need a month of afterripening following harvest before they'll germinate. Seeds you've purchased have had time, of course, to undergo any necessary afterripening in the months between collection and planting. Dormancy is not an uncommon problem when trying to germinate seeds of wildflowers, trees, or shrubs.

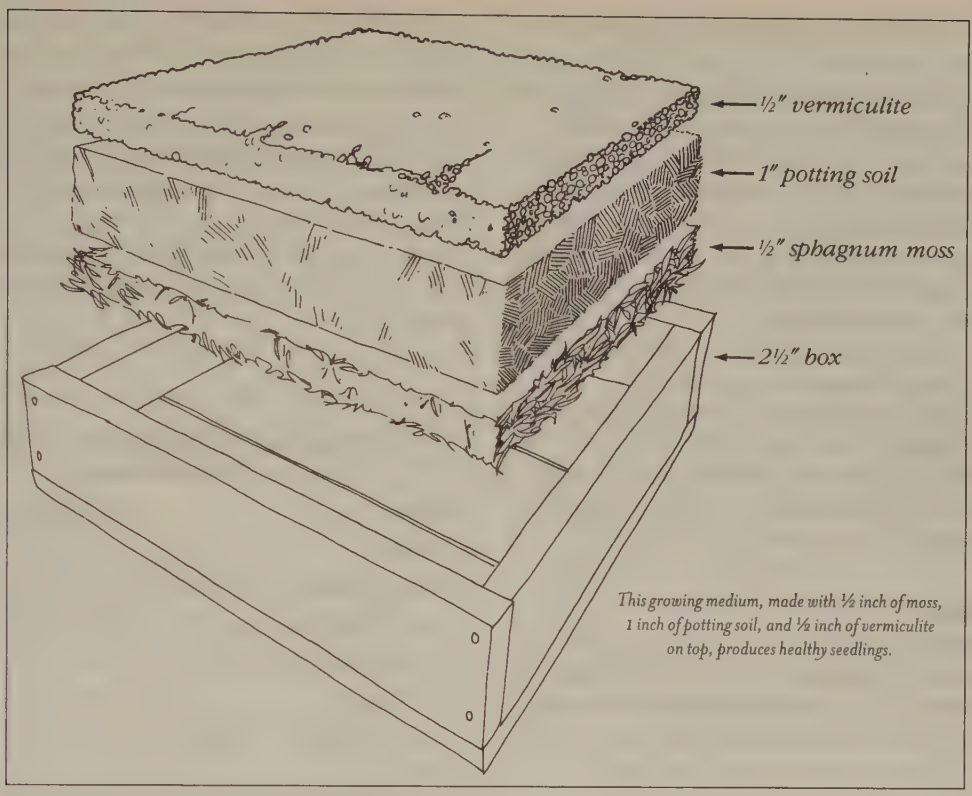
Choose Your Medium

Nancy Bubel

The first step in encouraging your seeds on their way to being the plants they really want to be is to prepare a starting medium that will nurture the seeds through the critical germination and seedling stages. The stuff to which you entrust your seeds should match the following description:

- Free from competing weed seeds, soil-borne diseases, and fungus spores.
- Able to absorb and hold quantities of moisture.
- Not so densely packed that vital air is excluded.
- Naturally derived and free from any substance you would not want to put in your garden.
- Noncrusting.

Since the physical conditions of their surroundings—temperature, moisture, air, and light—are more important to



This growing medium, made with ½ inch of moss, 1 inch of potting soil, and ½ inch of vermiculite on top, produces healthy seedlings.

germinating seedlings than the nutrient content of the soil, these first mixtures in which you plant your seeds needn't be rich. In fact, it's better if they're not. But they should be light, spongy, and moist. It's a nice touch to start seeds in one of the special seed-starting media, like vermiculite, and then to transplant the seedlings into a potting soil mix that contains more nutrients. Some gardeners prefer to plant seeds directly in a potting soil mix. Many good commercial mixtures are available, or you can mix your own potting soil from the recipes listed later in this section.

I wouldn't recommend starting seeds in plain garden soil, because it tends to pack and crust when kept in shallow containers indoors. In addition, unsterilized garden soil may harbor fungi that cause damping-off, a disease that makes young seedlings shrivel and wilt at soil level and sometimes even interferes with complete germination. Soil in which such diseased seedlings have been grown must be pasteurized (see Heat Treatment later in this section) before another batch of seeds is planted in it. I find it easier to use fresh potting soil for each new seedling crop and to use the old soil for potting up young trees or rooted herbs.

Three Favorites

I've had good results planting seeds in each of the following three media.

Vermiculite. This is a form of mica which has been "popped" like popcorn by exposing it to intense heat. The resulting flakes are light and capable of holding large amounts of water. Vermiculite also absorbs nutrients from fertilizers and other soil components and releases them gradually to plants. Be sure to buy horticultural vermiculite, not the kind sold for the building trade, which is coarser, highly alkaline, and often contains substances toxic to plant roots.

A Mixture. Equal parts of vermiculite, milled sphagnum moss, and perlite combine to make another good starting medium. This provides a spongy, friable seedbed that promotes good root development. Perlite, despite its plastic appearance, is a natural product, a form of "popped" volcanic ash, and while I do not like to use it alone, as I do vermiculite in some cases, it promotes good drainage in seed-starting mixes. The moss must be milled sphagnum, which is very fine, not peat moss, which is too coarse for small seeds and tends to dry and crust.

Mix these three components together thoroughly before dampening. A large old tub or bucket set on newspaper makes the job easier and spillage less of a problem. When moistening this and all other soil mixtures, I like to use warm water because it is more readily absorbed. This seems to be especially important for mixtures containing sphagnum moss, which tends to float on cold water in a dustlike layer that takes ages to soften and swell. It is also a good idea to prepare your soil mixture several hours before you intend to plant seeds. Then, if you have added too much water, you can simply pour off any that puddles on the upper surface, before planting the seeds.

Continued →

A Three-Layer Arrangement. This medium is composed of a bottom layer—about one-half inch—of torn pieces of sphagnum moss that has been well dampened, then a one-inch layer of good potting soil, topped by a one-half-inch layer of vermiculite. The bottom layer of moss should not be finely milled. I use clumps of moss gathered in our woods. The air spaces trapped by the ferny fronds of the moss promote excellent root development, I've found, and the moss retains water, too. I tear up the wads of moss into small pieces so that individual plants can be removed more easily when it's time to transplant them.

You can also mix chopped sphagnum moss with other potting soil ingredients. Some evidence has shown that sphagnum moss exerts a mild antibiotic effect that helps to control bacterial diseases of seedlings. (A disease-causing fungus, *Sporotrichum schenkii*, has been found in sphagnum moss. Wash thoroughly after handling the moss, and wear gloves if you have any skin breaks on your hands.)

Alternative Media

There's nothing absolute about the mixtures that I use. Other gardeners have obtained good results with the following seed-starting media. What you choose may depend partly on what is easily available to you and on your personal reactions to the feel of the stuff.

Other options include:

- Equal parts of milled sphagnum moss and vermiculite.
- One part milled sphagnum moss and two parts each of vermiculite and perlite.
- Shredded moss alone (well dampened beforehand).
- Potting soil, either commercial or home mixed.
- A cube of sod, turned grass side down, which works well for the planting of larger seeds, like squash, melons, and cucumbers, and supports the seedling until it is planted out in the garden.

Feeding the Seedlings

Neither vermiculite, perlite, nor sphagnum moss contains the nutrients necessary to support plant growth. Seedlings growing in these substances, or mixtures of them, must be fed regularly until they get their roots in real soil.

Such liquid feeding, carried on over a period of weeks, amounts to hydroponic culture, with the growing medium serving only to hold the plants upright and to condition the roots. Seedlings benefit from the more complex interactions taking place in real soil, so they should eventually be transplanted to a growing medium.

Potting Mixtures

A seed-starting medium provides good physical conditions for seed germination. A potting medium contributes nourishment for the growing plant. There are all kinds of potting mixture recipes from which to choose. Here are some options, along with a few hints about their suitability or limitations.

The amounts in each recipe are given in parts. A part, of course, can be any measure of volume ranging from a teacup to a bushel basket, as long as the measurement used is consistent. I'd suggest making up more soil mix than you think you'll need while you have all the ingredients assembled. Mix the components thoroughly as you go, just as if you were making granola.

Temperature Necessary to Kill Soil-Inhabiting Pests and Diseases

Pests	*30 Minutes at Temperature*
Nematodes	120° F
Damping-off and soft-rot organisms	130° F
Most pathogenic bacteria and fungi	150° F
Soil insects and most plant viruses	160° F
Most weed seeds	175° F
A few resistant weeds, resistant viruses	212° F

Source: George "Doc" Abraham and Katy Abraham. *Organic Gardening Under Glass* (Emmaus, Pa.: Rodale Press, 1975).

Cruso's Potting Soil

one part commercial potting soil or leaf mold
one part sphagnum moss or peat moss
one part perlite or sharp sand

This is the formula for potting soil that Thalassa Cruso recommends in her book *Making Things Grow*. For fast-growing seedlings, I like to change the proportions to two parts soil or one part soil and one part compost, mixed with one part moss and one part sand or perlite. As originally formulated, for houseplants, the mixture is a bit lean to support strong seedling growth.

Good and Simple Potting Soil

one part finished compost
one part vermiculite

Easy to mix. Moisten it well before setting plants in it.

Home-Style Potting Soil

one part finished compost
one part either loose garden soil or potting soil
one part sharp sand, perlite, or vermiculite, or a mixture of all three

This one can be made without buying any ingredients if you have access to sharp sand.

A Rich Potting Soil

one part leaf mold
two parts either loose garden soil or potting soil
one part compost or rotted, sifted manure
This potting soil is especially good for lettuce and cabbage transplants.

A Lean Potting Soil

one part either loose garden soil or potting soil
one part perlite
one part vermiculite
one part milled sphagnum moss
one part sharp sand
This is mostly physical support for the plants. Use this mixture for plants that should grow slowly, such as cactus.

Amended Potting Soil

four parts either loose garden soil or potting soil
two parts sphagnum moss or peat moss
two parts leaf mold or compost
two parts vermiculite
six teaspoons dolomitic limestone
The limestone helps to neutralize acids in the leaf mold and peat moss.

If you want to formulate your own potting mixture from what you have or can readily find, you'll probably be on safe ground if you include each of the following:

- Soil, preferably loam, for nutrients.
- Sand or perlite for drainage. Gravel may also be used in the bottom of a solid container but not as part of a soil mix.
- Compost, leaf mold, vermiculite, or moss for water retention.

Heat Treatment

Commercial potting soil should be free of harmful bacteria and fungi, but garden soil is, of course, teeming with organisms. Most of them are beneficial. I never heat-treat or otherwise "sterilize" my soil. Besides being a large nuisance, the process kills helpful soil organisms and, at temperatures above 180°F (82°C), releases dissolved salts that can be toxic to plants. Even at 160°F (71°C), some salt-releasing breakdown occurs.

If you decide to sterilize a batch of soil, the following methods will work. Plan a picnic supper or weekend trip when you do treat your soil, because the kitchen will smell awful!

Using the Oven. Before heating the soil, moisten it thoroughly so that small puddles form when you press your finger into it. Bake the soil in metal pans in a preheated 275° F (135° C) oven. Small amounts, a gallon or so by volume, should be ready within 30 to 40 minutes. Larger quantities, a half bushel or so, may need to remain in the oven for 1½ hours. It is important that the soil be wet. The steam generated by the water penetrates the spaces in the soil. Dry soil takes much longer to treat and smells much worse.

A meat thermometer inserted in the soil will indicate when it has arrived at the proper temperature to kill offending organisms. Damping-off fungi, for example, die at 130° F (54° C), and a temperature of 160° F (71° C) kills most other plant viruses and pathogenic bacteria. Avoid overheating the soil, for you want to retain as many of the more numerous helpful soil microorganisms as possible. Soil that has been baked should be rubbed through a hardware cloth screen to break up the clumps before using.

Using the Microwave. Soil poured into plastic bags can be sterilized in a microwave oven. Do this in batches of up to ten pounds. Placing the bags in the oven for 7½ minutes will kill most damping-off and root-rot fungi. Some researchers report, however, that microwave treatment changes soil pH, cation exchange capacity, and mineral content.

Using Solar Energy. An easier method recently developed at the University of California uses solar heat. Fill gallon-sized black plastic planting pots with moist soil and then place each pot in a clear plastic bag. Tie the bag closed and set the bagged pot in a sheltered location where it will receive full sun. Two weeks of direct-sun treatment in warm weather should kill most disease organisms.

Using Boiling Water. Pouring boiling water over a flat of soil does not sterilize it, but kills many microorganisms.

Helpful Hints

Perhaps the following hints will save you a bit of trouble, too.

Collect Soil in the Fall. The time to collect good garden soil for spring seed starting is in the fall, before the soil freezes solid. Even if you're lucky enough to have a winter thaw at the time you're doing your planting and transplanting, the soil is likely to be mucky, and you may not be able to dig very deeply, either.

Make Leaf Mold. There's leaf mold and there's leaf mold. Make your own seasoned pile for use in potting mixtures. One year I scraped up a bushel of lovely, crumbly, woodsy-smelling leaf mold from the edge of our woods and put it into my soil mixture. All the seedlings growing in this "special" mixture died. I'm not sure whether the stuff was too acid or if it was toxic in some other way, but from now on I test such soil amendments on a few plants rather than gambling my whole crop of early seedlings.

Avoid Peat Moss. Watch out for peat moss, too. Personally, I don't like it. It's chunky, unmercifully hard to moisten, and it crusts when it dries. I would never use peat moss in a soil mixture when I could get milled sphagnum moss. If you must use it, wet it very thoroughly several hours before you need it. I'd caution you, too, against using wetting agents (surfactants)

Continued ➔

in potting mixes or irrigation systems. They tend to reduce soil water retention, and their effect on people who handle and consume them hasn't been tested. Even mild soaps like Basic H, when mixed with soil in highly dilute solutions, reduced the growth of vital root hairs.

Use Builder's Sand. Sharp sand, specified in the soil recipes, is coarse builder's sand. Sand brought from the seashore is too fine and too salty. Don't use it for plants. Even lake sand or sand scraped up by the roadside is too fine for our purposes. It will pack into a cementlike mass that kills plant roots. I know—I used it by mistake . . . once.

Make Your Own Mix. What would I use if commercial potting mixture ingredients like vermiculite and perlite were unavailable? I would mix equal parts of compost, good garden soil, rubbed through a screen, and torn moss. I would not use garden soil alone, for no matter how good the soil, it tends to pack and harden when used indoors in small pots.

Containers

Nancy Bubel

Your seeds are ready. Your soil is mixed. Now it's time to comb closets, attic, and cellar for likely discards to hold the soil and provide a temporary home for your growing seedlings.

The ideal container for starting seeds should be no more than two to three inches deep. One that is deeper will only use up more potting soil. A shallow pan, though, will dry out quickly and limit root development. The soil holders you use for germinating seeds do not necessarily need to have drainage holes. You can prevent pooling of water around plant roots by choosing the right growing mediums to fill the containers. Long, narrow flats fit neatly under fluorescent lights; however, don't use flats that are so long that they will be heavy and difficult to handle when filled with wet soil.

Types of Containers

I've grown seedlings in all of the following kinds of containers, for different reasons and with varying results. Each has its place. Some are more useful than others. Certainly it is preferable, all else being equal, to make use of some of the many throwaways that clutter up our daily lives, but there are times when a specially prepared device will be more effective than anything else. It's silly to make do, unless you must, when with a little effort and some scrap wood you could rig up a really fine seedling-care system. At any rate, here's my list of container candidates, briefly evaluated for effectiveness, cost, and useful life.

Eggshells and/or Egg Cartons. They are inexpensive but not really much good in the trials I've run on them. Neither the shells nor the egg carton sections can hold much soil, and they dry out fast. I think it's a mistake, too, to start a child gardener with one of these cute but impractical gimmicks. The learning child deserves good equipment that will help him or her to be successful. Something about planting seeds in eggshells seems to have captured the imagination of armchair gardeners, and every spring you'll see articles in magazines suggesting the method. Go ahead and try it if it appeals to you. Just don't expect great results.

Milk Cartons. Yes, they're free, good for one growing season, and they fit together well under lights. You can either halve a half-gallon milk carton the long way or cut one side out of a quart carton. If you don't buy milk, no doubt your friends, relatives, or neighbors would save their cartons for you. Even the little pint and half-pint cartons may be used for larger individual transplants.

Aluminum Disposable Pans. The loaf pans make fine seedling trays. They last for several years, work quite well, and can be had free if you know people who will save them for you. The shiny sides of the loaf pan reflect light back onto the seedlings. One of my best generations of eggplant seedlings was raised in an aluminum loaf pan on the kitchen windowsill. Pie pans are more of a last resort for plants, for they are too shallow to hold enough soil for proper moisture retention and root development. They're fine for sprouting seeds, though, if you transplant promptly.

Peat Pots. A tray of seedlings all tucked into peat pots looks neat and satisfying, but despite the assumption that plant roots will readily penetrate the walls of the pot and find the surrounding soil, I have not found this to be true in all cases. More than once I've uprooted a plant and found its roots pretty well confined to the peat pot. Also, unless grouped closely together, peat pots dry out fast.

Peat Pellets. These compressed-soil pots in netting seem to offer less resistance to plant roots than the peat pots if you remove the net when you plant the seedlings out. However, even though the net has air spaces, it often appears to inhibit plant roots. The soil mixture of peat pellets sometimes contains a chemical fertilizer. Peat pellets are easy to use and neat, but they are expensive and can't be reused.

Plastic Gallon Jugs. Cut-down plastic gallon jugs have worked fairly well for me, but I prefer the long, narrow cut-down milk cartons, which seem to accommodate more seedlings and waste less space under lights. Plastic jugs are free, lightweight, last two or three years, and may be further recycled by saving the cutoff top to put over seedling plants in the garden for frost protection.

Shoes. Yes, shoes. I've tried planting melon seeds in cast-off shoes on the advice of an elderly gardener whose flourishing crops indicate he must be doing something right. The shoes were fun to use and they certainly made a stir when visitors

noticed them, but I can't honestly say that they made any difference in the plants that grew in them.

Bricks. For another unconventional and more widely adaptable seed-starter, use an unglazed brick set in an open frame of scrap wood that extends 1½ inches above the top of the brick. On top of the brick, put an inch-thick layer of moist sphagnum moss or vermiculite, and plant seeds in it. Then set the framed brick in a tray of water. The water should always touch the brick, but should not cover it. The continuous supply of moisture, coupled with good drainage and aeration, encourages good seedling germination.

Market Packs. These are rectangular trays made of pressed fiber. I think they are preferable to peat pots. The packs are not cheap, but they last for several years, fit together well in storage, and allow plenty of depth for root development. Also, unlike the larger flats, they may be kept on a sunny windowsill.

Clay Flower Pots. Clay pots last a long time and are fine for special transplants. They are the best containers for starting watercress seeds, because they can be kept in a tray of water so that the soil is constantly moist. As far as I'm concerned, though, they are too costly and unwieldy for most transplanting. I use small plastic pots to start cucumber and melon seedlings.

Household Discards. Chipped enamel broiler pans, rusty cake tins, or lopsided dishpans make good containers for groups of transplants. Old refrigerator crisper drawers work well, too, especially for lettuce and other leafy crops grown under lights in winter, because they hold plenty of soil.

Cottage Cheese Cartons. These cost nothing and outlast at least one use. I use them primarily for give-away seedlings, because in my setup the round shape of the containers wastes space under the lights. They do fit on most windowsills, though, which can be a boon to the gardener without lights. Incidentally, if you do set them at your window, you'll probably need to provide some protection—a tray or foil liner—to prevent spills and splashes from spotting your windowsills.

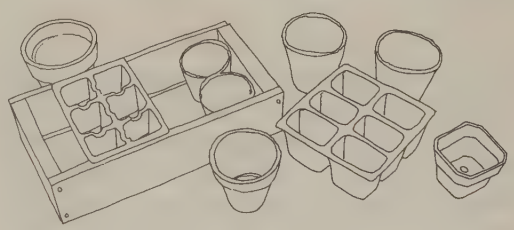
Flats. My favorite. When you raise your own seedlings, there is no such thing as too many flats. A flat is nothing more than a four-sided frame made of wood, about three inches wide, with slats nailed across one open side. The slats should be spaced one-eighth to one-fourth inch apart to allow for drainage. Most flats are rectangular, because that is the most efficient shape.

Six 12- by 16-inch flats will fit on each shelf of a 26- by 48-inch, double-bank fluorescent light cart. I wouldn't recommend making flats any larger than about 14 by 18 inches, or they'll need extra bracing to hold the weight of all that soil, and then they'll be too ungainly to handle. Flats are basic. Make as many as you can find time and materials for. You won't regret it.

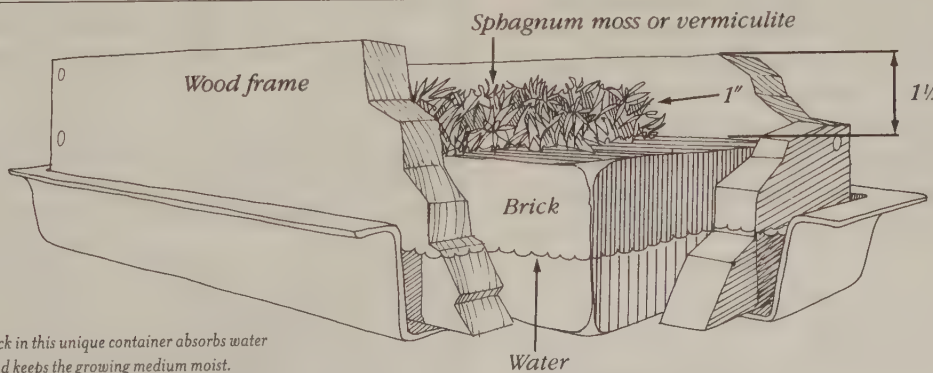
Plastic Trays. Commercial plastic trays 2 inches deep and 18 to 20 inches long work well and last a long time, but they are costly. Poke a few drainage holes in them with an ice pick.

Soil Blocks. These are better than peat pots because they promote good root growth without forming a barrier. They take time and special equipment to make, though. You need a soil-block mold, a metal device with a plunger that ejects blocks of soil from a mold; a tub for mixing; soil composed of two parts peat moss that has been rubbed through one-fourth-inch hardware cloth, one part garden soil, and one part compost; water; and a tray.

To make a soil block, wet the soil mix until it forms a slurry. Then pack a four-cube block maker with the wet mix, level off the top of the mold, and eject the cubes onto a tray. Plant a single seed in each block, or plant two and cut off the extra seedling if both germinate.



Any of a variety of containers, bought or found, can be used to start seedlings.



The brick in this unique container absorbs water and keeps the growing medium moist.

Continued →

In my experiments with soil blocks, I found that they do indeed promote good root growth. For me, though, they had two disadvantages. The first was the time and trouble necessary to make the blocks. Secondly, the blocks must be very carefully and frequently watered from above so they don't disintegrate.

Speedling Flats. A more serious competitor for my favorite plain old rectangular flat is the Speedling flat—a molded plastic-foam tray 3 inches high, 13 inches wide, and 26 inches long. The plant holding cells taper to a narrow open point at the bottom of each cell—an ingenious way to encourage a dense root ball that makes good use of the soil mix. In order to keep the roots confined to their spaces, the foam trays must be propped an inch or so above the surface to admit air. In my trials, foam-tray flats produce excellent seedlings, but they're a bit more cumbersome to work with than conventional flats. They're durable, though; mine is still in use after four years.

Like most gardeners who can't resist starting enough plants for the whole neighborhood, my spring seedling setup is a motley arrangement of all the flats I can muster, plus representatives of most of the other kinds of containers mentioned above, which just about sums up my advice for other seed-starters. Use what you have, buy what intrigues you, but aim for a growing supply of long-lasting, inexpensive wooden flats.

Sowing Seeds Early Indoors

Nancy Bubel

I've been starting spring plant seeds indoors in late winter for some years now, and I'm still learning—still making mistakes, too. Once in a while the cats will knock over a flat of transplants. Then I must start all over again. Quite often I experiment with a new vegetable or flower, which shakes up the routine a bit, but in general I've worked out a pattern for this yearly ritual. I no longer worry about whether the seeds will come up. I know now that they will, if I keep them warm enough. I no longer start my tomatoes in early February, because I've learned it's better to set out plants that are in active growth rather than overblown specimens I've been holding for three weeks until the weather was right. Neither do I sow seeds as thickly as I once did, although this bad habit of the amateur gardener dies hard. It has to do, I suppose, with a lurking reluctance to trust those seeds. Only time and repeated sowing and harvesting can soften that inner uneasiness and lead to the respect for each seed that gives it sufficient room to grow.

My Timetable

It is all too easy when you have a severe case of the February blues and long for an early start on spring to get out the flats and the soil mixtures and start a whole batch of spring vegetables. Now, that's perfectly all right, if you can chalk the whole project up to experience or winter indoor recreation and start another batch later at the right time. It's also all right if you live in one of those benign climates where frost won't hit after early April. However, most of us would rather try to do it right the first time. So here's a little timetable to give you an idea of safe indoor starting times for your spring-planted vegetables.

Onions—12 to 14 weeks before the safe planting-out date (which is 4 to 6 weeks before the last frost)
Peppers—8 to 12 weeks before the last frost
Eggplant—6 to 8 weeks before the last frost
Tomatoes—6 to 8 weeks before the last frost
Lettuce—5 to 6 weeks before the safe planting-out date (which is 4 to 5 weeks before the last frost)
Cole crops (cabbage, broccoli, collards, etc.)—5 to 6 weeks before the safe planting-out date (after danger of severe weather has passed, but while nights are still cold)
Cucumbers and melons—2 to 4 weeks before the last frost (but don't plant out until the weather is warm and settled)

When I raised my seedlings on sunny windowsills, I started them well within the range of traditionally recommended times given above. If anything, I started them a bit on the late side, since late-winter sun is still quite weak, and it's not until well into March that you can expect old Sol to do much for your windowsill plants.

Using Moss in Seedling Flats

Because it is easily available to me, I always spread a layer of torn moss (gathered from our woods) over the bottom of any container in which I start seeds, except when using all vermiculite. The moss serves as an insurance cushion, soaking up extra water so that it doesn't puddle around the roots. At the same time, it holds this moisture in reserve so that the flat doesn't dry out too quickly. If you use moss, it is important to tear it into small pieces, rather than leaving it in big wads, so that each seedling may be easily separated from the others at transplanting time. I thoroughly dampen the moss before adding the second layer. Moss should be dried for several months before it is used in seed flats; fresh green moss sometimes seems to inhibit plant growth.

Although most experts recommend punching drainage holes in all seed-planting containers, I have found that in many cases my seedlings have done quite well in containers without drainage holes, as long as I've put this cushion of moss on the bottom, and as long as I'm in control of the watering. Flats that are kept outside and that are rained on become badly waterlogged if they have no holes.

You can use commercially available sphagnum moss also, as long as it is not finely milled.

To make soil blocks, pack a soil block mold with wet growing medium, eject the blocks into a flat, and plant a seed in each.

The date you choose for starting your plants, then, will depend on the variety you're growing; whether you'll raise the plants in a greenhouse, on a windowsill, or under lights; and the average frost-free dates in your growing area. If you are unsure of when those dates are, check with your local county extension agent. The office is often in the county courthouse.

A Sowing Checklist

Now that we've settled the when of seed starting, let's go on to the how. Here's a checklist of seed-sowing steps:

1. **Gather your equipment.** Seek out and collect the flats or other containers, planting mix, seeds, watering can, newspaper, labels, and markers you'll need.
2. **Prepare a work space.** Choose a spot where you'll have room to knock things around. Spread a layer of newspapers over the area. It's easier to gather up and discard the papers than to mop up spilled potting soil.
3. **Review your seed packets.** Look over your packets of seeds and write out a label for each one before you plant the seeds. You won't believe, till you've done it, how easy it is to mix up different seed lots. And if you plant five kinds of pepper and eight kinds of tomato, as I do, labeling the seed flats is doubly important. A hot pepper seedling looks no different from a sweet bell pepper seedling, and you may want to plant out ten of one kind but only five of the other.

   Labels may be wooden Popsicle sticks, cut pieces of venetian blind slats, strips cut from plastic jugs, or ready-made labels from your garden supply store. I've also simply glued scrap paper labels to the sides of wood flats (glue new labels right over the old ones next year) or clipped tags to plastic containers to identify my plants. If you do any kind of experimenting with different fertilizers, kelp sprays, chilling treatments, or soil mixtures, accurate labeling and record keeping are even more important.
4. **Prepare your flats.** Spread a layer of newspaper on the bottom of each flat or container that has drainage holes or slits in the bottom to keep the soil from sifting through. If the spaces between slats are wide enough, wedge in a "caulking" of torn shreds of moss. Trim the newspaper so that it doesn't stick up above soil level, or it will act as a wick and draw off soil moisture. Fill the flats with the seed-starting medium of your choice or with potting soil if you prefer, up to about one-half inch from the top. A deep container, half-filled, will both shade the plants and interfere with ventilation of the seedlings.

   Sometimes I plant seeds in plain vermiculite, omitting the moss and soil layers. The seedlings that are started this way must either be transplanted sooner to a soil mixture containing nutrients or fertilized every four days or so.

   Finally, firm the top surface of the planting medium, preferably with a flat object like a boar or a brick. This prevents the small seeds from tumbling too far into the crevices.
5. **Prepare the seeds.** Certain seeds will germinate more quickly if given a little head start before sowing. Scarifying helps to hasten germination of hard-coated seeds like morning-glory or New Zealand spinach. Just nick the seed coats with a knife or file. Don't cut deep enough to damage the embryo.

   Presoaking cuts several days of germination time for slow-to-sprout seeds like carrot, celery, and parsley. I've had good luck planting these seeds after having poured just-boiled water over them, draining when cool, and mixing with dry sand to avoid clumping. Some gardeners put such seeds in small muslin bags to soak overnight before planting. Other seeds like peas and beans will sprout sooner if presoaked for an hour or so in warm water. Presoaking isn't necessary for most seeds you'll be planting indoors, though.
6. **Plant the seeds.** You can either scatter the seeds over the entire surface—especially when using a small container—or you can plant in rows—usually a good idea when raising seedlings in flats. At any rate, give each fine seed at least one-eighth inch of space from its neighbor; medium seeds need one-half inch of room, and large seeds one inch.

Continued →

Getting the seeds to go where you want them can be tricky, but the knack comes with practice. To disperse fine seeds, try sowing them from a saltshaker. Medium-sized seeds like tomatoes, which may come only 20 or so to a packet in the case of some hybrid varieties, may be placed exactly where you want them with fine tweezers. According to most of the pictures you see, the real experts sow seeds by tapping them lightly directly from the seed packet. I always feel that I have better control over distribution of the seeds by taking a pinch of them in my fingers and then gently rotating thumb and forefinger to gradually dislodge the seeds. If all this is new to you, you might want to practice by sowing a few batches of seeds over a piece of white paper so that you can check to see what kind of distribution you're getting.

7. **Cover the seeds.** Except for very fine seeds, which may be simply pressed into the soil, you will need to cover the seeds with soil. The few seeds that need light for germination are on page 147. These should be simply pressed into a damp seed-starting medium and covered with clear plastic or glass. The rule of thumb is that seeds should be covered to a depth of three times their size. A one-eighth-inch seed, then, would have three-eighth inch of soil over it. I hardly ever put more than one-half inch of soil over any seed, and then only for larger seeds. For indoor sowing I simply spread fine, light soil or vermiculite over the seeds. This last layer needn't be wet. If the planting medium on the bottom is well soaked, the top will soon become damp, too.

   The good thing about presoaking the growing medium is that it's then not necessary to water the planted seeds from the top. If you've ever tried this procedure, I'm sure you've found, as I have, that it's a surefire way to relocate all your carefully spaced seeds. If for some reason you do prefer to water your seedling flats from the top, either use a gentle spray from a rubber bulb sprinkler with a flat, perforated nozzle head, or spread wet burlap over the flat and water through that. In that way you'll avoid the flooding that would carry seeds willy-nilly to the corners of the flat. Be sure the top layer of vermiculite (or whatever) is pressed firmly over the seeds so that the seeds are closely surrounded on all sides.

8. **Cover the container.** You can use any one of the following materials to cover your container:

   - damp newspaper or burlap
   - a scrap piece of used aluminum foil
   - a plastic sheet or bag slipped around the flat
   - another seed flat

   You can build a stack of seed flats if they are roughly the same size. In fact, the soil surface will receive better ventilation if the flats don't fit exactly edge to edge. Watch for mold in this case, or if you cover your containers with plastic, and provide better ventilation if mold develops.

9. **Set the containers in a warm place.** Place all planted containers in a warm place where seeds can germinate.

   - Put flats in the corner behind a wood-burning stove, preferably not on the floor where cool air settles, but elevated two feet or so on a small table or box.
   - Set flats on a high shelf above a floor register. Watch for excessive drying, though.
   - Set small batches of seeds on the pilot light on a gas stove.
   - Set flats on top of a turned-on fluorescent light fixture, like a light cart setup with several tiers of lights, and they'll receive steady warmth at the ends of the tubes. Once you have the early plants (onions and peppers) sprouted and under lights, you can set the next batch of seeds that you want to germinate on the dark but warm tier above the lighted plants.

A Second Method

An alternative method of indoor seed planting, used by an accomplished gardener with whom I enjoy trading lore, goes like this. Fill a cut-down milk carton or plastic jug with starting medium, water it well, and plant the seeds. Enclose the container in a plastic bag and keep the whole shebang good and warm. After three or four days, punch drainage holes in the bottom of the container (use a pick or knife). Keep warm and covered, but allow to drain and check for mold until you see the seeds have germinated.

Presprouting Seeds

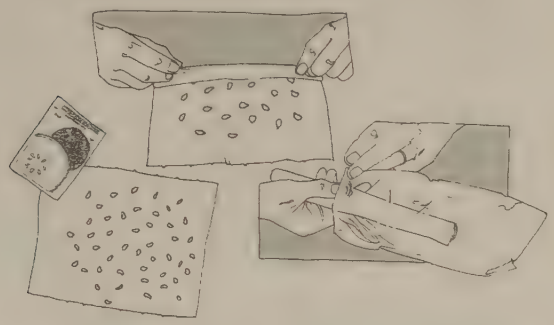
Ever since I picked up the idea from Dick Raymond's book *Down-to-Earth Vegetable Gardening*, I've been presprouting seeds of tender crops like cucumbers, squash, pumpkins, and melons. The first three are planted directly in the ground after they've germinated. Melons bear earlier if pre-germinated and then planted in individual pots for a two-week head start indoors. (Some gardeners feel that cucumbers also do, but I've not been convinced of that yet.)

Presprouting melon and other cucurbit seeds has given me a much higher rate of germination than I was able to get when planting two seeds to a peat pot, probably because the seeds receive more constant warmth and moisture. I highly recommend presprouting seeds of those crops that need especially warm conditions during germination.

How to Presprout Seeds. To start the seeds on their way, space them evenly on a damp double layer of paper toweling (or several thicknesses of paper napkin). Be sure that no two seeds touch. Carefully roll up the towel, keeping the seeds as well separated

as possible, and tuck the rolled cylinder into a plastic bag. If you label the rolls, you can put more than one variety in the bag.

Put the bag full of damp, rolled, seed-filled towels in a warm place. I use the warm top of a fluorescent plant light fixture or the top of my insulated hot water heater.



To presprout seeds, first spread them on a damp paper towel. Roll up the paper carefully and place it in a plastic bag. Set the bag in a warm place until the seeds have germinated.

Check the seeds each day. Nothing will happen for several days, but germinating seeds do need a certain amount of oxygen, and the small amount of air that wafts in when you peek at the seeds will do them good.

Signs of Life. The first sign of germination in cucurbit seeds will be the development of the root. Be sure to remove your sprouted seeds from their incubator before the root hairs grow together and tangle. If one should grow through the towel—and this often happens—just tear the towel and plant the damp shred of paper right along with the seed.

Planting Presprouted Seeds. Plant the presprouted seeds in a good rich potting mix that you've scooped into individual containers and premoistened. Cucurbits don't take kindly to transplanting, not with those fleshy, sappy, easily bruised roots, so your plants will stay right in these containers until they go into the garden. Individual half-pint milk cartons work well, since the bottom may be easily removed and the whole plant dump set in the hill. I plant my sprouted cucurbits in small plastic pots, which are easily overturned to free the seedlings when it is time to set them out. Cover the presprouted seed root lightly but firmly with soil, and set the pots under lights immediately, or put them on your sunniest windowsill.

Germination

Nancy Bubel

If you've ever lost track of a flat of germinated seeds, as I have, and discovered them too late—when the thready white stems had grown an inch before putting on pale little leaves—then no doubt you've also muttered ruefully, "Out of sight, out of mind." It is easy, in the busy spring rush, to overlook flats of planted seedlings tucked in out-of-the-way corners. For that reason, I like to keep my flats together in a place where I'll see them every day and remember to check on them.

The Process of Germination

What's going on in those flats while we wait? We commonly think of germination as being equivalent to sprouting, and it's true that the final test of complete germination is the emergence of a growing root or leaf sprout from the seed, yet the process by which a dry, dormant embryo quickens into tender, new green growth begins well before we have visible evidence of the new root or leaf.

The first step in the process of germination is the absorption of water by the seed. This is a necessary preliminary to the internal changes in the seed that trigger growth. The uptake of water by the seed (called imbibition by botanists) depends in turn on the content of the seed, the permeability of its outer layer, and the availability of the necessary amount of liquid. Seeds that contain a high percentage of protein imbibe more water than those that are high in starch. (Only under very acid or hot conditions, which don't exist in nature, will seed starch swell with water intake.) Seeds with hard coats, like morning-glories, will absorb water more readily if their hard outer shell is nicked with a file. Furthermore, the seed depends not only on the presence of moisture in the soil, but also on close contact with soil particles, to permit sufficient water uptake. The fact that a seed has absorbed water is not, by the way, proof of its viability. Even dead seeds can imbibe water.

As the seed swells with water, it develops considerable pressure, pressure that eventually ruptures the seed coat (which has already been softened by the surrounding moisture) and eases the eruption of the root. These are the physical effects of the seed's absorption of water. At the same time, internal metabolic changes are revving up life in the seed, changing its chemistry from neutral to first gear, you might say. As the seed tissues absorb water, food stored in the endosperm is gradually changed into soluble form, ready to be used as a component of new tissue.

In order, though, for the starches and proteins in the endosperm to dissolve, they must often be changed into simpler forms—the starches into simple sugars like glucose and maltose and the proteins into free amino acids and amides. The enzymes, necessary to split complex forms of stored food into simpler forms of usable food, are activated in response to the stepped-up metabolism of the seed. You will remember that even dormant seeds carry on respiration. They take in oxygen and release carbon dioxide. The rate of respiration is markedly increased in the germinating seed and both generates and supports the many interacting internal changes in the embryo.

**Daily fluctuation to 60° or lower at night is essential.*

Enzymes, then, direct the breakdown of certain useful stored foods. Hormones, also present in the seed, control both the transportation of newly soluble foods to different parts of the seed and the building up of new compounds from the components of those that have been broken down into simpler forms. Pea seeds, for example, synthesize new compounds during the first 24 hours of the germination process.

The product of all this stepped-up activity within the seed is new tissue, originating at growing points in the root tip, the stem, the bud, and the cotyledons. This new tissue is formed in two ways: Cells already present in the seed grow longer, and cells divide to produce new cells, which then elongate.

Seed germination.

Studies done on lettuce seeds, for example, show that cell division begins about 12 hours after germination has begun; the root cells show some elongation at about the same time. In corn, the first change to be observed is the enlargement of the cells, followed by cell division in the root as it emerges from the seed coat. Both kinds of tissue changes are necessary to the normal development of the seedling.

Factors that Influence Germination

Many internal and environmental conditions influence the course of germination in seeds.

The Condition of the Seed. A shriveled seed that has been stored too long or under poor conditions will have a scant supply of food stored in its endosperm. The seedling that grows from such a seed, if it germinates at all, is likely to be weak and stunted.

Mechanical injury to the seed during harvesting or drying can injure the cotyledons, stem, or root tip, or produce breaks in the seed coat that admit microorganisms, which in turn deteriorate seed quality. The hormones that promote cell elongation are produced by the endosperm and cotyledons. Any injury, therefore, that interferes with the soundness of these hormone-producing tissues is likely to result in stunted seedlings.

Flower Seeds That Need Light to Germinate
(Do not cover these seeds with soil.)

Annuals	*Perennials*	*Biennials*
Ageratum	Alyssum saxatile	Bellflowers
Begonias	Balloonflower	English Daisies
Browallia	Chinese Lanterns	Foxglove
Coleus (tender perennial)	Chrysanthemums	Columbines
Godetia	Edelweiss	
Impatiens	False Rock Cress	
Kochia	Feverfew	
Lobelia	Gaillardia	
Mignonette	Maltese Cross	
Petunias	Oriental Poppies	
Portulaca	Primroses (except Chinese)	
Scarlet Sage	Rock Cress	
Snapdragons	Shasta Daisies	
Strawflowers	Sweet Rocket	
Sweet Alyssum		

Flower Seeds That Often Germinate Best in Some Light
(Cover these seeds very lightly, if at all, with soil.)

Annuals	
African Daisies	Nicotiana
Balsam	Stocks
Celosia	Tithonia (Mexican Sunflower)
Cleome	Transvaal Daisies (tender perennial)
Cosmos	Wishbone flowers
Monkey Flower (Mimulus)	

Flower Seeds That Germinate Best in Darkness
(Cover these seeds with ¼ inch of fine soil, well firmed down.)

Annuals	*Perennials*
Bachelor's Buttons	Delphiniums
Butterfly Flowers	Poppies (except Oriental)
Calendula	Shamrocks
Globe Amaranth	Soapwort
Nasturtiums	
Nemesia	
Painted Daisies	
Pansies (biennial)	
Phlox drummondi	
Salpiglossus (painted tongue)	
Sweet Peas	
Verbena	

The Presence of Water. Water must be available to the seed in amounts sufficient to start the quickening of respiration that leads to germination. However, few seeds will sprout if submerged in water. Some air must also reach the seed for it to absorb the oxygen it needs. Water serves several purposes in the germinating seed. Initially, it softens the seed coat so the root can emerge more easily. Then it combines with stored foods to form soluble forms of nourishment for the seed. As growth proceeds, it helps to enlarge new cells, as directed by the hormones, and serves as a medium of transportation to take soluble foods and hormones to parts of the seedling where they're needed.

Sufficient Air. Even quiescent seeds in storage need a certain minimum supply of air. The requirements of a germinating seed are more critical. Our atmosphere contains a mixture of gases, with the oxygen portion fairly constant at 20 percent. (Some seeds—certain cereals and carrots—have been shown to germinate more completely in an even richer oxygen concentration.) The oxygen taken in by the seed in respiration combines chemically with the seed's fats and sugars—a process called oxidation.

Seeds also need a certain amount of carbon dioxide in order to germinate, but they don't do well if surrounded by a considerable concentration of carbon dioxide. Cucurbits (squash, melons, pumpkins, and cucumbers) have seed membranes that admit carbon dioxide more readily than oxygen, so they are acutely sensitive to low-oxygen conditions. As gardeners, we can't manipulate the composition of the air that surrounds us, but we can make sure our germinating seeds are supplied with enough air by planting them shallowly, in a loose, friable medium, and by keeping the soil moist but not waterlogged, so some air spaces remain.

Temperature. In general, seeds need warmer soil temperatures during germination than they will need later when they've grown into plants. There *are* differences in heat and cold sensitivity, though, among the different species. Some seeds, like lettuce, celery, and peas, germinate best at low temperatures, while peppers, eggplant, melons, and others prefer more warmth. Extremes of heat and cold inhibit germination of most kinds of seed. There are, for most seeds, optimum temperatures at which they do best. This doesn't mean your seeds won't germinate at higher or lower temperatures; the drop in germination with less-than-ideal temperatures is gradual, not abrupt. Seeds that germinate best at a soil temperature of 75°F (24°C) will put forth some growth at 65°F (18°C), although it might occur later and might be less.

Continued ➔

Some seeds, like dock, tobacco, and evening primrose, need alternating warm and cool temperatures in order to germinate. According to studies done with these plants, it's not the rate or duration of the temperature change but simply the fact of the change itself that affects them.

The most favorable germinating temperature for most garden seeds started indoors is between 75°F and 90°F (24°C and 32°C). That's soil temperature. Remember that whereas the air temperature in a room may be 70°F (21°C), a moist flat of soil set on the floor may be cooler unless kept near a source of heat.

A soil-heating cable may be used to speed germination of some seeds that are more difficult to start. Applying bottom heat directly to the flat uses less power than heating the whole room or greenhouse. In most households, though, there is usually at least one spot—over the furnace or water heater, on top of the television set, near a wood stove or heat register, or on a pilot light—where seed flats can be kept warm during germination.

Light. A fair number of flower seeds and some tree seeds either require light for germination or germinate more completely in the presence of light. Most vegetable seeds are indifferent to the amount of light they receive during germination. We used to think that darkness was essential to germination, but recent studies don't seem to support that conclusion as a generality. Some flower seeds, like those of the pansy, germinate best in darkness, and germination of onions and chives appears to be retarded by exposure to light. A few vegetable seeds germinate more completely under some conditions when they receive some light. In the case of lettuce and celery, for example, light promotes more complete germination only when the temperature is higher than that at which these seeds usually germinate best. At the lower temperatures they prefer, exposure to light doesn't seem to make much difference. The lesson from this is clear: When putting in a late planting of lettuce or celery when the weather is warm, press the seeds into moist soil, covering them lightly, if at all, with fine soil—although you could also spread a few dry grass clippings over the row to prevent crusting.

Vegetable seedling flats can be covered with wet newspapers, damp burlap, or used aluminum foil. Flats of seeds that need light to germinate should usually be covered with clear plastic sheets, bags, or food wrap, except for seeds that are known to germinate within a week, which may be left uncovered.

Soil Conditions. Apart from the physical conditions of friability, aeration, moisture, and freedom from waterlogging, all of which promote germination, there are other conditions in the soil that may affect the outcome of seed planting.

Organic Matter. Soils containing a high percentage of organic matter along with many microorganisms may have a higher concentration of carbon dioxide than the surrounding air. This can retard germination, depending on the permeability of the seed coat to carbon dioxide. Seeds don't need a rich mixture to start germinating.

Salt. A high salt content, found in some seaside soils, can block germination by drawing water from the seeds.

Calcium. Some seeds respond favorably to a high calcium content in the soil.

Leaf Mold. Leaf mold from the woods may contain germination-inhibiting substances. Beech tree leaves, for example, develop a compound that inhibits germination after they've been exposed for a winter. The fresh leaves do not contain this compound. Eucalyptus leaves also contain germination-inhibiting substances. I once killed a whole batch of seedlings by planting them in a mix containing some perfectly lovely leaf mold I had scraped up at the edge of our woods. Leaf mold, on the whole, is great stuff, and I use it regularly in our garden and compost pile with no ill effect. But since many of these interactions are still little understood, I no longer collect my leaf mold for seedling mixtures in the woods, but rather save maple leaves from our yard trees for this purpose.

Monitoring the Process

Keeping all these factors—water, air, temperature, light, soil conditions—in balance, while we wait for those first spears of green to show, calls for checking the seed flats at least once a day. The soil should be kept moist but not soggy. Air should be allowed to reach the soil surface at intervals, at least enough to prevent the formation of mold on the surface. Although I formerly surrounded each container of seeds with a plastic bag until the seeds germinated, I found that mold often formed on the soil because of poor air circulation. Now I simply cover the top of the flat, without surrounding it with a moisture-proof barrier. If you do find mold on the soil, chances are that exposing the flat to the air for an hour or so will take care of the problem.

Then, one day—often, in the case of peppers, just about when you'd given up hope—you'll notice little elbows of stems pushing through the soil surface.

What Seedlings Need

Nancy Bubel

The most crucial time in the life of a seedling is the period just before it has broken dormancy. Each tentative-looking little plant sprout is rather like a baby. It must have its needs met immediately. If it finds only darkness when its cotyledons break through the soil surface, it will send up a pale, weak stem in search of the light it must have. If the soil in which it is growing dries out, it can no longer enter a holding stage like the

dormancy it went through as a seed. There is no going back. It has started into growth, and if it is to continue, there must be moisture within reach of the roots and light on the leaves.

Light and Temperature

As soon as the plants have germinated, then, they must be given light, either from fluorescent tubes or from the sun by way of a house or greenhouse window. I try to catch my seedlings even before the whole cotyledon has emerged, when the seed is still just a sprout. This is easier to determine when the seeds haven't been deeply buried. Then when I put them under lights I know they'll have the stimulation they need from the very beginning.

Temperature requirements of seedlings are not as critical as light, perhaps, but nevertheless are important. Once the plants are growing above ground, they need less warmth than is required for germination. The majority of vegetable plants that germinate most rapidly at 70°F to 80°F (21°C to 27°C) do well when grown at 60°F to 70°F (16°C to 21°C), with night temperatures about 10°F (5.5°C) lower. Cool growers like lettuce and onions will still flourish when temperatures drop to 50°F (10°C).

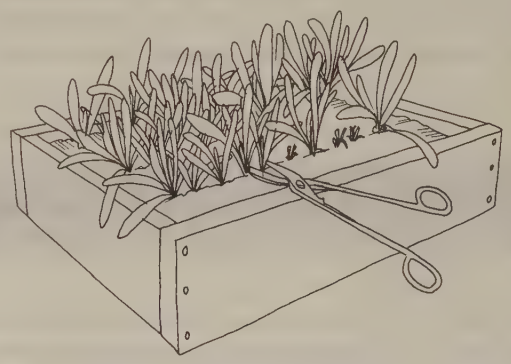
In a severe winter, seedlings kept in an unheated room must occasionally be moved or covered to protect them from freezing. Undesirably high temperatures may be a more common problem. Although I keep flats of germinating seeds in the warm corner (70°F to 80°F, 21°C to 27°C) where heat rises from our wood stove in the kitchen, I move the flats to our cool solar greenhouse as soon as the seedlings are up. Plants grown indoors in warm rooms put on weak, spindly, sappy growth that is difficult to manage under lights and to prepare for the transition to colder outdoor temperatures. Start seeds warm and grow seedlings cool.

There is, in fact, some evidence that judicious chilling of tomato seedlings, at just the right time, promotes earlier and heavier fruiting. Dr. S. W. Wittmer of Michigan State University found that tomato seedlings kept at temperatures of 52°F to 56°F (11°C to 13°C), starting immediately before the seed leaves opened and continuing for 10 to 21 days, developed up to twice the usual number of flowers in the first cluster and often in the second. Since the position of the lowest group of flower buds on the plant is determined approximately a month to six weeks before blooming, the plant must be chilled during this early stage, before the opening of its first true leaves, in order to induce earlier flowering lower on the stem.

Other vegetable horticulturists report that peppers may also be induced to form early buds by chilling the plants in the seed-leaf stage. When I read these reports, it dawned on me that I'd been prechilling my pepper seedlings for years, though not through any planned program aimed at early bloom. The peppers are in bloom when I set them out in the garden in May, partly because I always start them extra early—in January—thus inadvertently chilling them at the right time.

Space

Soon after the seed leaves unfold, conditions often become crowded in the flat, unless you have spaced your seeds with mathematical precision. I know I usually need to thin mine, especially lettuce and cabbage. The best way to do this is not to yank the extra plants out of the soil, but to cut them off, using small embroidery or nail scissors. A considerable amount of root growth often takes place even before the green leaves go into operation, and the roots of plants you want to save may be damaged by pulling out neighboring roots.



When thinning seedlings in a container, snip the tops. Pulling them can disturb the roots of nearby plants.

There is more going on in the roots of even the youngest seedling than most of us ever fully recognize. Roots not only anchor the plant and absorb nourishment, but are also responsible for maintaining the pressure that enables the plant to raise water, against the force of gravity, to its topmost leaves and stems. In many plants, roots give off exudates that help to define and sometimes defend the plant's territory. Roots of all plants synthesize many of the amino acids that control the plant's growth.

Give seedlings a little tender loving care.

Continued ➔

Roots are examples of "being and becoming," to borrow Aristotle's phrase, used perceptively by Charles Morrow Wilson in his book *Roots*.

Miracles Below.

Root growth is continuous. It does not stop, ever, as long as the plant lives. At the same time, root filaments are continuously dying. Root hairs, the tiny fibers that form the point of contact and exchange between the soil and the plant, constantly extend into new territory. They need moisture, but they also need air. A soil mix that is half solid matter and half pore space, with about half of the pore space filled with water, provides ideal conditions for root growth.

Superfluous seedlings are just like weeds. Thinning the seedlings, so that their leaves don't overlap, cuts down on competition for light, moisture, and nutrients and also helps to promote better circulation of air around the plant.

Transplanting into New Containers

Nancy Bubel

There comes a time shortly after your seeds have germinated when you will want to transplant them into a deeper container with a richer growing medium. Some seedlings, though, should not be moved from their original containers until you plant them in the garden.

Why Transplant?

Those seedlings that can be transplanted benefit in several ways.

Stimulation of Feeder Roots. Some fine roots are broken in the transplanting process. As a result, a new, bushier network of feeder roots is formed. If roots are very long and thready, as in the case of onions, I often prune them to one inch or so, at the same time pruning the top growth to correspond.

Room to Grow. Crowded seedlings become weak and spindly, and the lack of air circulation around them can encourage disease. Giving them more root and leaf space promotes the health and strength of the plant and ensures that the root ball of the plant will have sufficient protective soil around it when you cut the plants apart later to set them out in the garden.

Richer Soil. Although seedlings started in soilless mixes seem to be able to subsist on liquid feedings for quite a while, I like to get my plants into a good soil mixture so that they can take advantage of the micronutrients and the beneficial interactions in the microscopic soil life, limited as these may be in the small space of a wooden flat.

Easier Selection and Evaluation. Discarding a new young green sprout is always a painful process for me. In fact, I usually keep a small container of these extra plants by the kitchen window for a week or so after transplanting, in the hope that some visitor will adopt them. Selection, nevertheless, is a necessary step in raising the best possible nursery plants. No matter how sparingly I try to sow the seeds or how carefully I thin the seedlings, I usually have more seedlings in a starting flat than I will have room for under lights or in the garden row, and so I choose, as I transplant, the seedlings that appear most vigorous.

I look for good green leaves that are symmetrical and well developed. Deformed cotyledons sometimes indicate early damage to the seed. Vegetable seeds that sprout early usually grow into vigorous plants unless they are retarded by waiting without light for the other, slower seeds to come up. There is, in fact, some evidence that early emergence is an indication of seed vigor and ultimate high yield.

Good root growth (left) versus poor root growth (right) in a tomato seedling.

Root growth is as important as top growth in evaluating seedlings. Look for a compact, well-developed root ball. A fringe of well-branched feeder roots will do far more for the developing plant than a single, thready trailing root. It is also difficult to transplant a long, single-filament root without tangling it, bruising it, or doubling it back on itself.

When to Transplant

By the time they have developed their first true leaves, your seedlings are ready to be transplanted. It's better to get the job done before the plant has a second set of fully developed leaves, because from then on the likelihood is that the stem will be longer and more easily injured, and the roots may be lengthy and trailing and difficult to trace through the soil mix.

Some accomplished gardeners prefer to do their transplanting when the seedling is even younger, just after the cotyledons have emerged completely, and the plant is standing upright in the soil. This method does have advantages. It permits you to save almost every plant grown from expensive seed, the kind that comes ten seeds to a $2 packet, since none are lost in thinning. It puts the plants into a richer soil mix at an early age and frees your seed-planting trays and mixes for the next wave of plantings.

I have used this method occasionally for selected flower and vegetable seeds, but generally I prefer to thin my seedlings in the

cotyledon stage and let them develop their first set of true leaves before transplanting. This allows me to choose the very best ones from the flat.

How to Transplant

Transplanting is more than a technique. When done well, it involves respect for the young life of the plant, even a certain empathy that can sense the thrust and direction of the tender growing roots, the reach and promise of the unfolding green leaves. The plant wants to grow. It is, you might say, programmed to grow. Having set the process in motion by planting the seeds, we now have the opportunity to give each seedling the most careful treatment so that it will continue growing smoothly on its way to producing our food.

Let's suppose that you have a flat of seedlings that you want to transplant into a larger, deeper flat of richer potting soil. The following steps will guide you through the transplanting process:

1. **Prepare the container.** Your first step will be to prepare the flat. Flats or other containers used for growing seedlings should have drainage holes in the bottom. Spread a double layer of newspaper on the bottom to keep soil from sifting through the drainage cracks. Next, arrange a one-inch layer of torn pieces of moss on top of the newspaper. This is not absolutely necessary, but in my work with young plants I've found that those planted over a torn-moss foundation develop excellent root systems. If you have no source of fairly coarse natural moss or commercial unmilled sphagnum moss, I'd use plain potting soil, but I'd be sure to include some perlite or sand in the mix to promote drainage. Don't use a bottom layer of plain finely milled horticultural sphagnum moss. It's too fine.

   Moisten the moss, pat it down flat, and fill the rest of the flat to within about one-half inch of the top with potting soil. Usually I moisten the soil thoroughly before setting the seedlings in their places, although at times I have put the seedlings into dry holes, watered them in, pulled fresh soil over the roots, and then watered again lightly. This unorthodox method has given me equally good results.

   Plant Bands. Transplants may also be moved into plant bands, which should be wedged snugly together in a bowl or pan to prevent drying. To make plant bands, first take a piece of doubled newspaper about seven or eight inches long and four inches wide, and tape it around a jar two to three inches in diameter to shape it. While the paper is on the jar, fold in one end as you would a package, but don't tape it shut. Remove the plant band from the jar. Place your plant bands side by side in a pan—an old roasting pan works well—and put one-half inch of soil in the bottom of each band to anchor it in place before inserting the seedling. The folded-over bottom, if it hasn't rotted away at planting time, may simply be peeled off before setting the plant in the garden.

2. **Prick out the seedlings.** Most seed-starting gardeners soon acquire a favorite tool for this purpose. The miniature houseplant shovels that usually come as part of a set are too clumsy for most small, closely spaced seedlings. I use the slim, slightly pointed handle of an old salad fork. Wooden popsicle sticks, pencils, and old screwdrivers can serve the same purpose. What you want is an instrument that will lift out the seedling while causing the least damage to its roots and those of its neighboring plants.

Transplanting a seedling into a new flat provides it with richer soil and more room to grow.

   When seedling roots are compact enough to come up in a relatively dense cluster, it is often a good idea to water the old flat shortly before removing the seedlings from it so that enough soil will cling to the roots to help prevent transplanting shock. Seedlings raised in vermiculite, which generally falls away readily anyway, or those with long, extensive root systems, won't benefit from prewatering. By the way, it's better not to dip the roots of seedlings in water before planting them in their new location. This makes the roots cling together when, instead, they should be individually surrounded by soil.

   Remove the seedlings one by one from their old quarters, planting each one before digging up another. Even a few minutes of air drying will adversely affect those delicate roots. Hold the seedlings by their first leaves rather than by the easily bruised stem, or support the root ball in your hand.

3. **Replant the seedlings.** You have several options here. You can, as suggested above, set the plants in already-moistened soil. A second option is to plant them in dry soil (over wet moss); then firm the dry soil around the seedling, and finish with a light watering to further settle the seedling.

   Or, if you are putting the young plants into pots, you can tuck a wad of damp moss in the bottom, set the plant on it, half fill the pot with soil, water the plant in, and add enough additional dry soil to fill the pot.

   If you're potting up a plant that has long roots, put some soil or moss in the pot and turn it on its side. Position the plant in the pot with its roots spread out on the growing medium, and gradually fill in with soil as you tilt the pot bit by bit back to its normal position. Instead of being coiled around each other, the roots will have more of their surface exposed to soil.

Continued →

Plant bands, used as containers for transplants, can be made by shaping newspaper around a jar and taping the sides together.

To pot a plant with a long root, lay the pot containing some growing medium on its side and spread the roots over the medium. Gradually lift the pot to a vertical position as you fill it with growing medium.

When transplanting, set the seedlings just slightly deeper than they were in their original container. Tomatoes can be planted as deep as the root will allow. Plants that form a leafy crown, though, like lettuce and cabbage, should not have soil pulled over or into the crown. When settled into place, the first leaves of young transplants should be at about the same level as the sides of the container.

Press the soil gently but firmly over and around the roots. Roots need a certain amount of air, which should be provided by a good soil mix that is not overwatered, but they also need close and immediate contact with soil particles in order to absorb necessary nutrients.

Except for onions, leeks, and chives, which grow spears rather than spreading leaves, transplants should be spaced at least two inches apart in the flat. Three inches is better for tomatoes, cabbage, and eggplant that won't be transplanted again.

4. **Watch your seedlings.** Check for signs of wilting. If they droop, even though you've watered them well when planting them, don't pour on more water. The roots are already doing all they can. Instead, help to balance the plant's moisture supply by arranging a tent of damp newspaper over the flat or by enclosing it in a large plastic bag or covering it with a large roaster lid or other protective layer that will not rest on the plants. Keep new transplants out of direct sun for a day. I put mine back under fluorescent lights half a day after moving them, as long as they show no signs of wilting. Wilted plants should be kept shaded and cool until they perk up, which shouldn't take more than a day or two at the most.

Growing On

Nancy Bubel

Your young plants should be showing more new growth within a week after transplanting. The trick now is to keep them growing steadily until it's time to prepare them for planting outdoors.

Watering

It's important to remember, first of all, that soil in containers dries much more rapidly than the deeper, heavier soil you have in your garden. Wilting that lasts more than a day may retard the seedling, so it is best to check the flats every day to see whether they need watering. I usually water my transplants in flats about every third to fifth day, but I base the decision on the condition of the soil, not the time schedule. Short of letting the plants wilt, it is a good idea to let the soil dry out from time to time. Then the roots are stimulated to grow into the air spaces between the soil particles in search of water.

When to Water. Water is powerful stuff. It can nourish your plants, or it can kill them. Water is necessary to maintain the turgidity of the plant so that there is a continuous column of moisture in the cells. It is also indispensable to the intricate intracellular chemical processes that keep the plant growing. However, too much water ruins the soil tilth and spoils the plant. Soil that is continuously waterlogged has no air spaces to promote root growth and support helpful soil bacteria. In such a situation, other less beneficial organisms take over, rot sets in, and the roots suffer.

How do you tell when a flat needs watering? By touch, by feel, and by sight. Touch the soil. Poke your finger into a corner where it won't disturb any roots. If the soil feels powdery or dry, it needs water. When you've been handling flats for a while, you can judge by feeling the weight of the flat whether it has lost most of its water. A well-watered flat is heavier than a dry one. Other than dry soil surface, visible signs like drooping plants indicate a serious lack of water.

Water Temperature and Composition. Does water temperature and composition matter? I think it does.

Temperature. Our well water is cold, but I always use tepid water for seedlings of heat-loving plants like melons, cukes, peppers, eggplant, and globe artichokes. Water temperature is less critical for the brassicas (which include kale, cabbage, cauliflower, broccoli, and mustard), lettuce, onions, and such, which prefer a cooler environment; still, I try to temper extremely cold water to a more moderate 70°F (21°C) to avoid shocking the plant.

Chlorine. If your water is chlorinated, I'd suggest letting it stand overnight with as much surface as possible exposed to the air—in a bucket or dishpan—before using it to water seedlings. High levels of chlorine can harm plants and kill beneficial soil bacteria. Symptoms of chlorine damage include yellowing along leaf veins and, in extreme cases, curling of leaves.

Soft Water. Water that has gone through a water softener should not be used to water plants. It contains potentially toxic amounts of sodium.

Some gardeners who are good at planning ahead fill plastic jugs with water and keep them ready so that they always have room-temperature water available for their plants.

How to Water. Yes, there is more than one way to water your seedlings. Some expert seedling-raisers water their flats from the bottom. This practice supplies water quickly to the root zone and avoids excess surface dampness that can encourage damping-off disease. It is a messy business if you don't have a good setup for it, but if you have a large waterproof trough in which you can partially submerge a flat, or preferably two or three at a time, the method might be practical for you. Each flat must, of course, have drainage slits or holes in the bottom so that water can be absorbed. Leave each container of seedlings in the water until the surface of the soil starts to look dark.

Bottom watering is really more of a greenhouse refinement than it is a necessity. I've had no problem at all with top watering either seedlings or more mature plants. Watering from above carries nutrients down through the soil to the roots and makes it feasible to top-dress the plants with compost or rich soil if necessary. I often use the muddy water left from rinsing root-cellar vegetables to water my indoor seedlings.

Maintaining Humidity

Humidity—the amount of moisture in the air—is important to plants. They lose a great deal of moisture through their leaves when the air is excessively dry, as it can be both in centrally heated homes and in rooms warmed by a wood stove during cold weather. Plants suffer when humidity falls below 30 percent. They do best in the 50 to 70 percent range; higher humidity invites fungus and other disease problems. Misting plants helps, but only temporarily. The best way to increase humidity around potted seedlings is to set them in containers of damp moss or vermiculite, or in a container that holds an inch of pebbles in half an inch of water.

Potted seedlings that spend more than a month or two on this damp bed may send out roots into the moss or vermiculite. You can prevent this by setting a rack or some kind of improvised support between the damp bed and the plants.

Draping a plastic tent over the indoor garden helps to hold humidity in, although it also cuts down on air circulation.

During the winter, air circulates well in a heated house, because the decrease in air pressure caused by burning fuel prompts an intake of fresh air and keeps interior air in motion.

If you notice green algae or fuzzy mold growing on the soil surface, your plants probably have more water and less air than they need. Run a small fan in the area, remove any plastic covers, and hold off on water for a few days. You might also try sprinkling some powdered charcoal over the soil surface to correct the problem.

A purple coneflower seedling shows healthy growth in a flat.

Fertilizing

Fertilizer, like water, is a necessity that should not be overdone, or salts will accumulate in the soil to a toxic concentration. It is better to give frequent small feedings than occasional large feedings to very young seedlings. For the first three weeks, in fact, any fertilizer the seedlings receive should be half-strength rather than the full-strength mixture (1½ teaspoons to a gallon of water, for example, instead of 1 tablespoon to the gallon).

A good way to increase humidity around potted seedlings is to place them in trays containing an inch of pebbles and ½ inch of water.

When to Fertilize. Newly emerged seedlings, still in the cotyledon stage, have absorbed enough of the seed's stored nourishment to get them well off the ground. I don't fertilize my seedlings until they've begun to develop their true leaves. Seedlings growing in nutrient-free vermiculite should receive about two feedings of diluted fertilizer a week. Later, when they have been transplanted to a richer mixture containing soil and/or compost, they can go on a ten-day to two-week fertilizing schedule.

Types of Fertilizer. You can choose from a few effective fertilizers to feed your seedlings.

Fish Emulsion. I use diluted fish emulsion, a source of trace minerals as well as the three major elements, nitrogen, phosphorus, and potassium, to feed my seedling plants. The usual dilution, one tablespoon to the gallon, seems to hold true for most of the commonly sold fish-fertilizer preparations. The labels of these bottles usually become hopelessly frayed and streaked before the contents are used up, so I'd suggest jotting

Continued →

down the appropriate dilutions for different plants while you can still read the label.

Sprout Water. Water drained from sprouting seeds, such as that I collect from the alfalfa mung bean sprouts I raise in our kitchen, is valuable food for plants. I am convinced that sprout water helps to foster plant growth, although I can't cite any scientific studies as proof. In my one "controlled" experiment, two flats of Elite onion seedlings that I watered-in at transplanting time with sprout water grew thicker, sturdier tops than two untreated flats of the same variety in the same soil. They maintained their advantage until planting-out time. Since gibberellins (growth hormones) are known to be abundantly present in seeds, it makes sense to me to suppose that the water used to soak and rinse sprouts might well contain dissolved growth hormones.

Eggshell Water. Some gardeners save their eggshells and soak them in water until the brew develops an odor you wouldn't want in the house. (Leave them on the back porch or in the barn.) The resulting solution, diluted by an equal volume of water, is used to fertilize half-grown seedlings and other plants. Unless you're especially partial to essence of rotten egg, I'd use this on greenhouse, cold frame, and outdoor plants only, but it seems a good use of an otherwise neglected resource.

Providing Light

Plants need light in order to combine airborne elements, water, and soilborne food into the raw materials of growth. There's no sense in fertilizing a plant that receives insufficient light (less than eight to ten hours a day in the case of vegetable seedlings). The plant can't make use of the food.

If, due to conditions beyond your control, your plants don't receive as much light as they should, keep the temperature low so that new growth will be less spindly. At lower temperatures, plants can tolerate less light.

Plants do a large part of their growing at night. The side away from the light adds more new tissue than the side closest to the light. This is what causes them to stretch and lean in the direction of light. Plants grown at a window should be rotated one-quarter turn each day so that no one side elongates and leans too far in any one direction.

Light

Nancy Bubel

Seedling plants may have all their other needs met—nourishment, air circulation, correct temperature, water, good growing medium, humidity—but without sufficient light, they will amount to nothing.

People are limited to using the sun's energy in indirect ways, but green plants have the ability to absorb energy from sunlight directly and to use that energy to make food they can store. Light striking a green leaf sets in motion the process of photosynthesis—the conversion, through the action of chlorophyll, of water and carbon dioxide to simple sugars and starches. Only the green parts of leaves carry on this process. White stripes, blotches, and leaf margins do not contain chlorophyll and so are not capable of photosynthesis. Red-leaved cabbage, coleus, ruby lettuce, and similar plants contain chlorophyll, but red pigment in their cells masks the green.

The Facts about Light

Light, although it may appear white to us, is actually a mixture of a rainbow of colors. A full spectrum of light includes the following color gradations, each of which has a different effect on plant life.

Green-Yellow Light. The chlorophyll in the plant reflects green-yellow light. Its effect on growth is thought to be negligible.

Orange-Red Light. This light stimulates stem and leaf growth.

Violet-Blue Light. Enzyme and respiratory processes are regulated by the violet-blue portion of the spectrum. In addition, this light encourages low, stocky growth.

Infrared (Far-Red) Light. This stimulates germination of some seeds, but can inhibit others. Its full effect still isn't completely understood.

Full-spectrum light, like sunlight, includes invisible ultraviolet rays, too. It is only the visible part of the spectrum described above, however, that provides the energy necessary for photosynthesis.

Making the Most of Natural Light

If you have a greenhouse, of course, your plants will receive the well-balanced light they need. The quality of sunlight that shines on windowsill-grown plants is the same as that in a glass-enclosed greenhouse, but the intensity is much lower, especially on cloudy and early winter days when the sun is low in the sky. You can boost the amount of light your windowsill plants receive by positioning shiny metal reflectors or boards painted with flat white paint behind the plants to bounce the light back onto their leaves. Use foil-covered cardboard, shiny cookie tins, or other household findings. The resulting arrangement may not win any interior decorating prizes, but it *does* get more light to the leaves. Try it with eggplant, a real sun and heat lover.

Another problem with raising seedlings on windowsills is that few houses have enough south-facing windows to provide a place for more than a few pots or flats. If you are limited to raising your seedlings at the window, choose the kinds of vegetables that most need an early start—main-crop tomatoes, peppers, and eggplant, for example—and sow lettuce, cabbage, and broccoli seeds in the open ground or in a cold frame. You can also raise two generations of indoor seedlings if you put

your tomatoes and peppers in a cold frame about the first of May and then use your windowsills for the melons and cucumbers. Where space is limited, you can plant seeds of a hardier tomato like Sub-Arctic directly in the garden rather than raise your early tomato seedlings indoors.

Other places to put your seedlings where they will receive natural light include the following:

- A sunny corner in an outbuilding or barn; best in mid to late spring in an unheated building.
- A roof garden, protected by a plastic tent, cloches, or some other covering, which can be effective but may be cumbersome to care for. A flat, black garage roof or house roof absorbs a lot of heat.
- Cold frames.
- A solar greenhouse.

Artificial Light

A few sources of artificial light are available to choose from, but fluorescent light seems to work the best.

Sunlamps. Sunlamps might sound like a good light source for seedlings, but any gardener who tries them will find that they are death on plants. The high concentration of ultraviolet rays in the sunlamp interferes with normal plant growth.

Incandescent Light. Incandescent bulbs produce red light, which alone makes the plant grow leggy. They also produce a great deal of heat in relation to the amount of light they give off. It is not practical to try to raise seedlings under incandescent lights. In lighting supply stores, you will see special incandescent bulbs with built-in reflectors designed for raising plants. These are used as auxiliary light sources in greenhouses or for houseplants. They must always be installed in a porcelain socket, and care must be taken to prevent cold water from splashing the bulbs when watering the plants, or the blown glass may break.

Fluorescent Light. The discovery that plants do well under fluorescent light has made it possible for many more gardeners to get a good early start on the outdoor growing season and to produce plants as good as any raised in a greenhouse. Plants grown under fluorescent lights develop excellent color and stocky growth. Fluorescent light comes closer than any other artificial illumination to duplicating the color spectrum of sunlight. In varying proportions, according to the type of the bulb used, these lamps emit light from the red and blue bands of the spectrum. The tubes give off more than twice as much light per watt of power consumed as incandescent lights.

Fluorescent tubes of various kinds give off different shades of light, including warm white, cool white, natural white, and daylight. The different kinds of fluorescent powder used to coat the inside of the tube account for the range of light quality available.

Reports of results from growing plants under fluorescent light at the North Carolina State University School of Agriculture and Life Sciences and at Cornell University, as well as from experienced nonprofessional gardeners, indicate the following:

- Plants do well under a variety of tube combinations.
- Special plant-raising tubes are not necessary for starting vegetable plants.
- Best results are often obtained by mixing tube colors: For example, using one warm-white and one cool-white or daylight tube in each fixture.

Cool-white tubes emit a bright bluish white light. Warm-white tubes have a faint tan or pinkish cast. The cool-white tubes are the easiest to find, but most hardware stores will order warm-white ones for you if they don't have them in stock.

Special plant growth tubes give more blue-red than green-yellow light. Their effect on plants is mostly cosmetic: The plants look good but do not necessarily grow any better than they do under cool-white bulbs, which are the most efficient. In addition, the special-purpose fluorescent tubes are more expensive and have a shorter useful life.

In the early days of fluorescent tube experiments, incandescent lights were thought to be necessary for flowering, but it is now known that they are unnecessary. They generate so much heat that they cause rapid drying of soil and air, and they burn out much sooner than fluorescent tubes.

Using Fluorescent Light Efficiently

The effectiveness of your fluorescent lights will be influenced by the way you use and care for them.

Length of Tubes. If you are preparing a fluorescent-light setup for your plants, buy the longest tubes you can manage to fit into the space you have. Why? Light at the ends of the tubes is weaker than that in the center and falls off more as the tube ages. If my experience is any guide, you never have enough light space under the tubes. The more you have, the more plants you're tempted to start, and when they're transplanted, you'll need all the space you can muster.

Tubes are available in 12-, 18-, 24-, 36-, 48-, 72-, and 96-inch lengths. Each foot of length uses 10 watts of power. If at all possible, avoid using tubes under three feet in length; they simply don't put out as much light for the power they use. Forty-eight-inch tubes are long enough to be efficient but short enough to fit conveniently into most household arrangements.

Amount of Light. For growing seedlings, your fluorescent light setup should provide 15 to 20 watts per square foot of growing area. A single tube is, in most cases, both insufficient and inefficient, unless you have a long, skinny tray of seedlings under it. If you must use a single tube, construct a simple frame to hold foot-square mirrored tiles on both sides of the flats to

Continued →

reflect more light. A double row of tubes will give enough light for a flat up to about 16 inches wide, and two parallel double rows, like those attached to plant-growing carts, are even more efficient.

Types of Tube. If you are buying components and putting together your own light center or centers, you have a choice of the channel tube—a single- or double-mounted tube on a slim metal base, without a reflector—or the more common two-tube industrial-type fixture with a bent metal reflector. Channel tubes work well on shelves and undersides of cabinets, especially if surrounding surfaces are painted white to reflect more light. Industrial reflector fixtures may sometimes be obtained secondhand, but they are also widely available in lighting supply stores and from household mail-order catalogs.

High-Intensity Discharge Lamps. If price is no object, the most efficient lights you can buy today are the high-intensity discharge lamps, which—along with their fixtures—are costly to purchase but less expensive to run. There are two kinds of high-intensity discharge lamps: metal halide and high-pressure sodium. The metal halide HID lamps produce 94 lumens per watt (including ballast); cool-white fluorescent tubes produce 66 lumens per watt; and special plant-growth lights give off even less light: 37 lumens per watt for Agrilite, only 20 for Gro-Lux. The high-pressure sodium type is even more efficient (132 lumens per watt), but because its light has an unnatural yellow cast, some gardeners prefer the more natural, slightly less efficient white light of the metal halide lamps; these lose power more rapidly than sodium lamps. HID lamps cannot be mounted as close to the plant as fluorescent lights; the current limit is two feet for lights with wide-angle reflectors and six feet for those with standard mounting.

According to an industry spokesman, metal halide lamps of less than 400 watts, and those mounted in other than vertical positions, constitute a radiation hazard. Cracked bulbs can emit eye-damaging rays, much like those released by welding (according to a letter to the editor from Agrilite Company official, *Horticulture*, March 1987, p. 7).

Efficient Use. My first grow light was a 20-watt tabletop stand—a toy that helped me to get through a long northern Midwest winter when snow covered the ground until April. I raised tomato, pepper, lettuce, and pansy seedlings under that little light, and spring came after all. By then, of course, I was hooked. The following year, after moving back to Pennsylvania, to an old house full of nooks and crannies, I had a decentralized system—plant lights on every floor, from the basement to the kitchen to the bathroom, and I began raising all the seedlings we needed, racing the season to bring the earliest possible lettuce and cabbage to the table.

When we moved to our farm, we accepted a plainer, simpler house at first because we were hungry for land. In an old house that boasted not a single closet, we needed our shelves for books and canned garden produce, so I splurged on a four-shelf plant cart with four 40-watt tubes attached to three of the shelves.

I was delighted with the way my plants grew under fluorescent lights. They were stocky and green, with a special bloom to them. My only regret was that the lights consumed electric power. I tried to use them as efficiently as possible. The following tips can help you to get the most out of your lights.

1. Keep the tubes clean. Dust on the tubes decreases their efficiency.
2. Add reflecting surfaces to your setup. Use of reflecting surfaces like mirrors or aluminum foil under and around the lights gives the plants more light for the same power output.
3. Use flat white paint on shelves and reflecting boards. Flat white paint reflects more light than glossy paint.
4. Don't let the temperature drop too low. Fluorescent lamps seem to function best if the temperature doesn't fall below 50°F (10°C). Lights operated at around 40°F (4°C) may not perform as well.
5. Keep fluorescent lights turned on. To get more usable time out of the tubes, avoid turning them on and off more than absolutely necessary. A long burning time after each start is conducive to more economical operation and longer tube life. Most lamps last one to two years (10,000 to 20,000 hours) if turned on only one or two times a day. Efficiency decreases by 10 percent after a few months of use.
6. Get double use out of your lights. It is also possible, I've found, to save electric power by installing fluorescent lights for plants in spots where illumination is needed anyway. For example, we kept a fluorescent light stand on top of the refrigerator where the light it shed helped to illuminate a dark corner. We also installed a fixture on the underside of a shelf in the bathroom of our old house—light for the room and the plants. An imaginative look at your own home surroundings will no doubt suggest other possibilities.
7. Make use of the warmth of the lights. The tubes themselves give off little heat, but the ballast—the step-down transformer that makes it possible for the lights to use household current—does become warm. Most fluorescent lights have a ballast at the end of the fixture. Some recent arrangements have a remote ballast. Judicious planning of flat placement in relation to the warmer end zones of the tubes can make it possible to utilize this extra warmth to advantage, for example, in germinating seeds or starting sweet potato slips.
8. Reuse old tubes. Since light brightness decreases with the age of the tube, many gardeners routinely replace their seed-starting fluorescent tubes each year. You can still use the old tubes for general lighting purposes.

Grow-Light Setups

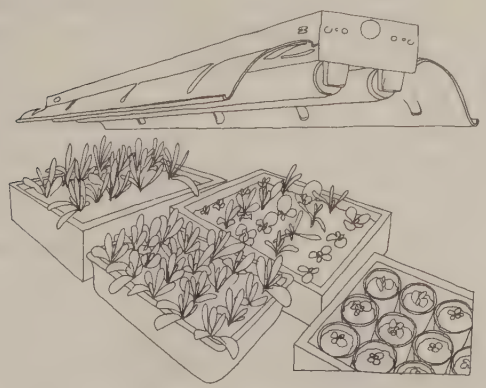
How you arrange your grow-light setup depends on the amount of space you have and the type of light you will be using.

When Space Is Limited. Not many of us have an entire room to devote to plants. A basement is often the most spacious area available, and that usually works very well unless furnace heat affects the plants or water is not readily at hand. Sometimes a bit of shoe horning is required to fit lights into an apartment or small home. Once, when plant space really got tight around here, I even tied a 36-inch two-tube light fixture to the underside of a piano bench so that it was suspended a few inches above a flat of plants. A crazy-looking arrangement, but it kept my tomato seedlings going until the cabbage and lettuce on the big cart were ready to graduate to the cold frame and leave room for the next wave of plants. If you're looking for ways to sneak in another light fixture or two or three, perhaps the following list will suggest some possibilities:

- Use a fluorescent study lamp you may already have.
- Install fixtures on bookshelves or storage shelves.
- Make a closet into a fluorescent light center with several tiers of lights and storage space for plant supplies.
- Install fixtures on the bottom surface of kitchen wall cabinets.
- Fit old buffet tables, radio cabinets, and other furniture with fluorescent tubes after removing interior partitions.

If your indoor seed-starting space is severely limited, you'd be wise to consider some of the following when deciding which plants to start early:

- Plants that need a long period of growth to prepare them for setting out.
- Those that are most costly or difficult to find commercially.
- Those that produce well over a long period.
- Fine-seeded plants that might get lost in the garden row.
- Vegetables you like best.



A typical grow-light setup.

Distance from Light. Seedlings, in general, need more intense light than mature plants. If they are not getting enough light, they will develop long stems before their first leaves appear. Either they're overcrowded or they are too far from the light. I keep my seedlings extremely close to the light tubes, as close as possible short of touching the leaves to the glass, and never more than three to four inches away for the first three or four weeks after germination. Then, if they are stocky and growing well, I lower them by an inch or two and continue to lower the flat placement gradually as plant height increases. Light spreads more when plants are farther from the tubes. It's also a good idea, since light at the ends of the tubes is relatively weak, to trade positions of the various flats of plants from the ends to the more fully lit center every week or so.

The shelves on my plant cart are adjustable, but I find it easier to jack up the seedling flats by using egg cartons, shallow cardboard cartons, piles of magazines, and other improvised supports that may be removed gradually as the plants grow.

Industrial reflector fixtures, the kind we once used in a basement light center, may be suspended by chains. If you leave enough slack, about 12 to 15 inches, in the chain to raise and lower the light so that it can be set at the right height for either small seedlings or taller plants, you'll have a good adjustable setup.

The Hours of Light

In my experience, seedlings do very well with 16 hours of light a day, the usual recommended time. I have made do with 12-hour light exposures under limited light space. The lights burned day and night, and the seedlings took turns basking under them for 12 hours at a time. The tomatoes got a bit spindly, but most plants grew surprisingly well on this schedule. Sixteen hours is much better, though. Even 18 hours is not too long, but it's longer than necessary for most seedlings. Lighting time should not be increased above 18 hours. Too much light will disturb a plant, just as too much water or fertilizer will.

Providing Plants with Darkness

The light a plant receives, you remember, makes it possible for the leaves to manufacture starches and sugars, the components of growth. But a period of darkness is necessary for the plants to put these new compounds to use. Plants don't "rest" at night. They digest and grow. Both processes go more smoothly when night temperatures are 5°F to 10°F (3°C to 5.5°C) lower than daytime levels. The ideal ranges are 70°F to 75°F (21°C to 24°C) during the day and 55°F to 65°F (13°C to 18°C) at night.

Scientists have concluded that plants are actually attuned to the dark period rather than to daylight. Darkness is indispensable to normal growth. Some plants, in fact, blossom only when nights are long (chrysanthemums and poinsettia). Others, like onions, need short nights to develop fully.

Continued ➔

Most vegetable plants are day-neutral, meaning their full development isn't dependent on a light-dark rhythm of any certain pattern.

Turning off the lights at night, then, is as important as turning them on in the morning. When I shifted two batches of plants under lights that were on continuously, I was careful to provide "night" for the plants that received illumination from 8 p.m. to 8 a.m. by covering them with cartons or newspaper tents during the day.

Problems

Nancy Bubel

Fortunately, seedling plants seem to thrive within a rather generous range of conditions. If your seedlings show compact growth, plenty of good green leaves, short internodes between leaves, and slow but steady growth, all is well.

Occasionally, though, excess or deficiency in one or another of the young plant's life requirements will cause trouble. If you interpret the problem correctly and treat it promptly, you have a good chance of saving the seedlings.

Signs of Trouble

Troubled plants give clues. What should you look for? Check for the following signs.

Leaf Curl. A plant whose leaves curl under, especially in bright light, may be suffering from overfertilization.

Solution. Naturally, you'll decrease the amount of fertilizer your plants receive if you notice symptoms of overfeeding. If the problem is severe, you might need to replant the seedlings in another flat of fresh potting soil. Be sure to leach out the extra fertilizer salts from the soil in the old flat before reusing it.

Yellowing of Lower Leaves. This is sometimes a sign of overfeeding, although it can also indicate magnesium deficiency.

Solution. Follow the same procedures as for leaf curl above.

Dropping of Leaves. Along with plant stunting, the loss of leaves may be caused by exposure of the plant to leakage of partly consumed gas from the stove or water heater. You can test for gas leaks by buying yourself a bouquet of carnations. If the flower petals curl upward, gas has probably escaped into the air. Tomatoes will droop in the presence of gas, too. Natural gases like butane and propane don't seem to hurt plants, but manufactured gas does.

Solution. Repair the leak.

Leggy Plants. Plants with long, often weak stems that have large spaces between the leaves growing from the stem may be suffering from any one of the following conditions: insufficient light, excessively high temperature, and crowding of plants.

Solution. A leggy plant can't be reshaped to conform to the stocky, well-grown ideal form, but there are steps you can take to promote more normal growth from this point on. First, of course, remedy the cause: Supply more light, lower the temperature, or thin the plants. Plants kept at a window might need some auxiliary evening light on cloudy days. Then, if at all possible, transplant leggy seedlings. The root pruning and general mild trauma of being moved will set back their growth a bit. Set the plant deeper in the new container.

Bud Drop. Particularly with pepper seedlings, bud drop may occur if the air is excessively dry.

Solution. Try setting the flat in a tray containing pebbles and water, or mist the blossoms with a fine spray of water at least once a day.

Leaf Discoloration. Discolored leaves usually indicate a nutrient deficiency.

Pale Leaves. In seedlings that receive sufficient light, pale leaves are a sign of nitrogen deficiency. Tomato seedlings that are severely deficient in nitrogen develop a deep purple veining, especially prominent on the undersides of the leaves.

Reddish Purple Undersides. A plant deficient in phosphorus will have a reddish purple color on the undersides of its leaves. In addition, the plant will often be stunted, with thin, fibrous stems. Soil that is too acid may contribute to the unavailability of phosphorus.

Bronze or Brown Leaf Edges. Leaf edges that have turned bronze or brown may reveal a plant in need of potassium. Brown leaf edges may also appear on plants that are overwatered.

Solution. The differences among the various symptoms of deficiency are not always clear cut, especially in young plants. Your best bet, if you do notice leaf discoloration that can't be accounted for otherwise, is—in the short run—to give the plant a dose of fertilizer that contains trace minerals. In the long run, include some compost in your next soil mixture, or transplant the ailing plants to a medium that contains compost.

Discolored Roots. This is often the result of a buildup of excess fertilizer salts in the soil. Either the plant has been overfed, or overheating the soil in an attempt to sterilize it has released a

high concentration of soluble salts into the soil. Waterlogged roots often turn dark and may have an unpleasant odor.

Solution. Replant the seedlings in fresh soil if possible. Your second choice would be to flood and drain the flats several times in an attempt to leach out the toxic salts. If the flat is waterlogged, either provide better drainage or replant seedlings in better aerated and drier soil.

Mold. If you see mold on the surface of the soil, it indicates poor drainage, insufficient soil aeration, possible overfertilization, and/or a lack of air circulation.

Solution. Remedy the cause and treat the symptom by scratching some powdered charcoal into the soil surface.

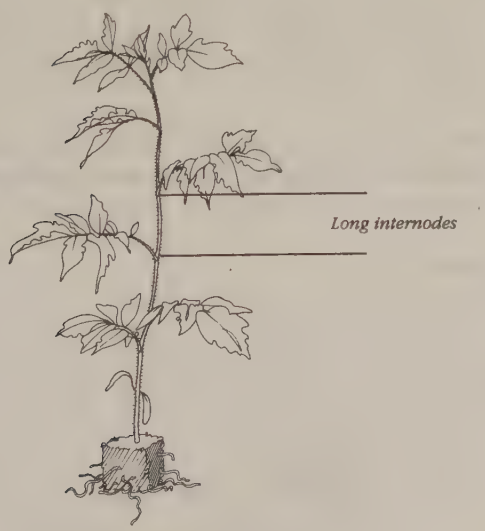
Insect Damage. Damage on seedling plants grown indoors most probably means that conditions are not ideal for the plant.

Solution. Control pest damage on plants grown indoors.

Damping-off. When damping-off occurs, you don't get much warning. Your first sign that the problem has hit your new plants is the total collapse of a few seedlings; the green leaves are still intact, but the stem has characteristically withered away right at soil level. Young seedlings are the most vulnerable.

Solution. Once a seedling has been attacked by the damping-off fungus (actually, there is a complex of microorganisms, any of which may cause the trouble) it can't be revived. The lifeline between root and stem has been cut off. However, you can try to prevent the problem by following these practices:

- Maintain good air circulation around seedlings by keeping the soil level high in the growing containers and thinning seedlings to avoid overcrowding.
- Avoid overwatering.
- Sow seeds in a sterile medium such as finely milled sphagnum moss or vermiculite.



A leggy plant has long stems and large spaces between leaves.

- Presoak seeds in a small amount of water containing one or two crushed garlic cloves—an ancient practice that still makes sense, now that we know more about garlic's fungicidal properties. You can also treat seedlings with a garlic spray. (Blend one clove of garlic with one quart of water and strain.)
- Sprays of chamomile or nettle tea are sometimes used on seedlings to help prevent damping-off.

It is often possible to save the remainder of a flat of seedlings if only a few have died. Immediately move the flat to a more open area; make sure that it is well drained; and remove the affected seedlings. There is no sense in transplanting the others—you'd just transfer the disease to new soil. You can save the flats though. Dry them out and ventilate them. I've salvaged several such flats and used them to produce early crops after all.

Skimpy Root Growth. This won't be evident, of course, until you transplant the seedlings. It may be caused by any one or more of the following factors:

- poor drainage
- low soil fertility
- concentration of excess fertilizer salts
- temperature too low
- insufficient air space in soil mixture

Failure to Sprout. If your seeds don't even sprout, the cause may be any one or more of the following factors:

- temperature too low or too high
- soil that was allowed to dry out
- seeds too deeply planted
- top watering that floated seeds off
- seeds that were old and poorly stored
- insufficient contact between seeds and soil
- toxic substances in soil
- damping-off disease
- lack of light for those seeds that need light in order to germinate, or lack of darkness for certain seeds, mostly flowers but also a few vegetables, that need this condition.

Hardening-Off Seedlings

Barbara Ellis

Indoors, you can control the light, water, temperature, and humidity to which your seedlings are exposed. However, seedlings need to be ready to withstand the more rigorous conditions that prevail in your garden—brighter light, wider

Continued →

extremes of temperature, as well as wind and rain—before they can be transplanted successfully. Sun, wind, and cold temperatures can kill succulent seedlings very quickly, or damage them enough to set them back for weeks. So, seedlings grown indoors need to be hardened off before they are moved to the garden permanently. Hardening off is a technique used to gradually introduce seedlings to their new environment. It also helps toughen them up by thickening succulent leaves and causing them to build food reserves.

Begin the process of hardening off your seedlings about a week before they're to be transplanted to the garden. If you have a cold frame, you can use it to graduate your seedlings from their cloistered conditions indoors.

1. **Slow Down Plant Growth.** Start hardening off your plants by watering them less often during the last week before transplanting and allowing them to dry out slightly between waterings. Also, don't feed them during their final week indoors. Another way to slow down growth is to keep temperatures on the cool side—if possible, a few degrees lower than what the plants have become accustomed to thus far. These steps will help thicken leaf surfaces and build food reserves.
2. **Blocking Out.** If you are growing any plants in flats, a few days before transplanting, use a knife to cut between the seedlings—a crisscross pattern from left to right and from back to front will suffice. Each plant should end up centered in a cube of soil, but leave them in the flat and otherwise undisturbed. Blocking out helps promote a well-branched root system and also cuts roots that would be broken during transplanting. Give blocked seedlings two or three days to begin their recovery before moving them to the garden.
3. **Acclimate Plants to the Garden.** After a week of cooler temperatures, as well as reduced watering and feeding, your seedlings are ready to be gradually exposed to the conditions outdoors. Start by exposing them to filtered sun outdoors on the north side of your house, in the shade of a bush, or under some other improvised shelter. Choose a spot that is protected from wind, which can dry seedlings out very quickly and cause them to wilt. Gusty spring winds can also break stems and whip seedlings around enough to damage roots. The first day, move them outdoors for about an hour in the morning or afternoon and gradually increase the exposure until at the end of a week or ten days they can withstand a full day of direct sun.

You'll need to keep a sharp watch on your seedlings during this process. They will need watering nearly every day because sun and wind cause the shallow flats to dry out quickly. Keep the soil moist enough to avoid wilting.

There comes a day in early spring when your seedlings have been hardened off and you're ready to plant them in the garden. Although clear, breezy spring days are beautiful, they're not the best kind for transplanting seedlings. Sun and wind cause seedlings to lose large quantities of water, which newly disturbed root systems have difficulty replacing. It's a far better idea to wait and transplant seedlings at the beginning of a spell of warm, damp, cloudy weather. That way, they'll have a chance to recover and put on root growth before having to withstand sun and wind.

Try not to rush seedlings into the gardens if cold weather still threatens unless you're prepared to cover them nightly with boxes or other protective devices when the weather turns cool. Jumping the average date of last spring frost pays off some years; in others, late spring frosts take their toll on newly transplanted seedlings. Although many plants grow well in cool temperatures, others are sensitive to cold and won't begin growing until the weather (and the soil) warms up. If you can't bear to wait, be sure to hold back a few of each kind of plant as insurance against a late cold snap.

Transplanting is a stressful operation for plants, and the more you can do to ease the stress a plant suffers in being put out in the garden, the sooner it will be off and growing. Here are some tips to make your transplanting day a success.

- Dig a generous hole for each seedling so that there is ample space for the plant's roots.
- If you're planting an entire bed of plants, work plenty of compost into the soil before planting, or add a handful to each hole as you plant, mix it in, and cover with ordinary garden soil before planting.
- Water seedlings before you transplant and try to keep as much soil around the plants' roots as possible so they will not dry out. If the potting mix falls away from the roots, it's a good idea to dip them in a slurry of thick, muddy water to be sure the roots stay moist.
- As you place each plant in its hole, take time to make sure the roots fan out evenly in all directions. They shouldn't double back on each other or stick up toward the top of the hole.
- Water the seedlings as you go, rather than waiting and watering after you've finished transplanting. If the soil is unusually dry, moisten it slightly before planting, because dry soil can quickly pull the water out of tender roots and damage them.
- To settle seedlings in their holes, fill the soil with loose, well-tilled soil, sprinkle at least a quart of water on each transplant, and gently firm the soil to eliminate large air pockets, so the roots will be in contact with the soil and there are no root-drying air spaces. A shallow, saucerlike depression will help catch rain and direct it toward the roots.

- As a general rule, set seedlings in the soil at the same depth they were growing in their pots. Tomatoes are an exception to this rule; if planted in a shallow trench on their sides with the top one or two sets of leaves above ground, the stems will grow roots and the plants will be less leggy.

Planting in Peat Pots

Seedlings grown in peat pots can be planted pot and all: That's why they are such a good choice for difficult-to-transplant species. However, keep in mind that the rim of a peat pot that sticks out of the soil will draw moisture away from the plant's roots. If this happens, the pot can become so dry it becomes a barrier that roots can't penetrate. When transplanting seedlings in peat pots, tear off the top inch or so of the pots so the remaining portion will be entirely underground. Cut slits down the sides to help roots penetrate them. Some gardeners prefer to gently tear away the entire pot if roots haven't already grown through. If you've started your seedlings in peat pellets encased in plastic netting, cut the netting off before planting. Then plant as you would any other seedling.

Don't Rush to Transplant

Although every spring gardeners rush to plant their gardens, late spring frosts and cool soil conditions can take their toll with many new plants. Many plants grow well in cool temperatures—cole crops such as cabbage, broccoli, and cauliflower, as well as peas, lettuce, spinach, and many annuals and perennials; however, others are very sensitive to cold, which can check growth or kill plants. When you begin the hardening-off process, be sure to bring your plants in each night. Seedlings that thrive in cool weather can be left out all night once they are fully hardened, but have boxes ready to cover them if frost threatens. Warm-weather plants such as tomatoes, peppers, eggplant, melons, and tender annuals and perennials also should be left out all night the last day or so of the hardening process. However, it's often best with these plants to wait an extra few days after the average last frost date before transplanting so that all danger of frost has passed and the soil has warmed.

Plant Protection

The transplanting operation doesn't end when the last seedling is in place in the garden, however. Sun and wind can still wreak havoc with your seedlings for the first week or so after transplanting, and freak, late spring frosts can reduce your carefully tended plants to mush. Be sure to keep them well watered and, if possible, screen them from heavy wind. Pale yellow leaves indicate sunscald. Cover afflicted plants promptly with screens, plastic sheeting, or anything else that will provide shade. Then gradually increase exposure to sun over several days.

Outdoor Sowing

Many kinds of seeds will germinate and grow perfectly well if sown outdoors in the garden. Vegetables such as beans, beets, corn, carrots, melons, peas, radishes, and zucchini are all direct-seeded. Annuals such as sweet alyssum, California poppies, cosmos, marigolds, nasturtiums, sweet peas, and zinnias, as well as many perennials, can also be sown outdoors where they are to grow. Plants that are difficult to transplant, including poppies, corn, cucumbers, parsley, melons, and dill, often are best sown outdoors.

Scheduling

Deciding when to sow seeds is as important for outdoor sowing as it is when you're starting seeds indoors. Check seed packets for recommended sowing dates and any other planting tips that will help improve your results. Plants that grow best when temperatures are cool, such as sweet peas, beets, carrots, and radishes, for example, can be sown as early as you can work the soil in spring. Other species, including marigolds, zinnias, squash, melons, and beans, are less tolerant of cool temperatures and should be sown after danger of frost has passed. Seed of many perennials and hardy annuals such as larkspur, poppies, and cleome, can be sown outdoors in late fall for germination the following spring.

Soil Preparation

The key to outdoor sowing success is providing seeds with a well-prepared seedbed. Seeds sown outdoors need rich, well-tilled soil in which to germinate. Before tilling in spring, make sure the soil is ready to work by squeezing a handful of it. If it forms a dense ball that doesn't crumble readily, the soil is too wet to work. Tilling wet soil can damage its structure, so if the soil is wet, wait a few days and test it again. If the soil is ready to work, use a shovel or rototiller to dig or turn it to a depth of 6 to 8 inches. Then spread a layer of compost or leaf mold over the bed and work it into the top 2 or 3 inches of soil. Compost will increase the amount of water held in the soil and will help prevent crusting after heavy rain. If you prepared your soil in the fall, you may need only to fluff up the top inch or so of soil before seeding.

When planning your garden and preparing your soil, you might consider the benefits of raised beds. Raised beds improve drainage and aeration, provide a warmer germinating area for plants, and prevent soil compaction because you can reach the center of the bed from either side and consequently don't

Continued

need to walk where you planted. Raised beds can be edged by wooden boards, bricks, cement blocks, stones, or railroad ties. Structured sides make gardening easier on you because you can sit on the sides when you work on the bed rather than stooping and bending. When you are planning the dimensions of your bed, make it 3 to 5 feet wide so that you can easily reach across from different sides to work on it.

Sowing

In a vegetable garden or cut-flower garden, you can sow seeds in rows marked off with string or a board. (Rows running north-south take best advantage of the sun.) In ornamental plantings, you'll want to arrange seeds in a more free-form pattern. Whatever you do, check the seed packets for recommended spacing and sow seeds thinly so the seedlings won't become crowded. Spacing the seeds properly from the start will reduce thinning chores later. After sowing, firm the soil in place around the seeds and water with a fine spray. Keep the bed weeded at least until seedlings can fend for themselves. Spring-sown seeds should be kept evenly moist until seedlings are well on their way. Autumn-sown annuals such as larkspur and cornflowers should be watered once when they are sown and can be left to germinate the following spring.

There are several methods for sowing seeds. Large seeds are often sown individually by hand. Smaller seeds can be planted in rows, scattered in broad strips, or broadcast over a large area.

Conventional Rows

Vegetable gardens have been traditionally planted in straight rows marked off with string or a board. After marking the row, make narrow V-shaped grooves or trenches, called furrows, for planting. Use the corner of a hoe to make furrows for large seeds or a garden tool handle to make them for smaller seeds. The rule of thumb is to sow seeds to a depth equal to 2 or 3 times the diameter of the seed. Sometimes, however, it's hard to apply this guideline with oddly shaped seeds, so check seed packets for planting depths. Packet information will also indicate if a plant requires light or darkness for germination. It's important to plant the seeds at the correct depth; they may dry out if sown too close to the surface or not be strong enough to break through the soil if sown too deeply. You can plant seeds a bit deeper in the summer if the soil is hot and dry to protect the seeds from the sun.

For small seeds, sow directly from the packet by tapping it and dropping the seeds out one at a time, or drop them in pinches from your fingers. You might want to use old spice shakers to spread seeds evenly. Large seeds can be placed individually.

When you complete a row, you can pinch together soil from the sides of the furrow to cover the seed or work along the row with a hoe and tap soil from the sides of the furrow to cover the seed. Don't forget to mark each row so you will know what crop is there. Water lightly, and keep the seedbed evenly moist until germination occurs.

Seed Tapes. If you really want to ensure correct seed spacing, you can use easy-to-handle seed tapes. Many companies offer both flower and vegetable seeds that are prespaced on tape, so you just trim the tape to fit the length of the furrow. Plant the tape at the correct depth and the tape will eventually dissolve. You can find seed tapes in well-stocked garden supply centers or through mail-order catalogs.

Broadcasting

Broadcasting is an easy method that's best for single-crop beds or broad strips of plants instead of conventional rows. It works best with fast-growing, small-seeded plants such as carrots, turnip greens, radishes, beets, and leaf lettuce. It is especially effective for sowing cover crops and lawn grasses. This method of scattering seeds lets you sow large areas quickly, but frequent weeding the first three weeks and some thinning or transplanting might be necessary.

Sling seeds outward in even motions the full width of the bed, letting seeds scatter in midair so they fall evenly on the soil. It's a bit difficult to sprinkle the small seeds evenly at first, so you might want to practice. To prevent seeds from sticking together, you can mix them with fine sand, dry coffee grounds, or dry soil and spread the mixture. White play sand, the type used in children's sand boxes, is especially useful for this purpose, because it lets you see where you've already sown. Using a mixture also makes it easier to handle very fine seeds. Next, gently press the seeds into the ground with the back of a hoe. Seeds need close contact with the soil so they can take up water necessary for germination. Gently tamp the seedbed again with a hoe and water with a gentle spray from a watering can or sprinkler. Very fine seeds do not need to be covered at all. Just rub soil between your hands, letting it lightly cover seeds, or

mist with water. It's important to keep the seedbed moist until the seedlings poke up. This is fairly easy in early spring, but will be harder as the days get longer and hotter in summer.

Hill Planting

Hill planting is a good way to provide space for vines like watermelon, squash, melons, pumpkins, and cucumbers because it gives room for them to spread. It also provides them with the rich, loamy soil they require for best performance.

To build a hill, form a 6- to 12-inch-high mound of loamy, fertile soil 1 to 1½ feet square. Amend the soil with plenty of organic matter such as compost to make sure it is porous and loose. Flatten the mound on the top so water won't erode it during heavy rains. A light covering of mulch, such as salt hay, will also help prevent rains from washing the mound away before plant roots bind it together.

Plant six to eight seeds in the mound at the correct depth, spacing them along the tops and sides. Later you can thin out your plants, leaving the two or three strongest. If the soil is poor or if you'd like to provide an especially rich environment for your plants, dig a hole 12 inches deep and 12 inches square before forming each hill. Fill it with well-rotted compost, manure, or other organic material. Then build a mound on top.

Spacing and Thinning

There are many factors to consider when determining seed spacing. In the end, you have to use your judgment and experience. You can start out spacing according to packet directions, observe how much certain plants expand as they grow, and decide if you can afford to tighten up your spacing next year. If you space too closely, they'll have to compete with neighboring plants for water and nutrients. If you space too far apart, you waste valuable garden space and leave room open for weeds.

Climate is a factor to consider. Wider spacing is recommended for planting in unusually dry climates, for example, because plant roots need to search farther for water. If your soil is not very fertile, heavy feeders also will benefit from wider spacing.

If your growing seedlings need more elbow room than you have allowed, you'll need to thin them. Overcrowded conditions result in competition for moisture and nutrients, which leads to weak, unhealthy plants. Try to thin as early as you can, because the longer you wait, the harder it is to disentangle roots of neighboring plants. You may have to go back and thin again as the plants grow. With many vegetable crops such as carrots, lettuce, and spinach, the thinnings are a blessing in disguise, for they make tasty additions to summer salads.

To thin, you can clip the seedling with scissors at the soil level, thus avoiding the problem of damaging entangled roots of the plants you are leaving in the row. Or you can simply use one hand to hold down the good seedlings and the other to gently pull out the extra seedling. This is easier to do when the soil is moist. You can also use a putty knife to carefully dig up the unwanted seedlings. Plants removed in this manner often can be moved elsewhere in the garden or given away.

Intensive Spacing

One way to maximize yields is to use intensive spacing. This technique involves spacing plants closer together than normally recommended on seed packets. Plants are spaced equal distances from each other so that when they mature, the leaves just touch and the entire bed is covered with foliage. Although vegetables planted in this manner will yield less per plant, because of the efficient use of space, overall yield is much higher. Intensive spacing also serves to shade the soil and help hold moisture in the soil.

Intensive Spacing for Vegetables

Here are some broad guidelines for intensive spacing. The best spacing guide is, of course, experience and knowledge of your particular climate and soil conditions. Carefully observe how well plants grow at different spacings and use that as your guideline.

Crop	Spacing (in.)	Crop	Spacing (in.)
Beans	4-9	Okra	12-18
Beets	2-6	Onions, bulb type	4-6
Broccoli	15-18	Onions, bunching	2-3
Brussels sprouts	15-18	Parsley	4-6
Cabbage	15-18	Peas	2-6
Carrots	2-3	Peppers	12-15
Cauliflower	15-18	Potatoes	10-12
Chinese cabbage	10-12	Pumpkins	24-36
Collards	12-15	Radishes	2-3
Corn	18	Spinach	4-6
Cucumbers	18-36	Squash	24-36
Eggplant	18-24	Sweet potatoes	10-12
Kale	15-18	Swiss chard	18-24
Leeks	2-6	Tomatoes	18-24
Lettuce, leaf	6-9	Turnips	4-6
Melons	24-36		

Raised beds are an essential component of intensive spacing. They provide the deep, rich, well-prepared soil required to encourage plant roots to grow down, rather than sideways to compete with neighboring plants.

As with conventionally spaced plantings, your experience and judgment are the best guidelines. Pay attention to factors like shading, companion planting, and planting combinations. For example, lettuce is a perfect choice for intensive spacing because it benefits from some additional shade. To use underground space efficiently, it's a good idea to alternate rows of leaf and root crops such as spinach and onions.

Top 10 Tips for Storing Seeds

Vicki Mattern

If you have leftover seeds or aren't ready to plant your seeds when they arrive, you'll need to store them properly to ensure good germination.

1. Think dry and cool no matter where you store seed. Humidity and warmth shorten a seed's shelf life.
2. The refrigerator is generally the best place to store seeds.
3. Keep seed packets in plastic food storage bags, plastic film canisters, Mason jars with tight-fitting lids, or glass canisters with gasketed lids.
4. Keep your seed-storage containers well away from the freezer section of your refrigerator.
5. To keep seeds dry, wrap 2 heaping tablespoons of powdered milk in 4 layers of facial tissue, then put the milk packet inside the storage container with the seed packets, or add a packet of silica gel. Replace every 6 months.
6. Store each year's seeds together and date them. Because most seeds last about 3 years, you'll know at a glance which container of seeds might be past its prime when planting season comes.
7. When you're ready to plant, remove seed containers from the refrigerator and keep them closed until the seeds warm to room temperature. Otherwise, moisture in the air will condense on the seeds, causing them to clump together.
8. If you're gathering and saving seeds from your own plants, spread the seeds on newspaper and let them air dry for about a week. Write seed names on the newspaper so there's no mix-up. Pack the air-dried seeds in small paper packets or envelopes, and label with plant name, date, and other pertinent information. Remember, if you want to save your own seeds, you'll need to plant open-pollinated varieties. They'll come back true; hybrids won't.
9. Or dry saved seeds on paper towels. They'll stick to the towels when dry, so roll them up right in the towel to store them. When you're ready to plant, just tear off bits of the towel, one seed at a time, and plant seed and towel right in the soil.
10. Even if you're organized, methodical, and careful about storing seeds, accept the fact that some seeds just won't germinate the following year. Home gardeners will find that stored sweet corn and parsnip seeds, in particular, have low germination rates, and other seeds will only remain viable for a year or two.

Saving Seed

Barbara Ellis

Although many gardeners depend on the annual winter deluge of seed and nursery catalogs for the seed they sow each year, there are at least two good reasons to save your own seed from year to year. First, by saving seed you can harvest, store, and replant seed of a cherished plant year after year. This is especially important when saving seed of antique or discontinued cultivars that may no longer be offered by seed companies. Second, saving seeds is the easiest way to experiment with plant breeding. You can cross-pollinate two different plants to create your own hybrid, then harvest, save, grow, and evaluate the offspring of your cross.

HARVESTING SEED

Before harvesttime rolls around, you'll need to take time to learn about and observe the plants whose seed you'd like to collect and save. The more you know about the plants from which you will be harvesting seed, the better your chances of success.

FLOWERING

If you know approximately when flowering occurs, you'll find it much easier to prepare for the harvest. You should know if the plant is an annual (produces seed in the single year of its life), a biennial (produces seed only in its second and final year of life), or a perennial (produces seed each year).

FERTILIZATION

If you wish to collect pure seed to preserve a species or special cultivar, try to find out if it is easily cross-fertilized by other species or cultivars. If so, cover the immature flower before it opens with a lightweight paper bag or other covering to prevent pollen from other plants from pollinating the flower. Then make sure the flower is pollinated with its own pollen or that from another bloom of the same type to ensure pure seed.

SEED

You'll also need to know how long it takes for the seed to ripen and the manner in which it is normally disseminated. Tiny seed can be easily lost during collection, so simply arch a seed head or pod into an envelope or other container, tap a few times to dislodge loose seed, and remove the seed head from the stem—taking seed head and seed together for cleaning afterward.

Some plants dispel their seed from pods that abruptly pop or shatter and scatter the seed in all directions. For these, place an envelope around the pod or seed head before it is ripe and ready to discharge its seed. Remove the seed pod and seed from the stem once it has ripened. Seed that is difficult to harvest can often be collected easily if entire branches are removed from the plant, placed into a large paper bag, and thrashed back and forth by shaking the bag. If the seed is mature the thrashing action will dislodge it readily. Also, most plants will signal the approach of seed maturation by losing flower petals, splitting pods or capsules, and changing the color of fruit, pods, or seeds. Be aware of these signals and use them in timing the harvest.

Keep in mind that many improved cultivars sold through catalogs don't come true from seed. They may be hybrids created by crossing specific parents or color forms that must be propagated vegetatively by means such as division or cuttings. Feel free to experiment with these plants, but don't be disappointed at the results.

Regardless of when the harvest takes place, there are several important points to keep in mind:

- Collect seed only from healthy plants.
- Harvest on a dry, calm, sunny day.
- Use a separate container for each different type of seed.
- Clearly label each collection container with the name of the plant and the collection date.
- If you are collecting seed of wildflowers or other native plants, don't be guilty of eliminating a unique species from its native habitat. Be sure you leave ample seed behind for the continuation of the species or variety.

CLEANING SEED

Before storing seed, remove all debris that might introduce contamination during storage.

Separate seed from fleshy fruit by gently working the fruit over a fine mesh screen with your fingers, and then rinsing the resulting mixture with water. The spray will force the fruit through the mesh, leaving the seed behind.

Remove fine chaff from seed by gently dropping it onto a large sheet of paper, from a height of 4 or 5 feet. When this task is performed on a slightly breezy day or in the presence of a fan, the light chaff will be removed in the air and the heavier seed will fall onto the collection paper.

Separate fine seed from large chaff and debris by gently working the combination through a fine screen; the fine seed will fall onto the collection paper and the chaff and debris will be held behind.

DRYING SEED

Seed must be absolutely dry during storage or it might germinate prematurely. Moist conditions will also encourage mold. Air drying on newspaper in a dry, airy location works well, but often requires one to two full weeks to accomplish. This time frame can be reduced to three or four days if the seed is dried on newspaper located 6 to 12 inches below a light bulb; the air temperature around the seed should be no more than 90°F, otherwise the seed may be burned or injured. Oven drying is not recommended, since rapid drying usually results in cracking of the seed coat.

After drying, add a small amount of silica gel (equal in weight to the seed) to the storage container. The silica gel is a desiccant, and will remove additional moisture that might be introduced during storage. You can substitute powdered milk wrapped in a paper towel, but it must be replaced about every six to eight weeks.

SEED STORAGE

Seed that has been cleaned and dried should be placed in a clean, dry container. Glass jars with screw tops work well; use small jars (baby food, medicine, or spice jars are ideal) for a single type of seed, or larger jars for holding envelopes of several different types. Remember to properly label each envelope or container.

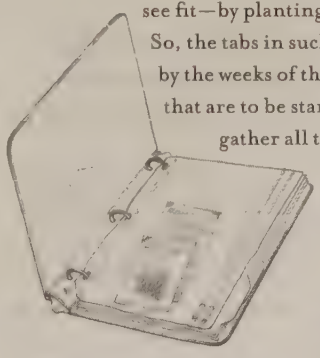
Place the containers in the refrigerator (32° to 41°F). As long as the seed remains dry, it will maintain its viability. Most seed will survive for at least a full year, and some will last for several to many years.

Upon removal from storage, allow seed to adjust to room temperatures for a few days before sowing.

Seed Projects

Roger Yepsen

If your seed packets tend to stray, and you habitually tear off the name of the plant, there is a tidy way to put whatever you're after right at your fingertips. Buy ring binder bags, place the packets in them, and use a three-ring binder to organize the packets as you see fit—by planting date, or by the type of plant. So, the tabs in such a notebook might be labeled by the weeks of the year, alerting you to the seeds that are to be started now; or, you might want to gather all the lettuces, the tomatoes, and the peppers in one section. The bags are available from office supply firms.



Seeds are tiny, and all the more difficult to store and organize because of it. Slip seed packets into resealable plastic ring-binder pages and come up with a system for putting them in order.

You can also store seed packets in three-ring binder photo sleeves. Choose sleeves that hold 3-by-5 or 5-by-7 photos, fold over the seed packet top, and insert the packets into the sleeve pockets.

Make Your Own Growing Mixes

What You'll Need

Seed-Starting Mix

1 part milled sphagnum moss
2 parts vermiculite
2 parts perlite

Potting Mix with Compost

1 part finished compost, screened through a mesh of ¼-inch hardware cloth
1 part vermiculite

Potting Mix without Compost

1 part commercial potting soil
1 part milled sphagnum moss
1 part vermiculite

Just about anything costs you more if you buy it in small containers, and that goes for bagged seed-starting and potting mixes. Instead, come up with your own custom blends for both in large quantities, and store them neatly in plastic garbage cans rather than floppy plastic bags that tend to spill. The one thing you don't want to do is include ordinary garden soil in your recipes, with its weed seeds, disease organisms, fungi, and insects. Not only that, but most soils are just plain too dense to get plants off to an optimal start.

To combine the ingredients easily, use a plastic tub of the sort sold for mixing cement. Or for larger volumes, spread the measured amounts of each ingredient on a tarp spread over the driveway or patio. Choose a relatively windless day to work. Even so, the dust may fly, and you may want to occasionally mist the medium with a fine spray from a hose. Use a dull hoe or a metal rake (tines up) to mix thoroughly. Then place the mixture in a new plastic garbage can—use one for seed-starting mix, and a larger one for potting mix. Keep a plastic bucket on hand in which to moisten small amounts of mix by stirring in water. Allow enough time to ensure that the medium in the bucket is completely moistened. Dry mix may dehydrate young seedlings, killing them. If you do a lot of seed starting and potting over a short period each spring, you may want to have several buckets of soaking mix on hand so that you don't feel tempted to rush the moistening process.

There are any number of recipes for seed-starting and potting mixes, so feel free to adapt the suggestions for mixes on this page. Be sure to include compost only if it is thoroughly processed, rather than half-degenerated plant matter.

Put the Damper on Damping-Off

Damping-off is a fungal disease that can rapidly lay waste to entire flats of vulnerable young seedlings. You'll know it by the afflicted stems, which may take on a water-soaked appearance or turn thin and wiry at the soil line. The unsupported seedlings topple and die. As a preventive, moisten the seed-starting medium with a mild homemade fungicide. To 1 gallon of water, stir in 1 tablespoon of clove oil (available at supermarkets and drugstores, as well as by mail order) and a drop or two of dishwashing soap. Among various powerfully scented herbs and spices, clove has been found to be particularly effective against two principal soil-borne pathogens.

Top 10 Tips for Seed Shopping by Mail

Vicki Mattern

Seed shopping by mail can certainly liven up a dreary winter's day. These guidelines will help you make the best seed choices for your garden.

1. Peruse a variety of seed catalogs to compare selection and prices.
2. Start seed shopping in winter so you can work out the details of your seed-sowing and transplanting schedule.
3. Keep all seed catalogs for use as reference once you begin planting.
4. Look for catalogs that specialize in plants that grow well in your specific region of the country.
5. Weigh the amount of variety you want versus the price of the seed packets. Small seed packets of individual plants are reasonably priced but only contain one type of plant. Seed mixtures give you many types of plants in a single packet but usually cost significantly more.
6. Realize that the number of days to maturity quoted in catalogs is an estimate. The actual number of days may be slightly different for your area.
7. Decide between hybrids and open-pollinated cultivars. Hybrids may produce earlier harvests and higher yields, but open-pollinated cultivars may taste better, produce over a longer season, and usually cost less.
8. Watch out for seeds that are treated with synthetic chemical fungicide. When ordering, specify untreated seeds.
9. Choose cultivars that have qualities that are important to you, such as plant size, habit, and tolerance of your soil conditions.
10. Look for All-America Selections because these tend to grow and produce well in a variety of conditions.

You also can buy a fungal control agent formulated to prevent damping-off, marketed as SoilGard. It contains dormant spores of a beneficial fungus. When mixed with water, the fungus comes to life and puts off an antibiotic substance. Another product, Mycostop, harnesses a beneficial bacterium that controls or suppresses damping-off and other soil-borne troublemakers as it grows among the seedlings' roots. It too can be mixed with water for use as a soil drench.

An additional step that takes little time is to scatter a dusting of milled sphaghum moss over the soil surface. This thin layer will help keep seedling stems drier, suppressing disease, and the moss also contributes a certain antimicrobial effect. Note that this product is marketed in small bags—don't confuse it with baled peat moss. To make it easier to apply a thin layer, you can give the moss a spin in a blender to reduce the particles to a dust.

Save with Soil Blocks

Instead of buying dozens of little pots or plug trays in which to seed next year's garden, you can skip the containers altogether by using a mold to make soil blocks. These blocks are nothing more than cubes of planting mix. They encourage a healthily branching root system that sets up plants for a happy transition to the garden. (Because the blocks are relatively shallow, however, they aren't the way to go with deep growers like carrots and beets.) The steps for converting damp mixture into planting blocks are easy enough, once you buy a blocker. These devices are available from nurseries and mail-order supply companies. You'll also need trays in which to place the blocks.

You can buy blockers in two sizes, with the smaller model making many little blocks that eventually will fit nicely within a square hole in the larger blocks, which look something like square doughnuts. This system avoids disturbing the seedlings as they're moved to a larger container.

1. Stir up a batch of planting medium that will keep its shape once popped out of the blocker. Johnny's Selected Seeds (www.johnnyseeds.com) sells a mix that will work well. Here's a recipe for making your own:
   - 2 parts peat moss, screened through a mesh of ¼-inch hardware cloth
   - 1 part vermiculite
   - 1 part finished compost, also screened through hardware cloth

   Do your mixing in a flat-bottomed container that's wide enough to allow you to press the blocker into the medium; a plastic tub sold for mixing concrete is ideal, and a clean wheelbarrow will also work. Make sure you allow enough time for the medium to fully absorb the water you add to moisten the mix.
2. Press the blocker into the medium so that the squares are filled. Then push the handle to eject the row of blocks into the tray.
3. Plant seed in the conventional way.
4. You can water the blocks from the top as you would seedlings in pots or flats. Use a misting nozzle or fine rosette on a watering can to avoid causing the block to come apart. The blocks will become sturdier as roots spread through them, but to avoid the risk of crumbling them, you can deliver water from the bottom up with capillary matting.

A Plug-In Welcome Mat for Seedlings

At a cost approaching $100, a thermostatically controlled seedling mat may seem like a luxury if you're accustomed to using the secondhand heat from the top of a furnace or water heater. But assuming you start vegetables and flowers from seed each spring, you'll appreciate the convenience—and the dependable results, especially for seeds that are tricky to germinate. And because plants get off to a quicker start, they may be less vulnerable to damping-off. Small-scale greenhouses and specialty growers have discovered that seedling mats create ideal conditions, meaning less work, less reseeding, and less babying of weak plants.

A less expensive alternative is to snake a length of heating cable under the flats to provide gentle bottom heating. The cables cost roughly a dollar a foot; you can expect to pay more than that for shorter cables, and less for lengthy ones. Adding a thermostat substantially increases the price.

Heat Helps Heaps

Supplying bottom heat can make a startling difference when starting seeds. Have a look at how long it took lettuce seeds to come to life at various soil temperatures, as reported in *Knott's Handbook for Vegetable Growers*, a resource for commercial market gardeners. If you're patient—fine. But if you're anxious for that first bowl of garden-grown salad, a heat cable or seedling mat makes good sense.

77°F—2 days	50°F—7 days
68°F—3 days	41°F—15 days
59°F—4 days	32°F—49 days

Presprout For Better Results

To increase the percentage of seeds that will make it as plants, presprout them rather than trusting that garden conditions will be favorable. The germinated seeds will get off to a faster start once they reach soil or planting medium. The system works particularly well for plants that need warmth to get under way, including cukes, melons, pumpkins, and squash. Here's what you do:

1. Dampen a sheet of paper towel that's been folded over once or twice to make a blotter.

Continued ➔

2. Arrange the seeds over the surface without allowing them to touch.
3. Place a single damp sheet of towel on top of the seeds, press down to help hold them in place, then slowly roll up the toweling.
4. Place the rolled toweling in a plastic bag. Leave the bag open and put it in a warm place, out of direct sunlight. Take a peek at the seeds each day to determine when they've begun to sprout.
5. Plant the presprouted seeds in potting mix and place them under fluorescent lights or in sunlight.

Cold Frame, Warm Plants

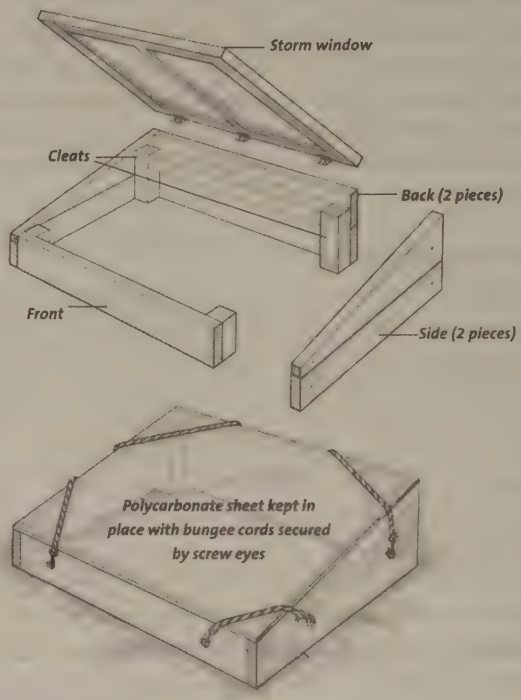
A cold frame might better be termed a warm frame, its purpose being to make use of heat stored in the earth as well as solar energy. You can use it at both ends of the gardening year, when the weather isn't quite so hospitable.

A variety of mail-order frame kits are on the market, typically with polycarbonate glazing and framing of cedar, redwood, or metal. If you are reasonably handy, you can assemble the frames with just a couple of hand tools.

BUILDING A WARM FRAME

A warm frame made of cedar will hold up better than those made with other woods, and there's no need to rely on preservative chemicals. (Exterior-grade plywood works well, and it allows you to make the sides and back from a single piece rather than with two boards each.) If you are having a sheet of double-walled polycarbonate glazing cut to size, you can determine the overall dimensions of the frame. Or, to make use of an old storm window, adjust the length and width of the frame to suit it. Just make sure that the frame has a front-to-back slope to take better advantage of the sun.

1. Cut the pieces as shown, choosing the dimensions to suit the storm window, if you are using one, and your own needs. Typically, a frame will be about 3 feet deep by 6 feet wide. The front should be roughly 12 inches lower than the back, with the sides sloped accordingly, to pitch the glazing toward the sun. The front, sides, and back are from ¾-inch-thick stock; the cleats are from 2 x 4s ripped in two pieces roughly 1½ inches square.
2. Five cleats add rigidity to the frame. Assemble the back by driving 1¾-inch screws through the two back pieces into the back cleats. (For these and all screws used in the project, drill pilot holes.)
3. In the same way, attach the front piece to the front cleats.
4. Assemble the frame by attaching the sides to the cleats, front and back. Note that the top inside edge of the back will be slightly above the sloping sides. Using a hand plane, bevel this edge to the angle of the sides.
5. Install the storm window using three exterior door hinges with the screws provided, attaching them to the outside of the back and underside of the window. Or, if you are using a sheet of polycarbonate, you can keep it in place with bungee cords, attached to screw eyes driven into the sides, front, and back, as shown in the detail. Keep the front two cords loose enough that a block of wood can be inserted under the front edge of the sheet to vent the frame.



An old storm window can serve again as the lid of a cold frame. Or you can use a sheet of polycarbonate glazing.

When a Seed's Battery Runs Down

If you start plants from seed, it's good to know how long the seed of each vegetable will remain viable. Otherwise, you risk planting a row from which nothing—except weeds—will appear. While some seeds can sit around for a few years without suffering a greatly reduced germination rate, cucumbers among them, others have to be purchased each year, such as parsnips. That's especially important if you have a modest-size garden and find yourself with leftover seed at the end of each growing season. It's also apt to be a factor if you save seed from your plants and can easily collect enough to last for the next several years.

Although it's possible to give general longevity figures for vegetable seeds you may find that your seeds are considerably more or less viable because of the way in which they're stored. Ideally, seeds should be kept cool and dry and out of direct sunlight. Jars with screw-on lids are a good choice. Place them in the refrigerator, if you have the space. For legumes, however, it's best to allow the seeds to breathe by storing them in a paper or cloth bag.

Iron-Clad Seeds

Read before you reap. Catalogs, plant labels, and seed packets often alert you to any diseases to which a particular variety is resistant. The more common afflictions may be listed as abbreviations, such as TMV for tobacco mosaic virus and VFF for verticillium and fusarium wilt. Resistance to a disease means that the plant is less likely to show symptoms; it does not certify that the plant is immune. Plant varieties also may offer resistance to problems other than diseases, such as tip burn in lettuce and the effect of cold on tomatoes.

Seed Tape Simplified

This pleasant off-season gardening project is one that's suited to doing along with kids. Using an icing decorating bag and a few household materials, you can manufacture your own seed tapes with the varieties (and spacing) of your choosing. Look for decorating bags at craft stores.

What You'll Need

Yardstick or other straightedge
Newspaper (black-and-white sections only) or newsprint
Wheat flour
Disposable icing decorator bag (or heavy-duty sandwich bag)
Seeds
Plastic food storage bags

1. Using the straightedge as a guide, tear off strips of newspaper about 1½ inches wide.
2. Make a paste of flour and water.
3. Fill the decorating bag or sandwich bag with paste, and cut off the very tip to make a hole. With the yardstick establishing the spacing given on the seed packets, make generous dabs of paste by squeezing the bag. (A decorating bag coupler and a star-shaped decorating tip will make the job even easier.)
4. Place one seed on each dab, tapping so that it will stay put.
5. When the paste has completely dried, gently fold or roll the strip and place it in a plastic bag along with the seed packet for identification.
6. Once it's time to plant, place the seed tape at the depth recommended on the seed packet.

Seed-Starting Glossary

Amendment Material that improves soil condition and aids plant growth.

Bolt To produce flowers and seed prematurely, usually due to hot weather.

Cotyledon Also called seed leaves. The leaf (or leaves) present in the dormant seed that unfolds as a seed germinates. Cotyledons often look different from the leaves that follow them. In seeds such as beans, they contain stored nutrients.

Damping-off A disease caused by various fungi that results in seedling stems that shrivel and collapse at soil level,

Direct-seed To sow seeds outdoors in garden soil.

Dormancy A state of reduced biochemical activity that persists until certain conditions occur that trigger germination.

Hardening off Allowing young plants to adapt slowly to wind, temperature, and light conditions outside by increasing the amount of time the plants spend outdoors each day.

Scarification Nicking or wearing down hard seed coats to encourage germination.

Seed A plant embryo and its supply of nutrients, often surrounded by a protective seed coat.

Seed germination The beginning of growth of a seed.

Seedling A young plant grown from seed. Commonly, plants grown from seeds are termed seedlings until they are first transplanted.

Stratification Exposing seeds to a cool (35° to 40°F), moist period to break dormancy.

Viable Capable of germinating.

Fern Marshall Bradley

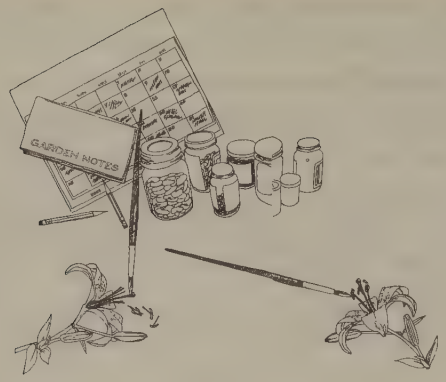
Do you feel overwhelmed when you page through garden catalogs or walk down endless aisles of plants at a nursery? How do you choose? We asked the experts for hints on how to get the most for your money and the best choices for your garden.

Hints For Healthy Bedding Plants

Don't make the assumption that all of the flats in the sea of plants at your garden center are equal. Inspecting plants before you buy can help you get the best quality for your money. Terry Humfeld, the executive director of the Professional Plant Growers Association, offers these four tips to help gardeners select top-quality bedding plants:

1. "Plants should have sturdy stems," Humfeld says. "Avoid any that are leggy or limp or whose leaves are curled, mottled, and yellowed. They may be infested by pests." Common pest

Continued →



problems for bedding plants include spider mites and aphids. Infested plants will have a harder time rebounding after being transplanted, and they may bring pest problems into your garden.

2. Stay away from plants whose lower leaves are turning yellow. It could be a sign that the flats were allowed to get too dry. Some roots may be permanently damaged.

3. Choose plants in packs that allow a larger root system and don't dry out quickly. These larger packs translate to 24 or 48 plants per flat. Flats may have as many as 72 cells per pack—an economical way to buy for large plantings. If you do choose flats with small cells, be sure to plant these plants immediately, before the roots become matted in the little cells.

4. Plants that aren't yet in bloom make a better transition to the garden than those in flower. When you have a choice, buy plants that aren't blooming. Sometimes that's not possible. Humfeld says, "If you can bring yourself to do it, pinch off the flowers and flower buds." Although most bedding plants are bred to flower in their packs, the plants will appreciate a chance to gain vegetative growth rather than flowering in their first days in the garden.

Study Your Seed Catalogs

While an impulse buy of a seed packet from a store rack might inspire you to grow a new crop or a flashy flower you've never tried before, you're best off relying on mail-order buying for seed. "Don't be carried away by the glossy package in the store," says Simon Crawford, a technical services specialist for the PanAmerican Seed Company in Illinois. "Use the store to give you some ideas, but get some catalogs. Compare prices. Do a bit of research. It's worth doing and it's quite fun!" Crawford also offers the following words to the wise:

Check the date on the packet. If you do decide to buy off the rack instead of from a catalog, be sure the current year is stamped somewhere on the envelope. If it isn't, don't risk buying it. Fresh seed germinates more reliably than old seed.

Don't confuse pelleted seed with untreated seed. Pelleted seed is coated to make the seeds easier to handle and sow. Pelleted seed packets look bulky but may not contain that many seeds. Read catalogs or seed packets carefully so you'll know whether you're buying pelleted seed, or you may feel disappointed when you receive fewer seeds than expected.

Research disease resistance. If your zinnias or other favorites always suffer from powdery mildew but you don't want to give up growing them, check for a mildew-resistant cultivar. Compare several catalog offerings to find the best choices.

Know what special labels mean. Cultivars that carry the All-America Selections Winner label have received an award for excellence after testing at trial grounds throughout the United States and Canada. This doesn't always mean that it will be the best cultivar for your garden. To receive the All-America Selections Winner label, a cultivar must perform well around the entire country; you may find that other cultivars perform better in your particular region.

Seed packets may also carry other marks of quality, such as Burpee's "Gold Ribbon Selection." This mark indicates a professional-grade product, generally a high-priced hybrid, in a small packet for home gardeners.

Crawford's bottom-line advice is: "Any seed you buy should give good results if you follow the instructions that you're given. If it doesn't, you need to complain."

Buy Bulbs Big

What makes a bounteous bulb? "'Bigger is better' is the rule," says Sally Ferguson, the director of the Netherlands Flower Bulb Information Center in New York. "You get what you pay for." That means that the biggest bulbs will produce the biggest flowers, and they'll generally be priced accordingly. So if you want the best show possible, buy the biggest bulbs you can afford. Ferguson also notes that many people will mistakenly reject tulip bulbs with a torn tunic (the papery skin that covers them). "A healthy tulip without a tunic will grow as well as a healthy tulip with a tunic," she says. In fact, some research shows that removing the tunic may encourage rooting after the bulb is planted. You should avoid bulbs that are soft, mushy, or spotted with disease.

Buying Healthy Annuals

If you're buying annual flowers and vegetables, get your garden off to a good start by selecting the healthiest plants you can find. Use these pointers to make your choice:

- Look for a sales display where the plants are well cared for. Plants subjected to hot, sunny sidewalks, allowed to wilt frequently, and watered unevenly are never a bargain.
- Look at the entire group of plants being offered for sale. If some seem to be in poor health, shop somewhere else. Those that look healthy today may be diseased tomorrow.

- Look for plants with deep green leaves and bushy, compact growth. Pale overall color indicates a need for nutrients, which is easy to correct. However, distinct yellow streaks or brown leaf spots indicate presence of disease.
- Choose plants whose buds aren't yet open. If plants are already in flower, pinch off the blossoms when you set them out. Pinching will help direct the plant's energy into growing roots, so it will be better able to support more flowers and fruit later in the season.
- Don't buy by the yard. Bigger isn't necessarily better. Overgrown plants that have long outgrown their pots probably have roots circling the stem and have already had their growth severely checked.
- Buy plants that are clearly labeled, unless you're game for a gamble. Labels help you choose the cultivars you'd like to grow, and therefore flower color, bloom size, and height.
- Finally, always look carefully for signs of insect infestations or disease. Don't buy plants that show evidence of whiteflies, aphids, spider mites, or other pests. Disease symptoms to look for include rotted lesions on the stem or leaves and yellowed or spotted foliage.

Healthy Plant

Bushy compact growth
Healthy white roots
Healthy green leaves
Pot and plant size compatible
Well-rooted but not pot-bound

Unhealthy Plant

Whitefly infestation under leaves
Leggy, overgrown plant
Yellowed, sickly leaves
Pot too small for plant
Rootbound; many roots circling pot

Have a Root Peer

Most gardeners look carefully at the leaves before buying a plant. But Andrew Schuerger, Ph.D., a senior plant pathologist at The Land Pavilion, an agricultural display at Epcot Center in Florida, says it's important to inspect the plant much more closely, not only to determine its general vigor but also to make sure it's not going to carry disease home to your garden.

"First," says Dr. Schuerger, "look at the base of the stem. If you see any rot, any soft black lesions, or other suspicious areas, don't buy that plant."

Bonnie Lee Appleton, Ph.D., an associate professor and extension horticulturist at Virginia Polytechnic Institute and State University, also suggests that gardeners inspect the roots of potential purchases. "I drive the retailers crazy, but I suggest that people take containers off of trees and shrubs before buying," Dr. Appleton says. Sometimes, bareroot nursery stock is potted just before sale. The only way to distinguish this newly potted stock from true container-grown stock is by checking roots. The roots of a bareroot plant will have less branching and be less well-developed than the roots of a container-grown plant. Why is this important? If you buy a bareroot plant thinking it was container-grown, you may not give it the extra care it needs after planting, and you could end up with a dead plant, explains Dr. Appleton.

To check roots without harming the plant, turn it upside down while holding the soil in place and supporting the base of the stem between two fingers. Now tap gently on the side of the plant's container. In most cases, the container will slip off enough for you to examine the root structure. Also check for root disease problems. "If the roots are nice and white and you don't see any rotted splotches, you can buy the plant," says Dr. Schuerger. "But sometimes I've pulled perfectly healthy-looking plants out, and their roots have been completely rotten." Verlin Schaefer, an assistant mail-order manager for Stark Brothers Nurseries and Orchards Company in Missouri, cautions gardeners that big doesn't always mean best when it comes to fruit-tree roots. "Look for a balance between the size of the root system and the size of the tree," says Schaefer. A 4- to 5-foot-tall, standard-size young fruit tree should have 10- to 12-inch-long roots. They should be well-formed with multiple roots coming out from the taproot. If you cut through the tip of a root, the inside tissue should be white. Brown or dirty-looking tissue is diseased.

The roots of dwarf trees will be different—shorter and fibrous, like the roots of an ornamental shrub—so don't be alarmed if the roots of your small trees don't measure up to those of the big ones. They aren't supposed to. According to Schaefer, the roots of dwarf fruit trees may be only 25 percent of the size of the roots of a standard-size tree. Semidwarfs will be about 50 to 75 percent of standard size.

Steer Clear of Wild-Collected Plants

Native plants can be a wonderful choice for your yard and garden. But when you buy these plants, make sure they are nursery-grown, warns Kris Medic Thomas, a landscape manager and arborist for the city of Columbus, Ohio. Many nurseries can legally dig plants from the wild—a practice that disturbs delicately balanced ecosystems. In addition, Thomas has found that the wild-collected plants often have a slim chance of survival.

Bob McCartney, a co-owner of Woodlanders, a South Carolina nursery that specializes in southeastern native plants, concurs that nursery-grown plants have a much better chance in the garden. He warns that certain species are more likely to be wild-collected than others are. "I know of no one propagating trilliums [*Trillium* spp.]," says McCartney. Others that fall into this category are native orchids such as lady's slipper orchids (*Cypripedium* spp.) and yellow fringed orchid (*Habenaria ciliaris*) and some of the native lilies (*Lilium superbum*, *L. grayi*, and *L. philadelphicum*). Others to question are native azaleas (*Rhododendron* spp.).

"One way to tell if a plant is nursery-grown is to inspect the root ball," Thomas says. "Most are planted in a clay-type soil, so the root balls will hold together well. The dirt surrounding the plants should be free of rocks and other natural debris." McCartney adds that nursery-propagated plants generally are uniform in size. "If you see odd, mixed sizes, oddly shaped plants, and native soil next to the roots, the plants probably were dug from the wild," he says.

A Check-Up For Mail-Order Arrivals

Hurray! Your plants have just arrived in the mail! Lavish your energy and excitement on your plants to make sure they're in good health. "Unpack them immediately, and set them upright," says Bob McCartney, a co-owner of Woodlanders, a South Carolina nursery that specializes in southeastern native plants. Then examine them as explained below. Be sure the soil or roots are moist. If not, water right away.

Look for flexible, green stems. Check for live wood on dormant deciduous plants by scratching the bark slightly with your fingernail. You should see a layer of green wood underneath the bark you peeled up. If you can't find green wood, you need to let the nursery know immediately.

Be sure that plants in leaf aren't wilted. If they are, soak the pot or roots in water and mist the foliage. McCartney even suggests placing the plants in a closed shower or garment bag or other location where you can fashion a cool, humid environment until the leaves become turgid again. If they don't recover, contact the shipper right away.

Examine bulbs. They should be firm and free of mold.

If you can't plant right away, store the plants in a cool place such as a basement, a garage, or the shady side of your house. If the ground is frozen when plants arrive, pot them in containers and put them in a cool, dark place until the ground thaws. Water only enough to prevent them from drying out. You don't want to encourage topgrowth.

Plant Swapping and Shopping

Fern Marshall Bradley

Once your site is prepared, it's time for one of the most exciting parts of perennial gardening—getting the plants!

Shopping for perennials, whether at garden centers or through mail-order catalogs, can be almost intoxicating. There's such a range of gorgeous plants to try, and it's so tempting to try them all. But while your first impulse may be to buy all your plants, don't overlook other sources. One of the delights of perennial gardening is swapping and sharing plants with other gardeners.

Sources of Free Plants

Gift plants. Gift plants can be a great way to enliven your landscape without spending a lot of cash. So if a plant you yearn for is growing in a friend or neighbor's garden, look it up and find out how it's propagated. Then ask boldly. Chances are she'll give you a stem cutting right now or a bit of the plant the next time it's divided.

Impassioned gardeners love to share the plants they care for. Some will whip a trowel out of their back pocket, separate a healthy chunk of the plant, and bestow it on you with a radiant smile on the slightest provocation. A friend and mentor like this is a budding perennial gardener's dream. Of course, gift plants can also become a problem if they carry disease, insect, or weed problems.

Garden clubs. Local garden club swaps or sales are also good places to pick up great deals on plants that thrive in your area. To find them, check newspaper ads or bulletin boards at nurseries and your local extension office.

The woods? You may be tempted to look to local woodlands or wild areas for free plants. *Don't do it.* When you wild-collect, you may be disturbing or destroying rare or endangered plants. You may also be collecting the seeds or roots of invasive weeds or be collecting plants that are diseased.

Plant societies. As you gain experience with perennials, you may want to become a member of a local, national, or international plant society. Many focus on a specific kind of perennial, like the Iris Society. For a reasonable membership fee, members have access to meetings, workshops, lectures, newsletters, seed exchanges, plant swaps and sales, experienced members who share information and plants, and/or garden tours.

Buying Perennials

When you shop for perennials, always take a plant list with you. Think of plant shopping like grocery shopping—go by your list or you may not end up with the ingredients you need for the results you want.

Once you have a plant list, you have more decisions to make. What size plants should you buy? And should you buy plants at local nurseries and garden centers, or via mail order from specialty nurseries? There are no universal answers to these two questions. But there are some guidelines that will help you make good choices.

Plant-buying strategies. Perennials are sold in three basic sizes: large, medium, and small. Price ranges tend to correspond to plant size.

Creating a new perennial bed or border from scratch can be an expensive proposition if you start with blooming-size plants, each of which can cost from $5 to $10 (or far more for certain desirable cultivars). You'll need to balance your need for immediate results or special cultivars against your need to stay within a budget.

Shopping in person. Buying locally offers two advantages: You can look before you buy, and you can ask questions face to face. Choose a garden center or nursery where the plants look well cared for and are clearly labeled. The staff should have answers for your questions or find answers quickly.

When you buy a perennial, what you're really looking for is a great set of roots. Tops are nice, too, but without the roots, they're just window dressing.

When you select plants, start by taking an overall look at the plants you're considering. They should have good leaf color and be perky, not thirsty and wilted. Yellowed or missing lower leaves suggest the plants haven't been cared for properly and may not do well for you. Check the undersides of leaves for signs of disease or insects. Reject any plants that don't meet the grade.

Also look at the soil. It should be moist, not dry or soggy. Potted plants should not have a gap between the soil and the pot (a gap indicates the soil has been allowed to dry out too much in the past).

Carefully turn plants out of their pots to check the roots. The roots should be white and firm. They should hold the rootball together, but they should not be circling around. Reject plants with too few or overgrown roots.

When everything else has checked out favorably, choose plants with flowerbuds rather than open flowers, especially if the plant has a limited season of bloom.

Shopping by mail. You can catalog-shop no matter where you live. It does require a leap of faith to buy plants sight unseen, but the wealth of choices offered by mail order is nearly impossible to match with local sources. Not all suppliers are equally reliable. Here are some tips to help you evaluate potential suppliers by their catalogs.

- Plant descriptions should include the botanical name. Some plants have several common names. You need to mail-order by botanical name to ensure that you get the precise plants you want.
- Be suspicious of photos with bright colors that don't look natural: They've probably been artificially enhanced. Also be wary of catalogs with fanciful illustrations or grandiose claims.
- Outrageously cheap prices often mean small or poorly rooted plants—or no service.
- Check the replacement policy. Some nurseries will replace plants that die or do poorly for up to a year, perhaps asking you to pay the postage on the replacements. Others only guarantee that the plants are in good condition when shipped.

Gardening magazines also carry advertisements from mail-order companies. Another good way to find reputable mail-order sources is to ask other gardeners who their favorites are.

Order early to avoid disappointment, or call and check availability before you order. Indicate whether you want substitutions or a refund if a particular plant isn't available.

Specify a shipping date that suits your climate and schedule. Have your plants arrive on Thursday or Friday if you plan to plant them on Saturday.

Open and examine your plants as soon as they arrive. Report to the supplier immediately. It's much easier to get replacements for plants that die a few months after planting if you've made your complaints promptly.

Buying Bare Root

Roger Yepsen

It may seem cruel and unusual to ship plants long distances without a speck of soil around their roots. But there are clear advantages to transporting them that way, for both the grower

Continued ➔

and you. You just need to make sure that the plants are treated with extra care as soon as you receive them.

Bare-Root Bonuses

Here are some advantages that bare-root stock has over potted-up plants.

- You stand to pay less, often saving from 40 to 70 percent, because these plants aren't as expensive to produce and ship.
- You can find hundreds of rare and unusual varieties not available in pots.
- Bare-root plants may adapt more quickly to your particular soil.
- The plants often arrive with more-extensive root systems.

Coddle Your Bare-Root Babies

To gently support tomatoes and other plants vulnerable to breaking and chafing, use strips of well-washed cotton.

Bare-root perennials, shrubs, and trees look awfully vulnerable when you pick them up at the nursery or take them out of a mail-order carton. In fact, they are vulnerable and need your immediate attention, unlike plants parked in generous-size pots.

To make sure they survive in good shape, you have to take action as soon as they arrive at your doorstep. If you can't promptly pop them in the garden, there are a couple of temporary stopgap measures.

- The simplest strategy, good for a couple of days, is to allow the plants to remain in the packing material. Open the carton and pour a bit of water around any roots that feel dry to the touch. Then keep the carton in a cool, dry place until you can get into the garden.
- Pot them up. Use any old plastic pots you have about the place, and set the plants in a mixture of good soil, compost, and peat moss. Don't forget to tuck identification tags in each pot. If there is just one label for a number of plants of the same type, this is the time to make more—before you forget what's what in the rush of spring planting. Keep the pots in dappled shade where you can water them conveniently.
- Heel them in. Make a shallow trench in a partly shaded area, again choosing a handy spot that will be no trouble to visit with a hose or watering can. Lay the plants on their sides with the roots in the trench, and cover them with a mixture of good soil, compost, and peat moss. Make sure each plant or trench is identified with a label.

Plants with bare roots are easy to transplant but require prompt attention once you receive them. For a makeshift holding area, place their root systems in a shallow trench, fill with soil, and water as necessary.

Potting Up Purchased Plants

Barbara Pleasant

When growing your own seedlings indoors, the most difficult thinning is the last one, when you must decide which of two seedlings will be allowed to remain. Many greenhouse growers skip the last thinning, intentionally leaving two or three seedlings in a container so the consumer will see a fuller, healthier-looking specimen. When shopping for plants, it is not unusual to see pots containing several basil, parsley, or impatiens plants. Multiples also are common with cutting-grown flowers, such as hibiscus or geranium, in which three cuttings have been rooted and left to grow in one small pot. If you provide such crowded plants with roomier quarters and appropriate after-care, you can save money and end up with many more plants.

Look for pots in which the main stems of multiple plants are spaced at least 1 inch apart—a good sign that each plant will emerge from repotting with an ample supply of roots. Thoroughly water the plants, and then get ready to repot or plant them. Work in a shady place. Have clean pots and potting soil ready, or ready-to-plant space in your garden. You also will need three pieces of equipment.

- A plastic fork from which the two outside prongs are broken off, leaving two prongs. This is the perfect tool for separating intertwined roots from adjoining plants.
- A sharp knife, which you can use to cut apart the roots of plants with thin, fibrous roots, such as impatiens and begonias.
- One large cardboard box with its top flaps removed, which you can set on its side and use as a temporary shade chamber for newly divided seedlings or cuttings that are moved into pots. If you are planting divided seedlings directly in the garden, be ready to cover them with small boxes or flowerpots for 3 to 5 days.

Separating Crowded Seedlings

Before you begin, pinch off any flowers or leggy stems. Pinching back the growing tips will encourage the plants to develop new branches, and reduce demands made upon injured or traumatized roots.

Remove crowded seedlings from their containers by pushing them out from the bottom, or use scissors to slice through the sides of thin plastic pots. Don't touch the main stems any more than necessary, and lay the mass of plants on its side. Use a fork or knife to separate the plants, and immediately pot them up or set them in the garden. Water thoroughly, and then provide the divided plants with some type of shade. Don't worry that they will suffer because they are deprived of light. Instead, they will be free to concentrate on growing new roots, the plant part most needed in the days immediately following division.

Jeff Cox

One of the best ways to ensure that plants will grow well is to do a good job planting them. Preparing planting areas thoroughly, so roots will quickly extend into the soil surrounding the planting holes, is time well spent.

Know Your Site

Before you dig that planting hole or plant those seeds, try to make a good match between the plant and its environment. Getting to know your soil and growing conditions—and using that knowledge to pick the right plants—is just as important as knowing the best planting techniques. So before you plant:

- Take a close look at your soil. Is it red clay or deep loam? Waterlogged or sandy and dry? Is it acid or alkaline?
- Check the amount of sunlight your site gets. Is it full sun all day or just afternoon sun? Is the shade dappled through the small, shifting leaves of a birch, or deep and heavy, as beneath a fir? A tomato plant must have six hours of direct sunlight daily for good fruit set, but the same amount of sun fades and burns ferns.
- Know your hardiness zone. Your local nurseries and garden centers generally stock only plants that are hardy in your area. But if you do any mail-order buying, knowing your zone will save you money and disappointment.
- Learn the growth rate and size of your plants. Choose a site where they won't cause problems or overgrow your garden. This is especially important for permanent plants such as trees and shrubs.
- Be aware of seasonal conditions. Is the spot you picked sheltered by a wall or windbreak, or does it get the full blast of winter winds? Is it low-lying and prone to late-spring frost?

Get Your Soil in Shape

If you set plants into poorly drained soil, the roots are likely to rot and die. If you plant seeds into poorly drained soil, they may never even germinate. Before you plant a pumpkin seed or a pine tree, be sure that your soil drains well. For very wet areas, your best bet may be to grow plants that can tolerate wet conditions.

If you till the soil for a vegetable garden or dig a hole for a tree when the soil is too wet, you'll destroy the soil's structure. Your soil will compact, causing water to run off or lie in puddles rather than penetrate. Without air, root growth suffers. If your soil is too wet, let it dry before planting. Pick up a handful of soil and squeeze it. If it crumbles, it's perfect for planting. But if it forms a muddy ball, the soil is too wet to be worked.

Most plants pay less attention to pH than gardeners do. If your soil is fertile and well drained and not extremely acid or alkaline, most plants will do just fine. But a number of plants are more demanding. Acid-loving azaleas and blueberries, for instance, will do poorly in soil that's alkaline. If you don't know the soil pH in an area you plan to plant, it's a good idea to test it.

Enrich flower and vegetable beds with lots of aged manure, compost, or leaf mold before planting.

Seedlings

There comes a day in early spring when your seedlings have been hardened off or your bedding plants have all been purchased and you're ready to plant them in the garden. Although clear, breezy spring days are beautiful, they're not the best kind for transplanting seedlings. Sun and wind cause seedlings to lose large quantities of water, which newly disturbed root systems have difficulty replacing. It's a far better idea to wait and transplant seedlings at the beginning of a spell of warm, damp, cloudy weather. That way, they'll have a chance to recover and put on root growth before having to withstand sun and wind.

Try not to rush seedlings into the garden if cold weather still threatens, unless you're prepared to cover them nightly with boxes or other protective devices when the weather turns cool. Jumping the average date of last spring frost pays off some years; in others, late spring frosts take their toll on newly transplanted seedlings. Although many plants grow well in

Continued ➔

Ring Around the Transplant

A little ring in the soil around new transplants creates a small basin to collect water so it goes right down to the roots. "Use your finger to draw a 4-inch-diameter circle around transplants in the soil," says Bibby Moore, a registered horticultural therapist from North Carolina. The rings don't need to be deep; just draw in the soil with enough pressure to make an indentation as you do when you write in the sand at the beach. This is also very helpful when applying fish emulsion. To fertilize, Moore waters thoroughly first, then applies 2 cups of fish emulsion per transplant. The emulsion is diluted at the rate of 1 tablespoon of emulsion per 1 gallon of water.

cool temperatures, others are sensitive to cold and won't begin growing until the weather (and the soil) warms up. If you can't bear to wait, be sure to hold back a few of each kind of plant as insurance against a late cold snap.

Transplanting is a stressful operation for plants, and the more you can do to ease the stress that a plant suffers in being put out in the garden, the sooner it will be off and growing. Here are some tips to make your transplanting day a success:

- Dig a generous hole for each seedling so there is ample space for the plant's roots.
- If you're planting an entire bed of plants, work plenty of compost into the soil before planting, or add a handful to each hole as you plant, mix it in, and cover with ordinary garden soil before planting.
- Water seedlings before you transplant, and try to keep as much soil around the plants' roots as possible so they will not dry out. If the potting mix falls away from the roots, it's a good idea to dip them in a slurry of thick, muddy water to be sure the roots stay moist.
- As you place each plant in its hole, take time to make sure the roots fan out evenly in all directions. They shouldn't double back on each other or stick up toward the top of the hole.
- When transplanting seedlings in peat pots, tear off the top inch or so of the pot so the remaining portion will be entirely underground. Cut slits down the sides to help roots penetrate them. Some gardeners prefer to gently tear away the entire pot if roots haven't already grown through. If you've started your seedlings in peat pellets encased in plastic netting, cut the netting off before planting. Then plant as you would any other seedling.
- Water the seedlings as you go, rather than waiting and watering after you've finished transplanting. If the soil is unusually dry, moisten it slightly before planting because dry soil can quickly pull the water out of tender roots and damage them.
- To settle seedlings in their holes, fill the hole with loose, well-tilled soil, sprinkle at least a quart of water on each transplant, and gently firm the soil to eliminate large air pockets so the roots will be in contact with the soil and there will be no root-drying air spaces. A shallow, saucerlike depression will help catch rain and direct it toward the roots.
- As a general rule, set seedlings in the soil at the same depth they were growing in their pots. Tomatoes are an exception to this rule. If they are planted in a shallow trench on their sides with the top one or two sets of leaves above ground, the stems will grow roots and the tomato plants will be less leggy.

PLANT PROTECTION

The transplanting operation doesn't simply end when the last seedling is in place in the garden, however. Sun and wind can still wreak havoc with your seedlings for the first week or so after transplanting, and occurrences such as freak late-spring frosts can reduce your carefully tended plants to mush. Be sure to keep them well watered, and, if possible, screen them from heavy wind. Pale yellow leaves indicate sunscald. Cover afflicted plants promptly with screens, plastic sheeting, or anything else that will provide shade. Then gradually increase exposure to sun over several days.

Hardy Bulbs

Planting hardy bulbs is easy when you do it right. By carefully selecting a site, determining planting times, and using proper spacing and planting techniques, you'll be following the path to foolproof planting.

SELECTING A SITE

Almost all bulbs are sun lovers and grow best in full sun. However, this is only true when they're actively growing. By the time spring-blooming bulbs go dormant, they can tolerate full shade. That's why spring bulbs like daffodils and crocuses grow well under deciduous trees and shrubs—their active growing season occurs before the trees leaf out. Some bulbs, like pink daffodils, will have better color if they're grown in partial shade.

Bulbs need loose, humus-rich soil for best performance; they won't bloom well in poor, compacted soils. Most bulbs also need well-drained soil and will appreciate the addition of decomposed organic matter like composted pine bark. If you have poorly drained or compacted soil, try growing bulbs in

Aftercare: A Timetable

How well your plants will thrive depends on the care you give them after planting. Use this care calendar to make sure you're giving your new plants what they need.

Right Away

Water: Water perennials as soon as you've planted them.

Cut back foliage: If the nursery hasn't already done this, cut off one- to two-thirds of the foliage on bareroot plants; otherwise plants will wilt. If they wilt even after you've cut them back, cut back to a few inches to give plants a chance to recover.

Mulch: Mulch your plants after watering them to maintain soil moisture and guard against wilting. Mulch will keep weeds from competing with your new plants, too.

Provide shade: Shade your newly planted perennials from direct sunlight until they've had a chance to recover from the shock of transplanting. Cover them with a sunbonded row cover like Reemay or with shade cloth, screening, or a lath cover.

The First Week

Water: Your plants' primary need will continue to be water. Check at least once a day—before and after work is even better.

Check for bugs: Check your perennials daily for signs of pests and pest damage. New plants are smaller, so they're particularly vulnerable to pest damage. Animals and birds can decimate a planting, too—if you see signs of their damage, protect your plants with screens.

Remove shade: Gradually remove your shade cover after the first few days—ideally, leave it on only during the heat of the day and remove it for the morning and late afternoon. If you can't get home to move the cover, take it off after the third day; make doubly sure that plants are well watered and mulched.

The First Season

Water: Make sure your perennials get 1 inch of water a week, from either rain or the hose.

Weed: Weeding is most important the first two years after planting; after that, plants will be large enough to shade out most weed seedlings. Mulch will help control weeds, but check for them every time you're in the garden.

Feed: If you've prepared the soil well, your perennials won't need more than an application of compost in the middle of the season, or compost (or manure or seaweed) tea once a month, to grow vigorously.

Monitor for insects and diseases: Continue to keep an eye out for pests and diseases, and apply appropriate controls.

Disbud: If you buy bareroot perennials in May or June that are late-blooming (like asters and mums), remove all their flower buds. They need to establish themselves the first growing season, not put their energy into flowering.

Deadhead: Cut off spent flowers to keep your perennials from wasting energy by setting seed.

Move things around: If plants don't look right where you've placed them, don't be afraid to move them around. (Don't move perennials in bloom.) If you find you've left a gap in your bed that won't be filled in by the following season, add more plants to cover the bare spot.

Enjoy: Take time to appreciate the beautiful garden you've made.

raised beds, which will enhance drainage and make for easier planting. Of course, bulbs will thrive in beds that have been double-dug, since they thrive in well-worked soil, but in most soils this extra effort isn't essential. Bulbs prefer a pH of 6.0 to 7.0 but will tolerate slightly more acidic soils.

DETERMINING PLANTING TIMES

Plant spring-flowering and early-summer-flowering bulbs in fall so they can develop a root system and meet their cold requirements. (Hardy bulbs usually need a certain number of hours of cold temperatures to bloom.) It's best to wait until soil temperatures are below 60°F at 6 inches deep before planting. Follow these rules of thumb: In Zones 2 and 3, plant bulbs in September; in Zones 4 and 5, September to early October; in Zones 6 and 7, October to early November; in Zone 8, November to early December; and in Zone 9, December. In Zone 9, precooling may be necessary.

You can plant bulbs later in the fall, as long as they're planted before the onset of hard freezes. Late-planted bulbs tend to bloom several weeks later and on shorter stems, and there is the possibility of aborted blooms or bulbs freezing before roots are established.

Soak anemone (*Anemone* spp.) and winter aconite (*Eranthis hyemalis*) tubers overnight in warm water before planting to bring them out of dormancy. Plant anemones in fall in Zones 7 to 9, or in the spring in Zones 4 to 9. Because it is difficult to tell the top from the bottom of anemone tubers, plant them sideways.

Continued →

SPACING BULBS

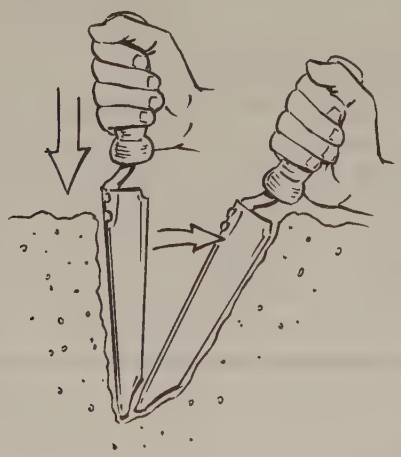
Place bulbs in your flower bed and space according to flower stalk height. For greatest impact, plant in clusters of ten or more rather than singly in rows. Plant large bulbs 5 to 6 inches apart and small bulbs 1 to 3 inches apart. Leave room to interplant with perennials, groundcovers, or annuals.

You can use 6-inch concrete reinforcing wire as a template to make a uniform bulb bed. Put this hardware cloth flat on the ground and place bulbs in the centers of the squares. Remove the hardware cloth before planting.

PLANTING TECHNIQUES

The general rule for planting depth is three to four times the height of the bulb. This depth will help to protect the bulbs against frost, animals, and physical damage from hoeing. Deeper planting will also help bulbs naturalize and perennialize.

The thought of planting a boxful of bulbs can be daunting, but with the right tools and techniques, bulb planting is easy. A heavy-duty tubular bulb planter large enough for daffodil bulbs is the ideal tool for prepared beds. It's a cup-shaped steel cylinder with a foot bar and long handle on top. Insert the bulb planter in the soil by stepping on the foot bar. Twist the planter, lift it out, then place the bulb in the bottom of the hole. Fill the hole with dirt from the planter, then repeat with the next bulb.



Planting bulbs in a lawn. Crocuses and grape hyacinths (Muscari spp.) brighten spring lawns and are easy to plant. Stab a bulb trowel into a soil like a dagger, and pull toward you to make a hole for the bulb. Drop in the bulb, and step on the spot to close the slot.

For planting bulbs in unworked soil, around tree roots, and in groundcovers, you need a stronger tool. Choose a naturalizing tool (a straight steel blade with a forked end, topped by a foot bar and long handle), a crowbar, or a narrow spade with a sharp cutting edge and a foot bar. Push the blade halfway into the soil and pull back, then push down hard so the blade goes completely into the soil. Push forward so the blade lifts up the soil to make a planting slot. Put in a bulb, remove the tool, step down to firm the soil, and repeat with the next bulb.

There's a special trick to planting small bulbs. Using a narrow trowel, one person can easily plant several hundred small bulbs in an hour. (See the illustration on this page for a discussion of technique.)

Perennials

Because perennials live a long time, it's important to get them off to a good start. Proper soil preparation and care at planting time will be well rewarded at bloom time. Prepare your planting beds before you order or buy plants. It is best to work a season ahead and dig in early fall for a spring planting. Be sure to mulch pre-dug beds, then turn the soil in spring when you're ready to plant.

SOIL PREPARATION

The majority of perennials commonly grown in beds or borders require evenly moist, humus-rich soil of pH 5.5 to 6.5. A complete soil analysis from your local extension office or a soiling lab will give you a starting point. For more on soils and soil testing, see Chapter 1.

Double digging is the best way to prepare a perennial bed. Despite the difficulty of the task, the rewards are unparalleled. Plants' roots will be able to penetrate the friable soil easily, creating a strong, vigorous root system. Water and nutrients will also move easily through the soil, and the bed won't dry out as fast. As a result, your plants will thrive. Have the necessary soil amendments and organic fertilizer on hand before you start.

If you can't double dig before you plant, turn the soil evenly to a shovel's depth at planting time. Thoroughly incorporate appropriate soil amendments and fertilizer as required. Break up all clods and smooth out the bed before planting.

PLANTING

Plant perennials any time the soil is workable. Spring and fall are best for most plants. If plants arrive before you are ready to plant them, be sure to care for them properly until you can get them in the ground.

Planting is easy in freshly turned soil. Choose an overcast day whenever possible. Avoid planting during the heat of the day. Place container-grown plants out on the soil according to your design. To remove the plants, invert containers and knock the bottom of the pot with your trowel. The plant should fall out easily. The roots will be tightly intertwined. It's vital to loosen the roots—by pulling them apart or even cutting four slashes, one down each side of the root mass—so they'll spread strongly through the soil when planted out. Clip any roots that are bent, broken, or circling. Make sure you place the crown of the plant at the same depth at which it grew in the pot.

Planting bareroot perennials and transplants requires more care. Inspect the roots carefully and prune off any irregularities, then soak the roots in a bucket of lukewarm water for one or two hours to hydrate them before planting. Dig a hole

large enough to accommodate the full spread of the roots. Build a mound with tapering sides in the center of the hole. Spread the roots of fibrous-rooted plants evenly over the mound, and rest the crown of the plant at its apex. Check to be sure that the crown will end up just below the soil surface. Build up the mound to raise the crown if necessary. Do not plant too deeply!

Position rhizomes such as those of iris at or just below the surface, depending on the species. Spread the roots evenly over a mound of soil as described above. Spread tuberous roots like those of daylilies evenly in a similar fashion. Fill in the planting hole with soil, then firm it down and add more soil if necessary before you water the new plant.

Water plants thoroughly after planting so the soil is completely settled around the roots. Give your newly planted perennials a layer of organic mulch to conserve soil moisture. Provide extra water for the first month or so while plants are becoming established.

Here's one last helpful hint that's important but easy to forget: Keep the plant labels that come with your perennials, and stick them firmly in the ground next to each plant as you plant it.

Trees and Shrubs

There's no doubt about it—trees and shrubs can enhance the value of your home, both by increasing your property's monetary worth and by adding beauty and variety to your surroundings. While the cost of a well-planted property can be measured in materials, equipment, labor, and maintenance, the daily impact for most of us comes from the effects of vegetation on our physical and emotional comfort. We plant trees and shrubs because they provide welcome shade, windbreaks, privacy, and—most important—beauty. Their spring flowers, lush summer foliage, autumn color, interesting bark, and variety of forms add color, texture, and appeal to the landscape.

Tips for Healthy Trees and Shrubs

The key to success with trees and shrubs is to know your site. You can't choose plants that will thrive in your yard or garden until you learn about the site and how to prepare it. Here's what you, or the designer or landscape architect who is choosing the trees and shrubs for your property, need to know:

Soil: Begin learning about your site with a soil test. The results will tell you your soil's pH and fertility, two of the most important pieces of information that you must have when making a plant selection.

Also look at your soil's consistency and drainage characteristics. Is the soil loose or compacted? Is it clayey, sandy, or loamy? Is it rocky and shallow, or chalky and poorly drained? Is it elevated, depressed, or sloping? Does water stand at any time of the year? Different plants have different tolerances for these conditions, and you're best off planting a tree or shrub that will be happy in the soil you have to offer.

Soil preparation: Till the planting area before you dig. This will reduce compaction and encourage aeration and drainage. Since roots tend to stay in the top 1 foot of soil, tilling can make a real difference.

Adding soil amendments to backfill isn't necessary for typical plantings, but it may be appropriate for certain plants in particular sites. For example, if you're planting trees in raised beds or berms (mounds), adding water-holding organic soil amendments can be very beneficial, since beds and berms tend to dry out faster than ground-level plantings.

Exposure: Is the planting site sunny or shady? Buildings and nearby vegetation can limit the hours of full sun that fall on a potential planting site. Be sure to check how many hours, and at what time of day, your plant will have direct sunlight.

Water: Note the amount of rainfall that you can expect your new tree or shrub to receive, and consider how you will water it during a dry spell. If your resources are limited select plants that can tolerate occasional drought.

Other factors: Other physical factors to watch include overhead and underground utilities (such as electric wires and water pipes); nearby buildings; actual use of the site (is it a quiet, out-of-the-way spot, or right near a path?); and the size of the area, which determines the appropriate size of the plant. Recognizing these physical limitations will enable you to make better choices. If there are overhead utilities, for example, choose plants that are naturally dwarfed or slow-growing, with an ultimate height considerably lower than that of the overhead lines and equipment. Or, if your site is near a path or sidewalk, a tree with low-hanging or pendant branches might pose a problem. Pavement and buildings may cause plants stress by reflecting heat, creating unnatural wind patterns, and limiting root space and water penetration. Finally, does the site have a vast, open, parklike scale or that of an intimate patio or enclosed backyard?

Site maintenance: It's important to maintain the planting site *after* planting, as well. If grass grows in the area covered by the mature spread of the tree's crown (the drip line), it can compete with the tree's roots for nutrients and water. To prevent regrowth of grass after you've tilled and planted, spread mulch around the tree as far out as the drip line. Don't allow the mulch to touch the base of the tree because this can encourage disease problems.

Continued

GETTING A GOOD START

When you are buying new trees and shrubs, you can avoid a lot of future problems by choosing locally adapted or resistant species. Trees and shrubs that are native to an area are often less prone to problems because they are growing in the environment to which they are best adapted. Read about the trees and shrubs you intend to buy, and avoid very pest-prone species. Look for this information in catalogs, or ask your local nursery owner or extension agent for more information on the trees and shrubs best adapted to your area.

Smart Shopping for Trees and Shrubs

Once you've determined which trees and shrubs will thrive in your chosen site, follow these guidelines when shopping to get the healthiest plants:

- Buy small to medium-sized trees. Big trees are difficult to move and plant. They take longer to get established than smaller trees, because more of their roots were lost when they were dug.
- Buy only trees and shrubs that are clearly tagged or labeled with the botanical and common names to make sure you get the flowers, fruit, and crown shape you want.
- When buying trees, look for a relatively straight trunk with a slight natural flare at its base—if no flare exists, the tree has had too much soil placed atop its roots.
- Buy trees with widely spaced, even branches, not trees with branches that are tightly spaced and mostly at the top of the trunk.
- Know how to spot a good buy when you go shopping. Look for plump, firm buds and leaves that are the correct size and color. Watch out for broken branches or scratched bark, dry or brown leaf margins, or dry root balls. B&B (balled-and-burlapped) or container-grown plants may be putting out new leaves; check for healthy growth. Examine leaves and bark for pests and diseases.
- Buy bareroot trees and shrubs only when they're dormant, and only if the roots have been kept moist. Roots that are evenly spaced around the base of the stem make a secure anchor. On B&B plants, look for a well-wrapped, secure root ball. Container-grown trees may be rootbound, with crowded roots wrapped around the root ball.
- Avoid trees that pull easily from the container, leaving the potting soil behind. Also avoid those whose roots have left the container and anchored themselves firmly in the soil beneath.
- Inspect container-grown shrubs, and don't buy rootbound plants. Many large roots on the outside of the root ball or protruding from drainage holes mean the plant may be stunted by growing in a too-small container.
- Be sure to ask about the nursery or garden center's guarantee. Some offer guarantees only on trees and shrubs that are planted by nursery staff; others will guarantee homeowner-planted stock as well.

Once you get your tree or shrub home, some basic care will help it get established quickly. Good soil preparation will provide the ideal conditions for strong root development. Providing ample water for the first few years after planting also encourages vigorous growth. A 2- to 3-inch-thick layer of organic mulch such as wood chips helps keep the soil moist and weeds down; just be sure to keep the mulch a few inches away from the trunk or main stem to discourage animal and insect pests from attacking the base of the plant. Do any necessary pruning or staking carefully, and avoid making wounds in the trunk or stems with lawn mowers or string trimmers.

PLANTING

The trees and shrubs you buy will be bareroot, balled-and-burlapped (B&B), or in containers. Many deciduous trees and shrubs, such as apples, maples, lilacs, and roses, are sold as dormant, bareroot plants. Evergreens are usually sold B&B because even when they're dormant, they have leaves that draw water from the roots. Container-grown plants have roots established in the container (sometimes a little too well established!); these plants are easy to add to your garden, even in full growth.

Plant a barefoot tree while it is dormant, either in fall or early spring. A few trees have roots so sensitive to disturbance that you should not buy or transplant them bareroot. Your chances of success are best when these trees are container-grown: Kentucky coffee tree (*Gymnocladus dioica*), crape myrtle (*Lagerstroemia indica*), sweet gum (*Liquidambar styraciflua*), black tupelo (*Nyssa sylvatica*), white oak (*Quercus alba*), and sassafras (*Sassafras albidum*).

You can plant most B&B or container-grown trees any time of year except when the ground is frozen. There are a few exceptions, however. A few trees, especially those with thick and fleshy roots, seem to suffer less transplanting shock if planted in the spring in areas where the soil freezes deeply during the winter. Though tree roots will continue to grow until the soil temperature drops below 40°F, these trees are slow to get established and are best reserved for planting in the spring: dogwoods (*Cornus* spp.), golden-rain tree (*Koelreuteria paniculata*), tulip tree (*Liriodendron tulipifera*), magnolias (*Magnolia* spp.), black tupelo (*Nyssa sylvatica*), ornamental cherries and plums (*Prunus* spp.), most oaks (*Quercus* spp.), and Japanese zelkova (*Zelkova serrata*).

A close examination of the roots of your new tree will prevent problems that can limit growth. Trim any mushy, dead, or damaged roots. Comb out potbound roots and straighten or slice through roots that circle the root ball before you set the plant in its hole. Look carefully for girdling roots, which can strangle the tree by wrapping tightly around the base of its trunk. This stops the upward movement of water and nutrients absorbed by the roots and needed by the leaves and branches.

PREPARE A PROPER PLANTING SITE

Do you know how to dig a proper planting hole? A few minutes of extra preparation can make all the difference. Although some trees' roots may go deep, the small but all-important feeder roots forage mostly through the top 6 to 8 inches of soil. Shape the hole to accommodate the feeder roots.

Don't Coddle the Roots Traditional planting advice once called for digging the biggest hole you could dig and filling it with a rich mixture of topsoil and compost. Now gardeners have learned that the best way to plant is to dig a hole just deep enough for the roots, widening toward the top, and filled with the same soil you took out. While the "big and rich" idea did indeed get the tree off to a good start, the tree roots had no inclination to leave the hole. A hole filled with peat moss and rotted manure encourages roots to grow only in the hole instead of branching out. These pockets of overly amended soil stay too wet during rainy periods and too dry during drought. This means tree roots can suffocate from too much moisture or can be more prone to wilting during drought. Also, since the roots don't spread and anchor the plant strongly, it will be more susceptible to wind throw—being toppled during high winds.

But there may be times when soil amendments are necessary. If the soil in the root ball is significantly different from your local soil, your tree may grow better if you amend the soil before planting. Roger Funk, Ph.D., the vice president of human and technical resources at the Davey Tree Expert Company, planted B&B trees that had been grown in sandy clay loam in a landscape where the soil was a heavy blue clay. He didn't amend the soil, and he found that water pooled up in the holes. "Since most nurseries are growing trees in sandy or loamy soil, and lots of gardeners have clay soils—especially in new developments, where they may have subsoil—this can be a common problem," says Dr. Funk. "It's best to evaluate the specific conditions and decide what to do on a case-by-case basis."

Encourage roots to reach out beyond the planting hole by loosening ground surrounding the hole. Plunge a garden fork in as deep as the tines allow, and wiggle it slightly to break up compacted soil. Repeat every 1 to 1½ feet to a distance of 5 feet or more on all sides.

Set It Straight After settling the plant in the hole, observe it from all angles to be sure it is positioned straight up and down. There's nothing more frustrating than filling your planting hole and then discovering that the plant is set crookedly. Once you're sure the plant is positioned properly, add soil gradually. For bareroot plants, give the tree or shrub an occasional shake as you refill the hole to sift soil among the roots. Level the soil around the base of the plant. Don't stomp all the air out of your newly filled hole: Instead of using your feet, tamp the soil with your hands or the back of a hoe to settle it and eliminate air pockets.

Water Thoroughly Water the soil thoroughly after planting. Apply a 2- to 3-inch layer of mulch to retain moisture, pulling it back a bit from the trunk. Water new plants once a week during their first year, especially if rainfall is less than 1 inch per week. By the time you notice wilting or other signs of stress, it may be too late.

STAKING

Staking is done to straighten or strengthen the trunk, or to prevent root movement and breakage before the tree anchors itself in the soil. Trees usually don't need staking if they aren't located in windy sites and are under 8 feet with small crowns.

Avoid rigid staking. Allow the trunk to flex or move slightly when the wind hits it. This movement encourages the tree to produce special wood that will naturally bend when the wind hits it. A tree that is rigidly staked will often bend over or break after it is unstaked. Given a choice, avoid buying staked, container-grown trees—you will generally be buying a weak stem.

Unstake all trees one year after planting. Any tree that had an adequate root system and was properly planted will by then be able to stand on its own. If you want to leave the stakes in place to keep lawn mowers and other equipment from hitting the trunk and damaging the tree, remove the guy wires or ropes but leave the stakes for a barrier.

Settling Them In

Your new trees and shrubs may be bareroot, balled-and-burlapped (B&B), or planted in a container. For best results, follow these guidelines when planting:

Bareroot plants: As long as you plant bareroot trees or shrubs while the stock is still dormant, your chances of success are good with these generally low-cost plants. Leave a small cone of undisturbed soil in the center of the hole. Remove any circling, broken, or diseased roots from the plants, spread out the roots over the cone of soil, and fill. Water well and mulch.

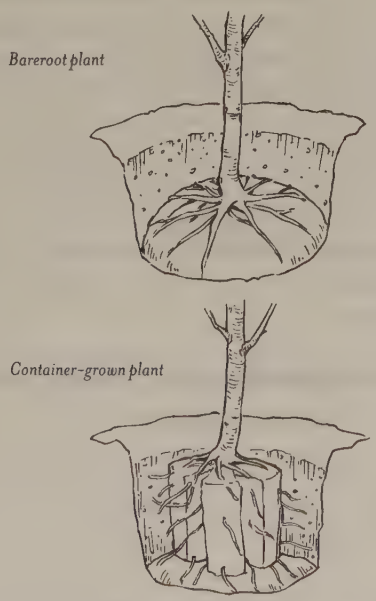
Balled-and-burlapped plants: It's best to get balled-and-burlapped plants in the ground while they're dormant so the roots can get a good start before they have to supply food and water to burgeoning topgrowth. But the B&B method gives you more leeway; even actively growing trees and shrubs can be held until the weekend for planting.

Continued →

To set a B&B plant in the planting hole, remove binding ropes or twine and all nails. Leave natural burlap in place: It will eventually rot. Slit synthetic wrapping material in several places so roots can penetrate it. Try to keep the root ball intact. If the root ball is in a wire basket, cut off the loops on top to keep them from sticking up through the soil, and snip and remove the top few wires. If the tree is large, have a helper hold it in place as you fill the hole. After every few shovelfuls of dirt, add water to help settle air pockets.

Container-grown plants: Remove any labeling tags to keep the tags or wires from cutting into the stems. Support the plant while you turn it upside down and remove the pot. Even fiber pots of compressed peat or paper are best removed; exposed edges wick away moisture, and the walls slow down root growth.

Carefully snip off dead or sickly roots and use your fingers to comb out any potbound roots. Cut through circling roots. Set the plant as deep as it grew before, fill, water, and mulch.



Finishing Touches

You don't need to prune newly planted trees and shrubs, except to remove branches that are broken, diseased, narrow-angled, or overlapping. If you cut back all the branches, you may actually slow your tree's or shrub's establishment, because buds produce chemicals that aid root growth. The exception is young fruit trees, which you must prune promptly if you plan to train them for easier harvesting and care.

A tree wrap protects the trunk from sunscald, nibbling rodents, and lawn mower nicks.

Mapping Out the Garden

Nancy Bubel

Once the soil has been prepared, it's time to find the planting plan we doodled over by the late-winter fire. Already much erased and revised, it will no doubt be changed once again as we confront the reality of freshly raked soil and extra last-minute seed purchases. Subject to revision though it may be, the planting plan is a valuable gardening tool.

Although I wouldn't presume to prescribe what form your plan should take, I *would* like to suggest several considerations to keep in mind while poring over the graph paper with seed orders and pencil in hand.

Planning Rows

If you are planning a row garden, consider the lay of the garden and the spacing of the rows.

Orientation of Rows. Your first decision, as you face that blank piece of paper, is to determine in which direction your rows will run. If possible, choose a north-south direction so that sun striking the garden from the east and west will cast a plant's shadow onto the space between the rows rather than onto the next plant.

On a sloping plot, where rain tends to carry loose soil downhill, contouring the rows so that they run parallel to the hill (and at right angles to the direction of the slope) will help to conserve much valuable topsoil. Mulching will help, too, as will terracing on a very steep slope.

Row Spacing. The space you leave between rows will be determined by the kind of plants you grow, the amount of mulch you can get, and the sort of equipment you plan to use to cultivate the garden. Rows must be separated far enough to give the plant sufficient room to grow and the gardener space to walk and often space to till or hoe.

Single rows of nonspreading plants like beets, lettuce, peas, carrots, and such are giving way, in more and more gardens, to 4- to 36-inch-wide bands of these vegetables. We've had good results with garlic, lettuce, carrots, peas, herbs, and beans planted in wide rows. Careful hand weeding between the vegetables is necessary in the early stages, but later the plants help to take care of each other by shading out weeds and keeping soil moist. Wide rows use space more efficiently than narrow drills.

Row middles that will be tilled should be about six to eight inches wider than the tine-to-tine measurement of the tiller. You can adapt some front-end tillers to work row spaces as

On a sloping plot, rows should run parallel to the hill to prevent soil from being carried down the slope by rain.

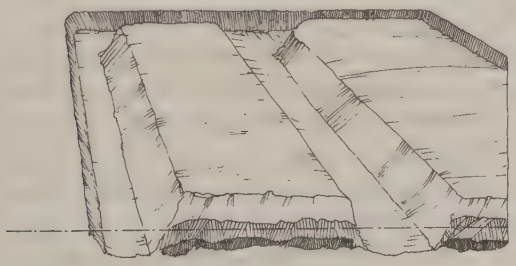
narrow as eight inches by removing the two outer tines and reversing the center tines so that their blades face inward rather than outward.

Mulched rows may be closely spaced, but if you have a lot of coarse mulch, as we do, you will want to plan your garden so that the loose, shaggy stuff will be used to mulch wide rows like tomatoes. The finer mulches like sawdust or old leaves, or neat bundles like hay, can be saved for narrow rows.

Garden Beds

Rows are customary, but not necessarily traditional. There are many good arguments for planting vegetables, herbs, or flowers, closely spaced, in small plots or blocks. Soil may be intensively improved. The beds may be raised to improve drainage. Weeding and harvesting are convenient. When well cared for, small garden beds are delightfully attractive. Many arrangements are possible. You can divide your garden area into blocks separated by paths. Each block will be solidly planted to a single vegetable or an especially chosen combination of vegetables. You might want to keep a grassy path between a double row of narrow vegetable beds. Vegetable beds may be located on the lawn, next to the house, or along a walkway.

One practical problem with garden beds bordered by grass is the encroachment of the grass into the bed. This may often be solved by sinking a thin metal edging strip between vegetable bed and grass or by building a raised vegetable bed. Some gardeners support the deeper soil with wooden boards or railroad ties, but such enclosures are not really necessary. Plant roots will hold the soil in place. When you form the beds, slope them slightly from the base to the top surface.



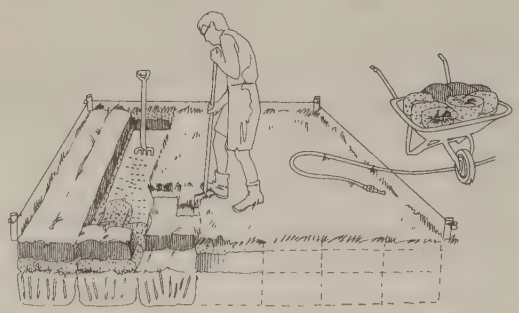
Raised beds.

Raised Beds. If I were starting a new garden today, I'd plant intensively in raised beds. Here's why:

- Raised beds are easy to work (once established).
- The deep, loose soil encourages excellent root growth.
- The absence of foot traffic prevents soil compaction.
- Compost and other soil-improving additions can be concentrated where they will be effective, not wasted on footpaths.
- Raised beds warm earlier in spring.
- The solid cover of plants helps to shade out weeds and conserve soil moisture.

When starting a raised bed, remove weeds and sod and add them to the compost pile. To add humus, dig in about one bushel of manure or compost to each 25 square feet of garden. Toss on a few shovelfuls of wood ashes. Rake up all loose soil from paths and, if possible, haul in some extra soil from elsewhere on your place.

Double digging. If you double-dig your beds, you probably won't be sorry, because deeply worked soil gives plant roots more of what they need. To double-dig, remove the soil from a 1-foot-deep trench at the edge of the bed and save the dug-up soil to fill the last trench. Then, using a spading fork, loosen the packed earth in the bottom of the trench. Fill the first trench with soil dug from trench number two and continue to dig your way down the bed, trench by trench. Beds should be 3 to 3½ feet wide and any convenient length. Wider beds are hard to reach into. Leave at least one footpath between beds.



In double digging, soil is removed from one end of the bed to be placed at the other end. Successive trenches are dug, and soil is moved up the bed. During this process, the soil can be worked deeply to benefit root growth.

I've talked to a fair number of gardeners who chose not to double-dig their raised beds, and they seem to be getting good results, too. One couple first tilled their ground and then shoveled all the loose soil aside and went over the same ground again with their tiller to loosen the soil more deeply. Others have simply piled up as much soil and organic matter as they could collect to raise the beds 8 to 12 inches above ground level.

Continued →

All are reaping the many benefits of the raised bed. It is a trade-off of more intensive preparation and careful planning for easier care and less tilling later on.

Where to Plant What

Once you've determined the basic design and layout of your garden, you'll want to decide where to place your plants. In general, tall plants like corn or sunflowers should be planted on the north side of the garden so they don't shade adjacent vegetables. If it is necessary to put them on the south end of the garden, plant parsley, lettuce, or other midsummer shade-tolerant plants next to the corn. Placement of your crops in the garden will be partly determined by their growing habits.

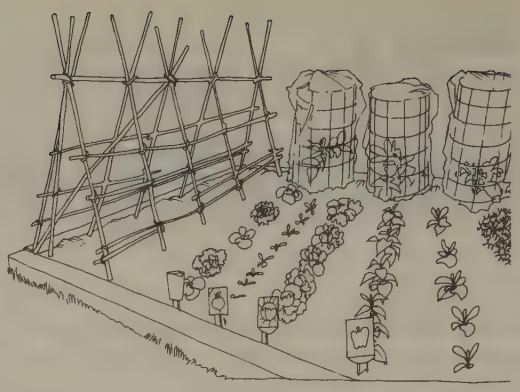
Rambling Vine Crops. Squash, pumpkins, melons, and cucumbers may be planted in rows or hills. There's a certain amount of confusion surrounding the term "hill." Generally, a hill is simply a small designated area, not necessarily raised, in which a group of seeds, usually those of spreading plants, is sown. Except in very small gardens, where vines can be trained to climb fences, hills use space more efficiently than rows when growing rambling plants. Planting vining crops in a hill rather than in rows allows for easier placement of compost and manure and simpler, quicker insect control early in the season.

Some gardeners do make hills, which are actually small elevated mounds an inch or two above the normal soil level. These small raised beds drain well and warm quickly.

Climbers. You can save space in the garden by planting cucumbers, pole beans, certain melons, Malabar spinach, and others if you put them at the edge, next to a fence or trellis, so save an end row for some of these space-takers.

Bush Vegetables. In recent years, breeders have developed space-saving bush varieties of popular long-vined vegetables like squash, pumpkins, and melons. Those shorter-vined plants also have shorter internodes—less space between the leaves. Some of them bear earlier, and some have a more determinate habit than their roaming cousins—that is, they may stop bearing and growing earlier in the season rather than continuing until frost. Most bush varieties produce full-sized fruit. Some previously developed bush-type vegetables were inferior in flavor to those grown on full-sized plants. This situation seems to be improving, though. Bush-type cucumbers seem to suffer the least loss of flavor, watermelons the most. Some of the muskmelons are so-so, but Musketeer has a fine flavor. A plant with more limited leaf area can be stressed by a large fruit load, so pinching off excess flowers and providing plenty of organic matter in the soil should help to encourage better flavor.

Overwintering Crops. Parsnips, salsify, and carrots, and late-fall bearers like brussels sprouts, escarole, parsley, and collards, should be planted at the edge of the garden where they will not be disturbed if you intend to till or plow the rest of the garden in the fall.



When planning a garden, try to place tall plants on the north side so they don't shade other crops. Plant climbers near an edge where they can grow up a trellis, and if you grow any perennial vegetables, give them their own bed, if you can, so they won't be disturbed.

Perennial Vegetables. Crops like asparagus, rhubarb, comfrey, and Jerusalem artichokes should, of course, be planted either at the edge of the garden where they will not be plowed up or in a separate bed.

Crop Rotation

Keep your vegetables moving! Alternating the kinds of crops you grow in a given space is just about the least expensive and least time-consuming method you can use to maintain and even improve the quality of your soil and the health of your vegetables. Each kind of vegetable that you might grow absorbs soil nutrients in different amounts. Corn and leafy vegetables need a lot of nitrogen; sweet potatoes get along with small doses of nitrogen; root vegetables need potash; legumes (with the help of nitrogen-fixing bacteria on their roots) actually add nitrogen to the soil. By alternating vegetable families, you give the soil a chance to replenish nutrients, and you discourage the proliferation of insect pests. If you plant vulnerable food crops in a different location each year, the bean beetles won't have a ready feast waiting for them the moment they hatch. In addition, plant diseases caused by fungi and bacteria are less likely to threaten successive crops if their host plants keep hopping around. The rotation unit can be a row, half-row, a raised bed, or even a separate garden plot.

What constitutes a vegetable group? Some folks simply alternate those vegetables that are generally considered more demanding on the soil—corn, cabbage, squash, melons and their relatives, and tomatoes—with those that are satisfied with somewhat leaner soil—legumes, root vegetables, herbs, and onions. A third-year planting of a soil-enriching cover crop like buckwheat, clover, oats, or rye would be a wise addition to such a simple rotation. At the very least, you'd want to rotate corn, which is an especially heavy feeder, as well as any

vegetables with which you've had serious disease and insect problems in the past.

For a more complete and effective rotation, divide your garden vegetables into seven categories: legumes; leafy vegetables; root vegetables; cucurbits; onions and their relatives; tomatoes and related peppers, potatoes, and eggplant; and corn and other grains. If you plant green manure crops, make that your eighth plant group. A sample rotation, then, might be a planting of spring peas followed by fall kale, with parsnips occupying the row the second year, squash the third year, onions next, tomatoes or related vegetables in year five, and corn the following year, after which you'd either put in a cover crop of oats or buckwheat, or begin again with legumes—perhaps soybeans—then cabbage, carrots, cucumbers, garlic, eggplant, and so on.

The most impressive garden rotation scheme I've ever seen was worked out by Vertis Bream, an accomplished Pennsylvania gardener who divided his garden into six raised beds, each 3½ feet wide, 30 feet long, and 8 to 12 inches high. The Breams plant a different group of crops in each bed every six years. For example, a bed that's growing beets, potatoes, carrots, and onions this year will be planted to wheat after the root vegetables are pulled up. After the wheat is harvested in the second year, they plant a clover cover crop, followed by corn in the fourth year, then beans, and finally, in year six, a bed of lettuce, tomatoes, and cole crops. They keep garden diagrams and move the potato row from row 1 to row 2, then 3, 4, 5, 6, and then back to row 1 as the years go by.

As these plans suggest, you will sometimes grow two different groups of plants in a certain row in a given year. Garden rotations can look complicated because we're dealing with limited areas and a large variety of plant types, and often with in-season plant successions. Don't worry about making it all come out straight, down to the letter and inch. Just do the best you can to give each kind of vegetable a different spot in the garden each year—a good reason for saving each year's mud-spattered garden plan.

Green Manure. With careful planning, you can end the season with a section of garden that is free of crops, a perfect chance to put in a soil-building crop of winter rye, or start in spring with oats to be plowed under before they head. Either way you'll add humus and nutrients to your garden. In order to have a solid block of land ready for a fall cover crop, it's necessary to group a bunch of early-maturing spring plantings together so that when they are harvested in August or September, the rye can be planted right away. (Be sure to get coarse-seeded winter rye, not the fine-seeded grass that may repeat on you in next year's garden.)

Succession Crops. To keep your garden continuously productive, plant crops in succession. They can be dovetailed in a very intricate way. All kinds of variations are possible. Here are a few examples, from my garden:

- An early planting of peas followed by a late corn planting (but use a fairly early-maturing kind of corn).
- Early cabbage followed by late beans.
- Spring lettuce giving way to fall beets.
- Early onions succeeded by fall lettuce.

Once I planted bean seeds along the row as I harvested leaf lettuce. By the time the lettuce row was used up, all the beans were up and growing. More often, I start seedlings in flats for transplanting into the garden when an early crop is finished. As I gather peas, the kale that will take their place is hardening off on the east patio. When I pull onions, I have Chinese cabbage seedlings ready to take their place.

Interplanting

When planning your garden, you might want to consider interplanting your vegetables. Interplanting saves space. It's seldom necessary, for example, to devote a whole row to spring radishes. Plant them, instead, along with your lettuce and carrots and use them as thinnings when they're ready. One year I grew a long row of bush beans between the widely spaced, just-planted rows of tomatoes and squash. By the time the vines closed over the gap, I'd harvested many meals of good green beans. Pumpkins do well at the edge of the corn patch where they have space to ramble. In studies at the University of Maryland, sweet corn and soybeans planted in the same row produced satisfactory harvests. Although individual vegetable yields were lower and corn ripened three days later, the total harvest from the row was larger.

Companion Planting

Companion planting, the pairing of plants that benefit each other in close proximity, adds yet another dimension to the juggling of rows and beds. Reports on certain vegetables sometimes vary widely; some authorities say that onions and beans do well together, while others warn that beans don't like onions. There is a firm scientific basis for the study of plant relationships, though: Plants are known to produce root exudates that do, in many cases, affect soil life and roots of other plants around them.

A whole body of companion planting lore exists that is difficult to dismiss, but difficult also, so far, to prove conclusively. Some of these protective interplanting arrangements seem to work for some gardeners but not for others. A few sound to me like myths that have simply been repeated from one writer to another without serious trial. Others have been proven effective in published studies—for example, the nematode-suppressing effect of French marigolds. Catnip oil, too, has been shown to repel 17 species of insects, but unfortunately, like the mints, it is an invasive plant that can choke out flowers and vegetables.

Make an Instant-Gratification Garden

Don't want to wait while a thick layer of organic matter breaks down before you plant stuff in your new bed? Modify the lazy bed technique to get a garden you can plant right away, without intense digging! Cover your intended bed with a thick layer of wet newspaper, just as you would for a lazy bed. Then cover the whole plot with a 4- to 6-inch-thick layer of equal parts soil and compost mixed together. (Many garden centers sell this "topsoil" and will deliver a truckload to you.)

Now you can sow seeds or set transplants of shallow-rooted annual flowers and vegetables right into the top layer of your lazy bed. In a couple of months, the newspapers will have completely smothered the grass and will be decomposed enough for deep-rooted plants to penetrate the paper and root in the soil beneath the sod. And earthworms will gradually mix the rich topsoil deeper into the bed.

In my garden, I make only a few intentional companion plantings, usually radishes with cucurbits and marigolds for nematode control, but I do try to keep different plant varieties well mixed. Although I don't follow the lore closely in my garden, partly out of busyness and preoccupation with other matters, I'm no more ready to dismiss it entirely than I am to endorse without reservation the various companion-planting combinations I've heard of. One thing is certain: Growing things relate and interact in amazingly complicated and subtle ways. Much study remains to be done, and close observation by gardeners continues to be a valid source of information about the success of companion planting.

Helpful Companions. According to traditional lore, certain herbs, weeds, flowers, and vegetables have the effect of deterring insects and encouraging plant growth when planted near compatible plants. Borage, chamomile, and lovage are supposed to enhance growth and flavor in nearby vegetables. Garlic planted near roses and raspberries should deter aphids. Horseradish has the reputation of repelling potato bugs. Marjoram is said to improve the flavor of nearby food plants. Mint, sage, and rosemary are the traditional enemies of cabbage moths. Nasturtiums, which actually attract aphids and thus are useful as a trap crop, are sometimes erroneously listed as an aphid repellent. Catnip is often planted to deter flea beetles. Yarrow planted near aromatic herbs is thought to enhance their production of essential oils.

Companions for Garden Space. Another branch of companion planting pairs shallow-rooted plants like onions and celery with others, like chard and carrots, whose roots delve deeply into the subsoil. This seems to me a sensible practice that makes good use of that third dimension of garden space—depth.

Interplanting. There seems to be no question that monoculture (planting large areas to a single plant species) encourages heavier insect infestation. In repeated studies, diversified plantings have suffered less insect damage than monocultured fields. Therefore, the practice of mixing aromatic herbs and flowers with vegetables, alternating rows of different species, and interplanting various species within the row should help, at least, to confuse the insects and, at best, to promote positive plant health.

Harmful Companions. Some plants, in the companion-planting tradition, harm rather than help each other. Fennel, the most notorious outcast, is said to discourage growth of most garden plants. Dill and carrots, basil and rue, sage and cucumbers, cabbage and grapes, and chives and peas or beans are all plants that reputedly make poor companions because one or both are badly affected by close proximity.

Allelopathy. The inhibition of seed germination and plant growth by certain plant-produced natural compounds is sometimes responsible for otherwise unexplained poor plant growth. Plant toxins are usually exuded by roots, but they are also generally present, in varying amounts, in stems, leaves, and fruits.

Walnut Trees and Juglone. Walnut trees release juglone, which retards many plants. I found that out the hard way in my own garden when I planted a row of beets near an English walnut tree at the edge of the garden. Beets, I have since discovered, are particularly sensitive to toxins in the soil. The beet seeds didn't even germinate. Other plants—onions and marigolds—have grown fairly well in the same spot, but most things I plant near that tree produce rather halfheartedly. Shade and competing tree roots could also be a factor, but 200 species of plants are known to be susceptible to juglone. Black walnut trees produce more of the toxin than English walnuts or butternuts.

Like beets, some crops are more vulnerable to the effect of toxins. Soybeans, tomatoes, okra, asparagus, alfalfa, lilacs, apples, peonies, and chrysanthemums, among others, have been shown to be seriously inhibited by juglone in the soil. Those plants that are resistant to juglone include red cedars, redbuds, quinces, black raspberries, corn, beans, carrots, and zinnias.

Other Allelopathic Plants. Other notorious allelopathic plants are ailanthus, artemisia, absinthium, eucalyptus, sunflowers, and sometimes sycamores.

Some crop plants inhibit weeds. For example, Kentucky-31 fescue grass retards growth of black mustard and trefoil. Weeds can suppress crop plants, too. In some experiments, residues of lamb's-quarters, pigweed, velvet lead, and yellow foxtail have inhibited the growth of corn and soybeans.

Black walnut.

Although published observations of the effect of plants on the growth of other plants date back hundreds of years, scientific study of the phenomenon has only begun to scratch the surface. So many plants and variables are involved that few sweeping generalizations can be made. Allelopathy can throw a wild card into some of your planting schemes, but keep an open mind and don't let it worry you. Just try to plant your sunflowers separately and keep your garden away from walnut trees. (A distance of 1½ times the height of the tree should be safe.) If the subject interests you, conduct your own experiments, and jot down what you planted and what you observed.

Taking Pollination into Account

When laying out rows and beds, remember that corn is wind pollinated and should therefore be planted at least four rows deep, preferably six to eight. If you plant only a small amount of corn, make a block of four or more short rows rather than planting a single long row.

If you are planning to save seeds of wind-pollinated garden vegetables like corn and spinach, you will want to follow recommended spacing requirements to avoid crossing.

Special Problems

Perhaps you have a spot in your garden that is poorly drained, a corner that is shady, a section with hardpan, or a rocky area. Each of these special situations may be met and sometimes even partially solved by your choice of plants.

Partial Shade. Plant summer lettuce, parsley, raspberries, or rhubarb.

Hardpan. Treat the problem by planting deep-rooted vegetables like comfrey or Swiss chard to break up the impervious layer of subsoil.

Poor Drainage. Avoid planting globe artichokes, sweet potatoes, or other lovers of warm, loose soil in that spot, until you've corrected the problem by trenching to divert water and/or digging in more humus or making raised beds.

Rocks. Potatoes will do well, especially under mulch, but any crop that needs frequent hoeing and cultivating will be a challenge. If you use a tiller, get pointed tines for working around rocks. When your whole garden is rocky, you accept it and work around it (and often have as fringe benefits a lovely rock garden and several fine rock walls), but when only one part is rocky, you might as well minimize the wear and tear on your hoe by selecting crops to plant there that can be mulched early.

Short of Space. If you're short of space, make some good management decisions to get the most out of the available ground.

The Vegetable Garden. Consider some of the following criteria when deciding what to plant in your vegetable garden and how to plant it:

- Plant vegetables with the highest cash value.
- Grow vegetables that lose quality in shipping.
- Plant earlier, making use of hardy vegetables, early varieties, and plant protectors such as tunnels and cold frames.
- Stretch the harvest with continuous succession plantings.
- Grow high-yielding vegetables such as tomatoes, lead lettuce, turnips, summer squash, and edible-pod peas.

The Flower Garden. Efficient use of space allows you to grow more flowers, too. Consider the following suggestions:

- For more flowers in a small space, grow climbers like morning-glories.
- Use container plantings on patios and porches.
- Plant flowers in windowboxes.

Planting Flowers with Vegetables

There's no good reason, other than staid custom, for keeping vegetable and flower plantings segregated. More gardeners now feel free to mix flowers, herbs, and vegetables in the same plot, with delightful results. Flowers brighten the patch in the backyard, and ornamental vegetables grow proudly in the front border. Not every vegetable plant assumes a pleasing form, but those that do—rhubarb chard, head lettuce, peppers, and many more—deserve their place in decorative planting.

Create lovely garden displays by growing flowers and vegetables together.

In a gorgeous display planting at Longwood Gardens in Kennett Square, Pennsylvania, vegetable and flower plants grow together in borders similar to conventional perennial beds. The plot is laid out as if it were someone's backyard, with one-third of the area in lawn and a path separating a border bed along the fence from the main vegetable bed, which curves gracefully in a long sweep down and across the yard. Where you'd expect to see masses of delphiniums and lilies, escarole, beets, and beans thrive instead, interspersed with marigolds, nasturtiums, and portulaca. A low border of alyssum sets off the arrangement. The surprising effect is that the true beauty of well-grown vegetables stands out. Boundaries between vegetables and

Continued →

flowers fade even more when you remember that blossoms of some flowering plants—calendula, nasturtiums, and chives, for example—are edible. When planning an ornamental edible garden, keep in mind Kate Gessert's advice in her book *The Beautiful Food Garden*: "Be playful, be flexible, take risks."

Planting and Transplanting

Fern Marshall Bradley

Planting and transplanting are at the heart of gardening. To build a garden, change a garden, or move a garden, you must plant or transplant. This section shares the experience of expert gardeners on what works and what doesn't and presents the basics of planting and transplanting properly to ensure success. Some of what you read here may surprise you by offering a new way to look at an old practice. Try a few new techniques, and see what works best for you.

Planting the Small Stuff

In this section, the experts offer special techniques for hardening off vegetable and flower seedlings and planting them out, as well as tips on how to get perennials off to a great start in the big outdoors.

HARDENING OFF FOR THE 9-TO-5 SET

Gardeners who have an office job and also have seedlings started indoors are in a bind when it's time to harden off the seedlings to prepare them for life outdoors. Although you can move them out in the morning when you leave for work, who will take care of the seedlings an hour or two later when it's time to bring them in? Heather Will-Browne, a bedding plant specialist at Walt Disney World in Florida, has found a way to let the seedlings take care of themselves. Put the flats or pots either on the porch or under the north eaves of your house so they are protected from the sun. (You don't need much room—even the stoop outside one of your doors will do.) "It's great because they're also protected from hard rains that will destroy tiny seedlings in just a few minutes," Will-Browne says. If they're on a porch, move the flats gradually toward the outer edge of the covered area so they'll be exposed to a bit more sun each day until they are conditioned for the garden.

A TANGLED TALE OF TRANSPLANT ROOTS

You can help bedding plants that are growing in cell packs and small pots make the transition to garden soil by untangling the roots before transplanting. "I have literally set annuals in a hole and dug them up at the end of the year to find that the roots had circled around and around in the hole. That's due to two things: the original root formation and the interface between the soil mix and the native soil," says Jim Wilson, a cohost of public television's *The Victory Garden*. Plants that don't stretch roots out into the garden soil aren't going to grow well, and they're more likely to dry out. To prevent this, Wilson gently pries some of the transplants' roots loose from the potting soil at planting time to open up the root ball and keep roots from spiraling.

TEAR THE TOPS OFF PEAT POTS

Peat pots are handy, but they need careful transplanting for best growth. "We like peat pots because they make it so easy to deal with large numbers of transplants," says Christina R. J. Pey, a supervisor for the production greenhouses at the Missouri Botanical Garden. However, when planting peat pots, Pey cautions that you should tear off the top edge before planting to be sure it doesn't poke up through the soil. If the pot edge is higher than the soil surface, the peat will dry out and act as a wick, pulling moisture away from the roots. The gardeners at the Missouri Botanical Garden also break off sections of the sides and bottom of the containers to make it easier for the transplants' roots to make the transition to garden soil.

A SECOND CHANCE FOR SEEDLINGS

Most of us know the frustration of having a flat of seedlings or transplants turn out to be leggy, with stems flopping in a jumbled mess. Deep transplanting can give lanky cabbage, tomato, and other seedlings a second chance on life. "Once seedlings get leggy, they're pitiful," says Bibby Moore, a registered horticultural therapist from North Carolina. Moore revitalizes the sorry seedlings by burying their leggy stem right up to the bottom two leaves when she transfers them to individual pots. This technique works with seedlings of cabbage-family crops, as well as lettuce, tomato, and even marigold seedlings.

Moore cautions that this is not an ideal practice, it's just a salvage technique. "The next time you sow seeds, give them adequate light to begin with," she says. It's important to give the potted seedlings increased light so you don't end up with floppy transplants as well. Of course, if you do, you can resort to deep transplanting in the garden. Dig an angled planting trench, strip off lower leaves, and lay the floppy stem in the trench. The plant will form roots along the buried stem.

SOIL CONES KEEP ROOTS GROWING

Cole Burrell, a Minnesota garden designer, has fine-tuned a method to set bareroot perennials quickly and effectively in their planting holes. "Don't straitjacket fibrous-rooted plants into narrow holes, or they'll produce new roots at the expense of top growth while the original roots slowly die off," says Burrell. You can try his special planting technique with your perennials.

1. Mound a cone of soil inside the planting hole. The mound makes it easy to spread roots out evenly so they point in all directions.

2. Turn the plant upside down and let the roots fall open.
3. Put your hand on the roots to keep them spread out, then turn the plant over and place it on the cone.
4. Refill the hole, making sure that the plant's crown is just above ground level.

"Don't use this method for taprooted plants like purple coneflower (*Echinacea purpurea*), baptisias (*Baptisa* spp.), and butterfly weed (*Asclepias tuberose*)," says Burrell. To plant these plants, prepare the planting site by loosening and amending the soil as needed, but don't dig planting holes. Instead, insert a shovel straight down into the soil and then push it forward to open a crevice. Line up the taproot in the crevice with the crown of the plant at soil level. Remove the shovel, and firm the soil in place.

Planting the Big Guys

Trees and shrubs are a great investment. They'll add beauty, shade, and privacy to your property for many years, increasing property value as they grow. But like most things, you get what you pay for—both in the initial cost of the plants and in the care you give them at planting time. Good planting practices are critical to the good health and longevity of trees and shrubs—and recent research has shown that a lot of the timeworn advice on planting is just plain wrong. In this section, you'll find accurate techniques, tips, and advice for giving these valuable plants the best possible start.

DON'T DIG TO CHINA

Old planting recommendations had you dig a hole twice as wide and twice as deep as the root ball of the tree or shrub you were planting. New research has shown that this advice could actually harm your plants. "The best way to plant is to dig the hole as wide as possible but no deeper than the root ball," says Bonnie Lee Appleton, Ph.D., an associate professor and extension horticulturist at Virginia Polytechnic Institute and State University. If the soil is dug too deep, the root ball can sink as the soil settles, so the plant eventually becomes too deeply buried. "We've found that the majority of roots stay within the top 8 to 12 inches of soil anyway," says Dr. Appleton. "Even the roots of big trees." It's okay to set the plant an inch or two shallower than the depth of the root ball. Apply mulch to cover the top of the ball, but don't let the mulch touch the base of the trunk.

SLICK HOLE SIDES MAKE BAD ROOT BINDS

How and when you dig a planting hole can be more important than how big it is. "Rough the surface of the planting hole by slicing the sides of the finished hole with the edge of the spade, or crack some of the soil off with a fork," advises Michael Maltas, the garden director of the organic showpiece garden for Fetzer Vineyards in California. "Then the roots will be able to find a crack and take off." Maltas also points out that you shouldn't dig planting holes in wet ground with a spade, or the sides will be smeared smooth. They'll harden, forming a barrier to the roots.

SITE PREP PAYS OFF

Tree planting involves much more than just digging a hole, says Tom Ranney, Ph.D., an assistant professor at the Mountain Horticultural Crops Research and Extension Center of North Carolina State University. "This is particularly true on urban or suburban sites where the soil is often compacted from heavy equipment and other factors," says Dr. Ranney.

Dr. Ranney recommends tilling the planting area before you dig. This will reduce compaction and encourage aeration and drainage. Since roots tend to stay in the top 1 foot of soil, tilling can make a real difference.

Adding soil amendments to backfill probably isn't necessary for typical plantings, says Dr. Ranney. But it may be appropriate for certain plants in particular sites. For example, if you're planting trees in raised beds or on berms, adding water-holding organic soil amendments can be very beneficial, Dr. Ranney says, since raised beds and berms tend to dry out faster than ground-level plantings.

It's important to maintain the planting site after planting as well. If grass grows in the area that will be covered by the mature spread of the tree's crown, it can compete with the tree's roots for nutrients and water. To prevent regrowth of grass after you've tilled and planted, spread mulch around the tree as far out as the drip line. Don't allow the mulch to touch the base of the tree, because this can encourage disease problems.

WHEN TO AMEND PLANTING RULES

"Research on whether or not to amend soil when planting has been generalized too much," says Roger Funk, Ph.D., the vice president of human and technical resources at the Davey Tree Expert Company. If the soil on your site is similar to the soil in the root ball, there's no need to amend the soil in the planting hole. But if the soil in the root ball is significantly different from your local soil, your tree may grow better if you amend the soil before planting. In one trial, Dr. Funk planted balled-and-burlapped trees that had been grown in sandy clay loam in a landscape where the soil was a heavy clay. He didn't amend the soil and found that water pooled in the holes. "Since most nurseries are growing trees in sandy or loamy soil and lots of gardeners have clay soils—especially in new developments, where they may have subsoil—this can be a common problem," says Dr. Funk. "It's best to evaluate the specific conditions and decide what to do on a case-by-case basis."

TOP SCORES FOR TREE ROOTS

Many planting recommendations suggest that gardeners slice a root ball in half from its bottom surface to about halfway

Continued ➔

through the depth of the ball. This technique may work well on bedding plants, but don't try it on trees and shrubs. "It's a harsh, destructive technique, and you face the likelihood of splitting the root ball," says Bonnie Lee Appleton, Ph.D., an associate professor and extension horticulturist at Virginia Polytechnic Institute and State University. Instead, Dr. Appleton recommends this procedure: Score roots that have grown into a meshlike mat by making shallow vertical cuts through the matted roots, cutting through the outer roots but not into the root ball. Make the cuts on two or three sides of the root mass. If woody roots are circling the root ball, cut through them in two or three places to stop the circling. Make your cuts with a knife or a pair of pruners.

AVOID THE BURLAP ROOT TRAP

Trees and shrubs with roots that are wrapped in burlap can run into problems if you don't pull off the burlap when you plant them. "Many of today's wraps are synthetic and don't decompose like the old natural burlap did," says Bonnie Lee Appleton, Ph.D., an associate professor and extension horticulturist at Virginia Polytechnic Institute and State University. She recommends that after you set the plant into the hole, remove the rope, pins, or wires on the wrap, then drop the wrap to the bottom of the hole and *leave it there*. Don't try to slide it out from beneath the plant—you might end up cracking the root ball, which can kill the tree or shrub. If the ball is in a wire basket, either cut away the top round of loops or cut the basket down opposite sides and push the wire down into the hole.

Planting Techniques

Barbara Ellis, Joan Benjamin, and Deborah L. Martin

Planting the Low-Maintenance Way

A well-done planting job is rarely a low-maintenance enterprise. Even in the best soils, planting means at least a little bit of digging, a little removal of existing vegetation, and a little soil preparation. And the bigger the plant, the more of those things you'll have to do. In rocky, compacted, or weedy sites, planting can mean hard work, even for relatively small plants.

But planting properly pays long-term dividends. Why? Because time invested in careful planting means you'll save time later when you're not nursing sickly plants or removing dead ones. Proper planting also helps plants stay healthy and grow vigorously. Not only will your plants look great, but you also reduce your chances of having to deal with pest and disease problems down the road. Finally, if you treat your investments with care at planting time, the money you spend on plants won't go to waste. There's nothing like having to replace a newly planted tree or shrub that didn't survive a slipshod planting job to remind you that it's worthwhile to do it right the first time.

At Planting Time, Put the Weather to Work

Sunny, breezy spring days are guaranteed to set gardeners planting, but such days aren't ideal from a plant's perspective. In warm sun and drying wind, new transplants suffer because their roots can't take up enough water to replace the amount they lose through their leaves. Instead, put in your plants under gray and drizzly skies.

If you do plant on a sunny day, make sure plants are well watered before you start, and don't leave them with their roots exposed to sun and wind.

After planting, water well to help plants get growing as quickly as possible. Watering also settles the backfilled soil around the roots and forces out any air pockets that formed during planting. Save fertilizer applications until you see signs of new growth.

Cut Post-Planting Care with Seasonal Savvy

Wouldn't it be great to just stick a plant into its chosen site and be done with it? Now *that's* low maintenance! Well, you can get away with this no-care approach—and still end up with healthy plants—if you choose the right planting time. To get off to a good start, plants need moist, warm soil for good root growth, as well as ample water to support top growth. All you need to do is make the most of the weather in your region.

In most parts of the United States, spring and/or fall are ideal for establishing plants with a minimum of fuss. (In the South, late or early winter is best.) The cloudy days and cool, moist air help reduce transplant shock by keeping moisture losses to a minimum. Here are some guidelines to help you decide which season is best for planting.

Spring planting. In spring, plants are naturally preparing for a flush of new growth, which is just what they'll need to get established in a new location. Spring rains naturally help keep new transplants well watered, too. In areas where cold weather arrives in early autumn and temperatures often fall below -10°F, early spring planting gives plants time to grow and establish themselves before harsh winter temperatures arrive.

Fall planting. Fall planting provides plants with weeks of good root-growing weather—moist soil and warm soil temperatures. Since aboveground growth slows or becomes dormant in the cooler air, the roots have a chance to catch up with topgrowth. Fall transplants also can begin growing in early spring, when the soil is still too wet for planting.

For the best root growth and winter survival, try fall planting only in areas where the soil temperature remains above 50°F for several weeks after the trees become dormant. And plant early in the fall to take advantage of good root-growing weather.

In areas with hot, dry summers and mild winters, fall planting gives new plants time to establish healthy roots before the following spring. By then, the plants' roots are also better prepared to survive the hot summer weather.

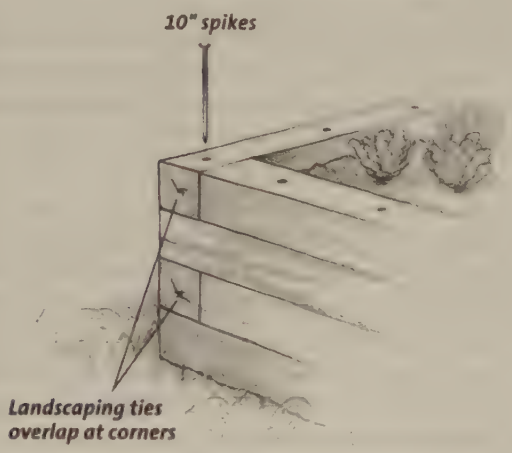
Elevated Beds for Wheelchair Gardening

Roger Yepsen

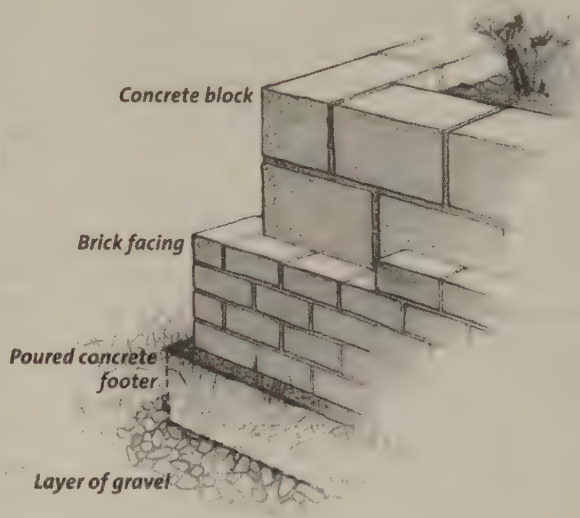
Gardeners in wheelchairs or walkers can till the soil if beds are raised to between 24 and 30 inches. Ideally, these beds should be just 2 feet wide if they will be accessed from one side, or from 3 to 4 feet wide if the gardener can work from both sides.

The beds can be an attractive addition to the garden if constructed with sturdy materials.

One approach is to stack and spike landscaping ties. Be sure to avoid using ties that have been pressure treated or preserved with pentachlorophenol. For a highly durable base, pour a concrete footer, then build low walls of concrete block, faced on the outside with a layer of brick. For better drainage, you can place a layer of gravel in the bed before adding soil.



A sturdy, long-lasting way to elevate beds is to construct a frame from landscaping ties.



For a good-looking piece of garden architecture, construct an elevated bed of concrete block and brick. A poured, recessed footer will support the weight of the walls.

Summer planting. You can plant successfully in summer, but summer installations generally demand more watering and care than plantings timed to take advantage of the cooler weather and natural rainfall in spring and fall.

Don't Dig Down, Dig Out

Simply digging a hole and plopping a plant into it may seem like the easy way to plant, but it causes long-term problems that may come back to haunt you. Plant roots are likely to circle around in a planting hole without ever extending into the surrounding soil. Eventually, they can choke, or girdle, the plant. A planting hole can also become a "bathtub" of loose soil that traps water around roots and drowns them.

To give your plants the possible chance for a healthy, problem-free life, give them a prepared planting site. To prepare a planting site, spade or till up a planting area that's about five times the diameter of the plant's root ball. This loosens the soil so the roots can spread freely. Amending the soil over the entire area with organic matter to a shovel's depth is ideal, but it isn't absolutely necessary if you've picked plants suited to your soil conditions. When you plant, dig saucer-shaped holes,

Preparing planting areas for groups of trees and shrubs is a great idea. Plants growing together in a large, mulched planting area will be healthier and more vigorous than ones planted individually in the lawn.

To Plant Right, Pick Right from the Start

To save yourself hours of maintenance, pick plants that like your site from the start. By choosing plants that will thrive in your site's conditions, you'll prevent years of maintenance headaches.

It's a losing battle to plant something in a site that doesn't suit it. You can amend the soil in the sunny border between your

Continued ➔

house and driveway to get rhododendrons to grow there, but you'll tire of the extra care they'll need every year just to eke out a so-so existence. Eventually, you'll want to replace them with plants that flourish without extra effort.

Take-It-Easy Planting Tips

Although you shouldn't cut corners when it comes to proper planting, here are some tips to make planting easy.

Wheel, don't carry. Use a garden cart or wheelbarrow to carry everything you need to your site at once—plants, shovel, trowel, mulch, and any other tools you might need.

Slide, don't lift. Rather than carrying large plants, use a large tarp to slide them over rough ground. On smooth surfaces, setting plants on a dolly may do the trick.

Use professional planters. Consider having large trees and shrubs planted by the nursery where you bought them. Large plants can easily weigh over 100 pounds, so professional planting can save your back. Also, many nurseries provide replacement guarantees on plants they install.

Measure before you plant. Make sure your hole is large enough before you set your plant into it. Measuring the height and width of both the hole and the root ball will save you from having to haul the plant out of the hole repeatedly while you make it larger.

Space before you plant. If you're planting a large area of groundcovers or annuals, space out the plants you have over the area you want to plant before you dig.

Spread the roots for no-fail planting. Before you settle container-grown plants into the ground, take a minute to encourage the roots to spread out into the soil. Using a knife or trowel to quarter the root ball seems like a drastic technique, but it's a very effective way to encourage the roots to branch and spread. When you quarter a root ball, cut upward about halfway from the base.

When you plant, spread the roots out in the planting hole and backfill around them. If your planting site is newly prepared, set plants slightly higher than they grew in their pots—they'll settle in as the soil settles. Otherwise, plant them at their container-grown depth.

Bareroot Plants Make for Easy Planting

Although bareroot plants may seem strange or intimidating, they make lots of sense for low-maintenance gardeners. Since they're sold without all the soil that accompanies container-grown and balled-burlapped plants, they're easier to lift and move around your yard. If you're mail-ordering, they're also less expensive to ship. Roses, fruit trees and bushes, strawberries, and grapevines are typically sold bareroot, as are daylilies, irises, and many other perennials. Many trees and shrubs are also sold bareroot.

Fortunately, bareroot plants are easier to handle than they might seem. They're typically shipped dormant, timed to arrive at your door ready for planting. Whenever possible, plant them as soon as you can. If you can't plant right away, moisten their roots thoroughly and pack them in moist potting mix or compost. Try to hold them this way for no longer than three days.

Before you plant, soak the roots in a bucket of water for at least an hour or two. Cut off any dead or damaged roots with sharp scissors or pruning shears. Then plant them as described above.

Check under the Burlap for Best Buys on B&B

If you buy a field-grown tree or shrub from your local nursery, chances are you'll get it balled-and-burlapped, or B&B. Before you buy, it pays to check what's under the burlap to make sure you spend all your planting efforts on a healthy plant instead of one that has been mistreated.

B&B plants are usually dug while they are dormant, and their root balls are wrapped with burlap. The biggest hazard of buying a B&B tree is that it may not have a large enough root ball.

To check the root ball size of potential purchases, use this rule of thumb: The root ball should be 1 foot in diameter for every inch of the diameter of the trunk at the base. There is no similar rule for shrubs, but bear in mind that the bigger the root ball, the faster the plant will establish itself.

Undersize root balls are a bigger hazard for trees, whose roots extend far beyond their drip lines (the point to which the tree's branches extend). The average B&B tree retains only 5 percent of its original root mass.

From Ground to Garden

If gardening were a board game, we'd all skip "start" (digging a new bed) and go straight to "win" (enjoying the results). But the old gardening wisdom is true: If you prepare the soil well in the beginning, you'll save time later on weeding, feeding, watering, and other chores. And your plants will reward you with robust health that promotes natural insect and disease resistance.

Digging In

There are as many ways to start a garden as there are gardeners. And there are also ways to make this task considerably easier. How you go about preparing your garden bed depends on a number of things, including the condition of the soil when you start and what you want to grow.

For example, double-digging is one of the best ways to build a raised vegetable bed. But if you plan to plant perennials, you can use a less work-intensive method of bed preparation, or even a no-dig method. Whatever bed preparation method you choose, remember that balanced soil holds the right amounts of air, water, and nutrients.

Before you dig in, read on, and use your answers to the following questions to help you decide which garden-making method will work best for you:

- What do you plan to grow in your garden?
- What type of soil and soil problems do you have to begin with?
- How hard are you willing, or able, to work?
- How soon after preparing the garden do you want to plant?

Double-Digging Delivers Double-Good Beds

There's no question that it's hard work, but double-digging is still one of the absolute *best* ways to prepare a garden bed. You loosen the soil to about 24 inches deep when you double-dig, which gives your plants' roots lots of room to roam. Double-diggers who've examined the benefits of this method report that they get much higher yields from double-dug beds—in some cases, 9 to 15 *times* the yields of similar-size-but-not-double-dug plots!

1. Using a spade or sharp shovel, dig a trench about 1 foot wide and 1 foot deep across the narrow end of the bed. Put *this* soil (and only this trench's worth of soil) into a wheelbarrow. This soil will be used to fill in the last trench when you're all done digging.
2. Loosen the soil in the bottom of that trench an additional 12 inches with a spading fork. Push the tines of the fork in to their full length, then use the handle as a lever and push down to move the tines up through the soil.
3. Now dig a second trench, also about 1 foot deep and 1 foot wide, next to the first trench. Use this second trench's soil to fill the first trench.
4. When the second trench is empty, use the fork to loosen the lower 12 inches of soil in it, just as you did in the first trench.
5. Repeat these steps, trench by trench, until you reach the other end of the garden bed.
6. After you've removed the top layer and loosened the lower layer of soil in the last trench, use the soil you saved in the wheelbarrow from the first trench to fill in this trench. Rake the whole bed level from outside the bed, so you won't step on the freshly "double-dug" soil.
7. Spread a 1-inch layer of compost over the entire bed for a nutrient boost and to prevent diseases.
8. Place your plants in your newly double-dug bed! Don't step on the bed or you'll compact the loose fluffy soil. If you can't reach the center of the bed, get a sturdy board and lay it on supports resting outside the garden so it extends over the top of the bed. Stand or kneel on the board when you're ready to plant in the middle of your garden.

Another Way to Make Your Bed

Some people look at their lawn and see, well, grass. Others see spaces where new flowerbeds and mixed plantings could be. If your interest in the soil involves ways to use it to support more flowers, read on to learn the steps to follow to turn boring expanses of sod into pretty perennial gardens.

1. We've said it before, but it's worth repeating: Don't dig in wet soil. Start your bed-building venture by checking to make sure the soil is dry enough to dig.
2. To create a straight-edged bed, drive stakes into the ground and stretch a clothesline from stake to stake to mark off the perimeter of the garden. You can outline a bed with a curved edge by laying a garden hose on the ground and adjusting it to the desired shape. To mark the edges before you remove the sod, drive your garden fork into the ground along the outline of the rope or hose, and break up the sod as you go.
3. If you don't plan to use the sod in another spot in your landscape, a garden fork is a good tool for turning the sod and the soil. You can also use a sharp shovel or spade for this task, but you may find the work easier with a fork because it's easier to push the tines into the soil.
4. To lift the sod, push the fork straight down into the ground with your foot, then use the handle as a lever to pry loose a clump of sod. Grab the sod and shake the soil from the roots onto the bed. Throw the remaining grass on your compost pile and repeat until you've uncovered the soil over the entire bed.
5. If you haven't already tested the soil in this new garden bed, now is the time to take a sample to send off for analysis. It's definitely worth it to do this now, before you invest time and money in fertilizers and amendments for your new bed.
6. Before planting, spread approximately 1 inch of compost or composted manure over the top of the bed. This is also the time to blend in any of the amendments that were recommended as a result of the soil test. Then use your fork to mix them 12 to 18 inches deep into the loosened soil.
7. When the soil is light and fluffy and the amendments are mixed in, grab a garden rake and level the surface of the soil with the tines. Then flip the rake over and smooth the soil with the backside of the rake. Now you're ready to plant.
8. Perennials of all shapes and sizes come in plastic nursery pots. The trick to unpotting them without damaging the roots is to turn the pot upside down, then cradle the soil surface and plant in one hand while gently squeezing the pot with the other until the roots and soil slide out. Untangle any roots that are circling the rootball. Then use a trowel to dig a hole deep enough to set the rootball of the plant at the same depth it sat in the pot. Make the hole wide enough so there's room to straighten out any long roots. When the plant is in its

Continued →

hole, firm the garden soil around the rootball. Then create a shallow trench around the root zone on the surface of the soil so water will collect and trickle down to the roots. Fill a watering can with water and soak the soil around each plant's roots.

9. When your plants are set in place and watered well, cover the ground around and between them with a 2-inch layer of compost. If you like, you can top the compost layer with an inch or two of a more attractive organic mulch, such as pine needles, buckwheat hulls, or shredded bark.

10. Edging your bed gives it a neat, finished look and has the practical advantage of keeping grass roots from taking hold in the bed's soft, fertile soil. Here's an easy and effective way to edge: Take a half-moon edger and push it straight down into the soil all along the edge of your bed. (These edging tools are inexpensive and really easy to use—the 4-inch length digs to exactly the depth of grass roots, and the curved blade is easy to push in.) Rock the edger back and forth to cut the sod.

    When you've made a straight cut around the whole perimeter of the bed, make a second cut on the flowerbed side, but this time push the edger in toward the first cut at a 45-degree angle. Pull out the wedge of sod and soil, leaving a narrow, V-shaped trench around the bed. This keeps grass roots out of your beds because when the roots break through the straight side of the trench and contact air, they will turn around and grow back into the soil on the lawn side of the trench. Over time the roots will weave through and reinforce the wall of the trench, without invading your garden.

Building a Lazy Bed

If you plan to put in a new bed several months before you plant it, why not take it easy and take advantage of the time you have to create a "lazy bed"? This no-digging method is easier on your back and kinder to the soil because it preserves the existing structure, pores, and worm tunnels. And with this method you'll end up with a raised bed, which will drain well and warm up quickly in the spring.

Start by mowing the sod or weeds or whatever is growing in your intended site as low as your mower will cut. This is the one time when it's okay to "scalp" the grass with your mower. Then completely cover the close-cropped sod with several thicknesses of newspaper. It helps to wet the newspaper to keep it from blowing away as you're laying it out.

Top the newspaper layers with 8 to 10 inches of organic matter. Be creative and thrifty and use materials that you have on hand or that are easy to come by. Shredded leaves, compost, grass clippings, wood chips, straw or hay, and even kitchen scraps are all fair game here. Just pile it on and wait for these riches to break down into healthy soil for future planting. Keep in mind that if your lazy bed is in a spot that you look at often, you'll want to top it with something that looks nice while you're waiting—choose a "pretty" mulch like wood chips or cocoa shells for the top layer. If looks are less of a concern and rich soil is the ultimate interest, tuck all that organic matter under a layer of black plastic for quicker decomposition.

If you build your lazy bed in late summer and let it "cook" until spring, it should be ready for planting when the local nurseries put their plants out for sale. While you wait, use your time to browse through glossy plant catalogs and make a map of exactly what you want to plant in the soft, rich soil of your new bed.

Raise Your Garden in Raised Beds

Few methods of gardening offer as many advantages as growing in raised beds. Raised garden beds are higher than ground level and are separated by paths. Plants cover the bed areas, and gardeners work from the paths. Typical raised beds are 3 to 5 feet across to permit easy access from the sides and may be any length. You can grow vegetables in raised beds, as well as herbs, annual or perennial flowers, berry bushes, or even small trees. Raised beds can solve problems of difficult soils; improve production; save space, time, and money; and improve your garden's appearance and accessibility. Raised-bed crops are more productive because they grow in deep, loose, fertile soil that is never walked upon. And you can grow twice as many crops in the same space: In a row garden, the crops occupy only one-third of the garden area while the paths between the rows take up two-thirds of the space. In a raised bed garden, the proportions are reversed.

First clear the site and remove weeds or sod, then use one of the following techniques to build your beds:

Mounding. This is the quickest and easiest way to make a raised bed. Simply till or fork up the soil to loosen it, then heap compost, well-rotted manure, and other organic matter on top and rake it together to create a mounded bed. If your soil is very poor or rocky, use purchased topsoil mixed with compost and amendments to build the beds from the ground up. Because a freshly built mounded bed is loose and full of air, it settles initially and can easily erode. Add more soil-compost mix if the bed loses height. Frame the bed if erosion is a problem.

Tilling and hilling. This bed-building method prepares the soil almost as thoroughly as double-digging but takes much less time.

1. With a rotary tiller, thoroughly till the entire garden area to a depth of 6 to 8 inches.

2. Using stakes, twine, and a tape measure, lay out the perimeter of the beds. Be sure you leave adequate space for pathways. From this point on, walk only in those pathways, not on the marked beds.

3. Loosen the subsoil in the marked-off areas with a garden fork.

4. Next, using a spade, scoop up the top 2 to 3 inches of soil from the pathways around the beds, and add it to the beds to produce nicely raised beds.

From Companion Planting to Crop Rotation

Sally Jean Cunningham

Companion planting captivates gardeners. We're charmed by the notion that plants have "friends" who help them grow better. And as organic gardeners, we're eager to try simple, nonchemical methods that may repel pests. There's also something satisfying about learning from old-time gardeners—and companion planting certainly has deep roots in history. I've discovered that companion planting makes my garden better, but it's not the whole story of my system. I also rely on insects, birds, earthworms, and even fungi and bacteria to create a healthy, bountiful organic vegetable garden. So companion planting is only part of the picture. It's intertwined with techniques like attracting beneficial insects, building soil, and planting intensively—all vital to my companion-gardening system.

Starting with Companion Planting

I first studied companion planting on doctor's orders. I was confined to bed during a rough pregnancy—during gardening season, too! I decided that if I couldn't garden, at least I could read about it. There was plenty to read. I found books full of recommendations for pairing up vegetables with other vegetables, flowers, and herbs. There were even companion-planting suggestions for fruit trees. I tried to memorize every possible companion-planting combination, but the recommendations were sometimes confusing and very unscientific. There were even contradictions and impossibilities. For instance: One source said that bush beans grow well with cucumbers. Another recommended pairing bush beans with potatoes but said that potatoes should not be planted with cucumbers. So what's a gardener to do?

My answer was to dig hard into the research on companion planting. I sorted through hundreds of recommendations, trying to find the ones that were recommended by several sources and backed by research. Some companion-planting suggestions made lots of sense, such as planting cucumbers and broccoli together to make it harder for cucumber beetles to find the cucumber plants. Others were more like fairy tales. For example, petunias, especially pink petunias, are supposed to repel squash bugs and Mexican bean beetles. (Maybe they don't like the color pink!) And planting lettuce and squash together is supposed to put rabbits to sleep so they won't be able to eat the crops. I think I'd rather put my money on a garden fence or rely on my dogs' frequent tours around the garden to deter rabbits.

By the end of my pregnancy, I'd compiled some important reasons why companion planting works and had listed hundreds of companion-planting combinations to try. Testing those combinations and choosing the best took a few seasons of experimentation. And while I experimented and refined my choices, I developed my system of companion gardening.

SEARCHING FOR ANSWERS

When I decided to study companion planting, I was searching for help with my own garden. I was trying to garden organically and was failing miserably. There were horrendous holes in the broccoli leaves, the potatoes were puny, and the weeds made August a nightmare! I was even teaching organic gardening at the time, and what I did and taught were fine—as far as they went. But I made a mistake that beginning organic or "switching over" gardeners often make. I substituted organic products like bonemeal for synthetic products like chemical fertilizers—*but I gardened the same otherwise*. Somehow I thought that if I avoided pesticides, used manure, and planted my rows of vegetables, Mother Nature (knowing I'd been good to her) would keep the pests in line. So wasn't I dismayed when the Colorado potato beetles arrived in droves, every ear of corn had earworms, and there were embarrassing little green worms floating in the pot when I cooked my broccoli!

The problem was that I had a very unnatural garden: a flat rectangle of straight single rows of plants with bare soil between. This gardening style works when you rely on chemical pesticides to kill pests and chemical herbicides to wipe out weeds. But for me, the few organic products or tricks I substituted (insecticidal soaps, black plastic to kill weeds, and home remedies for pests) just wouldn't cut it. I had to rethink the whole system. I needed a garden that could take care of itself without lots of artificial help from me.

Learning from Nature's "Garden"

So the season after my enforced bed rest, I started experimenting with companion planting in my garden. I was hooked on the idea of mixing and matching plants to create a beautiful garden with practically no pest problems. But I discovered that while companion planting was a great idea, it wasn't enough. I also needed to build up the diversity and richness of my garden soil and to create a diverse environment both in and around my vegetable garden. I began to study the examples of nature, paying close attention to what was happening around the pond and in the woods beside my garden.

I'd like you to imagine some of the things I saw in the woods. There were fallen leaves and hemlock needles covering the soil surface. When I bent to poke a finger under the leaves, I saw earthworms tunneling in the moist surface soil. Under

Continued ➔

a fallen tree limb, I saw centipedes and pillbugs doing some of the decomposing that turns dead plants into a rich type of organic matter called humus. There were ferns growing in the rich humus and wild blackberries clustered at the sunny edges of the woods. Both those plants thrive in the acid soil beneath the evergreens. I heard sounds, too: the hum of insects, the chattering of squirrels, and the warble of birds that were searching the woods for berries, seeds, and insects to eat.

Now, think what would happen in the woods if Joe Gardener came along with a pesticide to "get rid of those bugs?" What if he raked up the pine needles, added some lime, and planted roses or tomatoes? I'm sure you know the answer: Interfere with the links in the living chain, and the natural system starts to collapse.

So if modern human gardening styles ruin natural systems, should we move back into caves or walk around feeling terribly guilty all the time? Of course not! There aren't enough caves for all of us anyway, and feeling guilty won't make things any better. What we can do is set up gardens that take advantage of the natural processes that make the woods a successful, self-sustaining system. We can make a difference by planning gardens and landscapes that won't need chemicals to keep them looking good. And a very good way to start is by creating a more diverse environment in your own yard and garden.

GARDENING WITH NATURE

Can we re-create a natural forest or meadow in the vegetable garden? Not really—and we don't want to if we plan on producing a harvest. In our gardens, we want to choose which crops we're going to grow, after all. To mimic Mother Nature but still grow your choice of food and flowers, there are several techniques that will help.

Break up mono-crops. If you're growing a lot of one crop, plant several small plots in different parts of your garden, and mix the crop with at least one other vegetable crop.

Plant flowers and herbs. Interplanting flowers and herbs among your vegetables attracts natural predators such as birds and beneficial insects and makes it harder for pest insects to find the crop.

Shelter beneficials. Provide water, food, shelter, and breeding places for beneficial insects, toads, birds, lizards, and even snakes. Possible habitats can be hedgerows, perennial plantings, groundcovers, or rock piles. Putting out bird feeders, birdhouses, and birdbaths also helps.

Swear off pesticides. Even organic sprays like pyrethrum can kill beneficial insects. Butterflies have nearly no pesticide tolerance. And killing all the "pests" wipes out food that your beneficial insects might have eaten. Basically, if you spray, what you'll destroy is your effort to attract beneficials.

Leave some weeds. Learn which weeds or wildflowers provide habitat for natural predators, and leave a few of them in place when you weed. (Warning: Some weeds compete too well for nutrients, harbor pests or diseases, or take over too aggressively—so learn to identify weeds like Queen-Anne's-lace and goldenrod that are safe to leave in place.)

COMPANION PLANTING CREATES DIVERSITY

Creating diversity brings us right back to companion planting. My study of nature revealed the two best reasons for using companion planting in my vegetable garden, and I'll boldly state them here.

First, almost any combination of plants grown together is better than segregating crops into separate blocks. Combining plants increases biodiversity—the variety of living things in an area. And this variety is one of the big secrets of companion gardening! If you start mixing up your vegetables and adding in herbs and flowers, you'll also attract a variety of birds and beneficial insects to your garden. This alone will do a great deal to ensure a successful garden.

This leads to my second bold statement: When companion planting works to minimize pest problems, it is usually because the companion plants confuse the pest insects or attract beneficial insects. Certain plants do a good job of confusing pest insects in search of your crops. Other plants attract the beneficial insects that destroy those pests. In fact, I'll bet that many of the traditional companion plants that "repel" pests really work because the mixed-up planting confused the pest or because the companion plant harbored predatory or parasitic beneficial insects. So either Mr. Pest never found his dinner or he was eaten before he got there!

Quick Tip

Weeds in Cracks Breaking Your Back?

Here's an easy trick for dealing with stubborn weeds that pop up between the cracks in sidewalks, patios, and paved pathways: Put ¼ cup of table salt in 1 quart of boiling water, and pour the hot liquid on the offending plants. You'll kill the weeds—and they won't come back.

SORTING OUT THE COMPANIONS

As I played with companion planting and increasing diversity in my garden, I still found myself searching for a way to simplify what I was doing. I didn't want to review all the companion-planting books each year and re-create my garden from scratch! I decided to create plant groupings that worked well together and to keep using those groups from year to year.

I started with the vegetable crops that I wanted to grow. I broke these up into groups I call *families*. Then I chose friends

that would complement and assist the vegetables by attracting beneficial insects, confusing pests, and enriching the soil. Most of these are herbs and annual flowers, and many of them are traditional companion plants. However, I also drew from recent research on the best plants to attract beneficial insects, so my friends even include some perennial flowers, as well as cover crops, like buckwheat.

A plant family with its friends forms a *neighborhood*. I sometimes make small changes in the members of a neighborhood. For instance, one year I became very interested in fancy salad greens other than lettuce, so I added them into my lettuce neighborhood. I move my neighborhoods from bed to bed each year, a practice called crop rotation, which also plays a role in controlling insect and disease problems.

Taking Care of Your Soil

Plant neighborhoods are the heart of my system, but they're not the whole of it. My early attempts at organic gardening showed me that there's more to it than just not using chemicals, and there's more to it than mixing up your plants. Even if you plan wonderfully diverse planting beds, if your soil is in poor shape, your harvest will be poor, too. Soil is the source of food and water for my crops, so covering and protecting the soil are a big part of my companion-gardening system.

KEEP YOUR SOIL COVERED

I always cover my soil. Sometimes I'm tempted not to, especially when the garden looks so fresh and orderly, with neat little seedlings pushing through the soft, raked earth. The trouble is, the garden won't look like that for long. Not only do weeds sprout, but rain and wind start to batter the soil surface. Soon that soft, raked planting bed has gullies in it where topsoil has eroded. Or if the weather's been dry, the soil surface is baked, crusty, and hard. It will be impossible for seedlings to poke through, for roots to grow, or for water to soak in. And if you cultivate to fix things, you end up stepping on the soil, and it becomes even more packed down. To prevent this destructive sequence of events, I always cover my soil.

Make the Most of Mulch

Most gardeners use mulch to cover their soil. There are many kinds of mulch. I mulch with grass clippings, straw, newspaper (shredded or in sheets), leaves, pine needles, cocoa shells, and sometimes black plastic. (I leave bark chips for the landscape plantings.) I know gardeners who use rugs, carpet runners, tarps, and shower curtains for mulch. If you don't like the looks of these "recycled" mulches, just cover them with a more attractive natural mulch. That way you can use what you have available.

Cover Up with Cover Crops

Cover crops or green manures are special crops that we plant especially to keep the soil covered. I love using cover crops in my garden because they also shelter those all-important beneficial insects, and they're prettier than many mulches.

You can choose from many grasses and grains for a cover crop, including annual ryegrass, hairy vetch, buckwheat, clover, and alfalfa. You can plant some of these in fall to cover the soil during the winter, and then turn them under in the spring to build the soil's organic content. Or you can plant them in beds that need to "rest" for all or part of the growing season. They cover and protect soil, block weeds, and add organic matter.

I think the best trick with cover crops is to plant them next to or among your vegetable crops. This is called intercropping, or interseeding. It works particularly well with legume crops like clover and alfalfa. These crops improve soil fertility by "fixing" nitrogen. This means that with the help of special bacteria in the soil, their roots can change nitrogen gas from the air into nitrogen compounds plant roots can use. (Nitrogen is a building block of protein, which plants need to live and grow, just like animals.)

Keep Crops Close Together

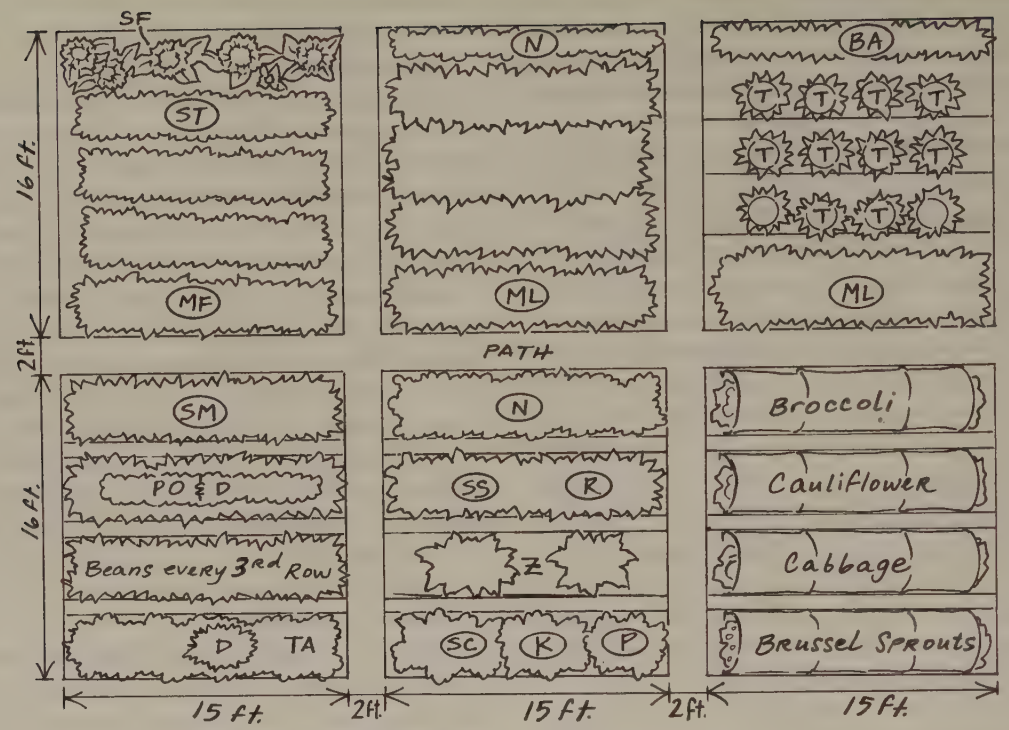
Still another way to cover the soil is by planting your vegetable crops close together—intensively—in wide rows. Wide rows can be anywhere from 1½ to 4 feet wide. You can space individual plants so closely that their leaves touch or overlap when they reach full size. This leaf canopy shades the soil so weeds can't get enough sunlight to grow well, and less moisture evaporates from the soil. You can plant a single crop intensively—for example, a 3-foot-wide row of beans planted 6 inches apart in all directions. Or you can plant two or more different kinds of plants intensively for the same effect. For instance, you can plant zinnias to fill in bare spots in the broccoli bed, or plant lettuce and spinach together across a whole bed.

BE A SOIL BUILDER

In a forest or meadow, the natural system works to continually build up the soil. Plants grow and die, then insects, bacteria, and fungi cause the dead plants to decompose, returning nutrients to the soil. Animals die, too, and their bodies also contribute nutrients as they decompose. Even rocks break down gradually and add minerals. But when we farm or garden, we use up the soil about 16 times faster than nature rebuilds it. In part, that's because we keep removing plants as we harvest, instead of letting them decompose and return to the soil. Poor agricultural practices that waste soil and cause erosion are also to blame. So we need to build the soil in our vegetable gardens all the time!

Building soil can be a lot of work, and common sense says it's easier to protect the good soil you already have. Covering the soil is a good start toward preventing soil loss. However, it's important not only to keep your soil but also to keep good soil structure. Soil with good structure has lots of pores, tiny openings that roots can grow through and that can hold water and air.

Continued →



My companion garden. My garden has six blocks of beds. In each block I interplant herbs and flowers and mix my crops to create a diverse system that's full of natural pest-control power. Each year, I rotate crops from one block to another.

BA—Basil
D—Dill
K - Kale
MF—Mixed Flowers
N—Nasturtiums
P—Parsley
PO—Potatoes
R—Radishes
SC—Swiss chard
SF—Sunflowers
SM—Straw mulch
SS—Summer squash
ST - Strawberries
TA—Tansy
Z—Zucchini

Once soil structure is destroyed, it can take two years or more to re-create it. Good structure, or tilth, is something that you can feel, especially as you gain experience with gardening. Good soil crumbles in your hand because it's made up of lots of little clumps of particles that contain both moisture and air.

The best way to protect soil structure in your vegetable beds is to stay off them. When we step on the soil, our body weight compresses it, crushing all those tiny openings that hold water and air. That's why I raise my beds slightly and put clear paths between them.

YOUR SOIL IS FULL OF LIFE

Imagine that you're in your garden, where you can scoop up a handful of soil and look at it. Aside from a centipede, grub, or pill bug, you might not see anything that looks alive, but that's only because your eyes aren't powerful enough to see most of the tiny organisms at work there.

In that handful of soil, there are millions of bacteria and fungi that break down organic matter, making nutrients available to plant roots. Special nitrogen-fixing bacteria work with the roots of leguminous plants to fix nitrogen. There are microscopic wormlike creatures called nematodes—some helpful and some destructive. Root-knot nematodes infest roots of many vegetable crops and can stunt their growth, while beneficial nematodes kill termites, grubs, and other pest insects.

FEEDING THE SOIL

When I was a little girl, my Grandpa Harper taught me to "feed the soil and not the plant." So when I saw him put kitchen scraps into trenches in the garden, I thought he was actually "feeding" the soil! But what he was really doing was feeding the microorganisms, insects, and animals in the soil. They feed on organic matter—which can be anything from apple peels to those overgrown zucchini that you couldn't manage to give away.

For organic gardeners, getting organic matter into the soil probably takes more time than any other single gardening activity. That's because we know that our soil is our garden's gold—our most precious resource. We make and spread compost, sow cover crops, put down mulch, and dig spent crops back into the soil. One year, I used my gardening journal to jot down how I spent my time in the garden. My notes showed that

I put about half my time into gathering and moving organic matter (manure, leaves, yard debris, mulch from the town), making compost, and getting the stuff into the garden!

Once we add the organic matter, the soil life takes over. The microorganisms, insects, and other soil-dwelling animals munch on it, eventually decomposing and converting the organic matter into simple forms that plants can use. Earthworms are the best-known soil-building organisms. They can process or digest their weight in organic matter daily, converting it into nitrogen, phosphorus, potassium, and other nutrients, which they leave behind in a material called castings. If you supply organic matter, you'll have a soil neighborhood of earthworms and other happy organisms that will create a rich, productive soil.

Making the Most of Your Garden

My system of companion gardening relies on some tried-and-true techniques that increase productivity and add pest-protection insurance to your garden. These methods are succession planting, relay planting, and crop rotation. Using these techniques helps make the most of garden space and also makes the garden more diverse and naturally pest resistant. That fits right in with companion gardening!

SUCCESSION AND RELAY PLANTING

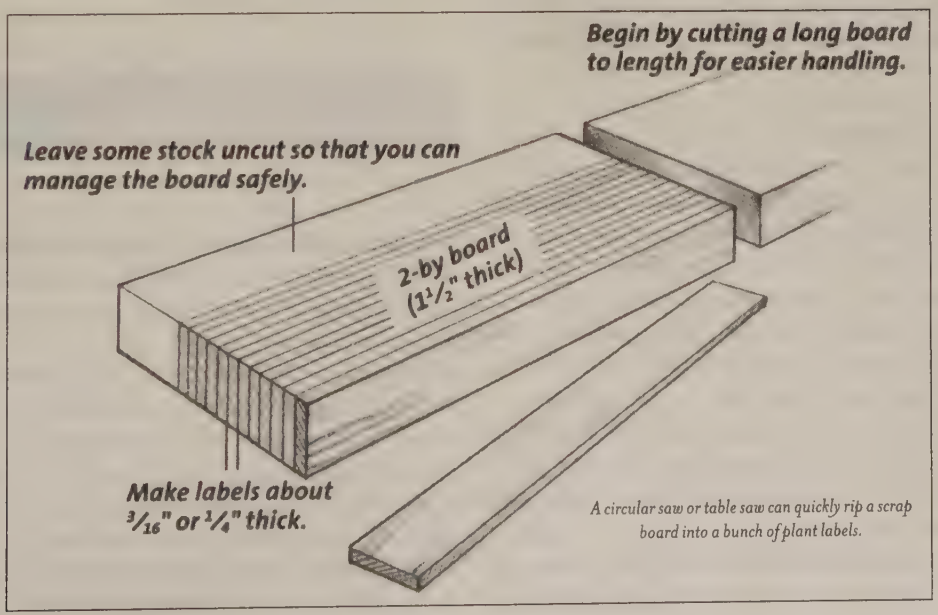
Successions and relays are two planting techniques that use space well and keep the soil covered. Succession planting is planting a new crop as soon as you pull up the plants from a crop that's finished. A typical routine would be to harvest a cool-weather crop like peas and then plant a warm-weather crop like beans or squash in their place.

Those %$#@!! Labels

Ellen Phillips and C. Colston Burrell

Have you heard about an evil race of slugs that sneak into your garden at night and steal all your plant labels? Well, neither have we, but it's as good an explanation as any as to why plant labels always disappear. Perhaps "always" is a bit strong. Sometimes they break instead, sometimes they appear yards from the plant they came with, and sometimes—most of the time—they just fade away. Inevitably, this is just when those knowledgeable plant friends you were hoping to impress come by and say, "What's that plant?" To make sure you can answer them, try these tactics.

- **Keep good notes.** Write down what you planted, where it came from, and when and where you planted it. Keep a sketch of your garden and fill in the new plant's name and location, (This is especially useful when your labels start to wander.) And keep the nursery bill (with the plant list) in your notebook with your planting notes.
- **Make more.** While you can still read the label, make several more wooden "tongue-depressor" labels and an indelible marker. When you inevitably see that the plant's name is fading fast on the original label, you can pop in a replacement.
- **Make 'em last.** If you can afford it, buy metal labels and write the names of your plants on them with a pencil, then attach them to the plants' stems. These labels should stay put, and they'll last at least as long as your plants.



Begin by cutting a long board to length for easier handling.
Leave some stock uncut so that you can manage the board safely.
2-by board (1½" thick)
Make labels about 3/16" or ¼" thick.

A circular saw or table saw can quickly rip a scrap board into a bunch of plant labels.

Continued ➔

Relay planting takes a bit more strategic planning. When you plant in relays, you start one crop next to, or under, an existing crop that will finish soon. For example, you may plant bush-bean seeds under broccoli plants two weeks before the broccoli harvest. That way, the beans will already be growing when you pull out the finished broccoli plants.

Another sequence I like involves overlapping plantings of early spring lettuces, onions, carrots, and more lettuce. As your harvest leaves spaces among one crop, just plant a few of the next.

CROP ROTATION PAYS OFF

For me, crop rotation is a gardening basic: It just makes sense to locate your crops in a different part of the garden each season. Crop rotation minimizes disease and insect infestations. For example, if you plant tomatoes in the same bed every year, you'll probably end up fostering a tomato disease like Verticillium wilt. The fungi that cause the disease will remain in the soil over the winter and will just start up again if you plant more tomatoes in the same spot in the spring.

On the other hand, if the tomatoes are in a new bed as little as 15 feet away, the fungi may not find their target in time to survive. The same is true for pests. How soon to repeat the same crop in one location varies by the crop and the situation. I recommend waiting at least four years before replanting a crop in the same spot, especially if a soilborne disease has been present.

Smart rotations also help make the best use of soil nutrients. That's because different crops have different nutrient needs. Some crops, such as cucumbers and tomatoes, use up lots of nutrients, while others, such as beans and potatoes, use very few or actually add nutrients. I group my vegetable crops as heavy feeders, light feeders, or soil builders when I plan rotations with soil in mind. I've built crop rotation right into my companion-gardening system, as you'll see when you create your own crop groups.

SUMMING UP MY SYSTEM

By now you know that my companion garden has a mixed-up look, and it's a real mix of gardening techniques. Companion planting is a key element, but feeding and protecting the soil are equally important. I've also worked to make special areas to attract and shelter beneficial insects and animals. And of course, I plant all my crops intensively, I plant crops in successions and relays, and I rotate crops from year to year.

The techniques themselves aren't new, but the way I've combined them is, and it adds a sense of adventure to my gardening. I'm always on the lookout for beneficial insects I might not have seen before, and I'm always thinking about new ways to make my vegetable garden even more self-sustaining. For example, one new technique I'm experimenting with is planting a hedgerow next to my vegetable garden specifically to attract and shelter those good insects and animals that prey on insect pests.

It's easy to enjoy experimenting because my basic system works so well. As I plant cosmos with my eggplant and add compost to my intensively planted raised beds, it's nice to know that I'm part of a long tradition of gardening wisdom. The techniques and principles were always there. It's just our turn to apply them.

We'll start with garden layout and making raised beds, then move on to the nitty-gritty of setting up plant families, friends, and neighborhoods. The end result will be a successful, diverse garden, full of food and flowers and lots of life!

Plant Labels, Cheap

Wooden plant labels aren't inexpensive, and they're usually flimsy by the end of the growing season. If you have a table saw, or are handy with a handheld circular saw, you can quickly reduce a scrap length of lumber, such as a 2 x 4 or 2 x 6, into a bunch of sturdy labels. Wider boards (such as a 2 x 6 or 2 x 8) are easier to handle because you can saw off a good number of label-thickness slabs and still have some stock to hold on to. It also can help to begin by cutting boards to a manageable length that is a multiple of the desired label length. If you want 12-inch labels, for example, make cuts at 2- or 3-foot intervals.

These won't be untrasmooth, rounded pieces of art, but they'll do the job. And if they're thicker than the commercial kind, they may hold up better. Wear safety eyewear when sawing. Either rip the board by running it through a table saw, or clamp the board securely and run a circular saw along it with a ripping guide attached. Use a chop saw, table saw, circular saw, or hand saw to cut the strips to length.

Cold Frames and Hotbeds

Barbara W. Ellis

Designing and Using Cold Frames and Hotbeds

Cold frames and hotbeds are among the most useful of gardening structures, regardless of the type of gardening you do. Although most commonly used in early spring for starting or hardening-off seedlings, both can be used year-round for a multitude of purposes. Throughout much of the country, these structures can help extend the growing season by three months or more. Cold frames, and to a lesser extent hotbeds, can also be used for winter storage of container-grown plants that might not survive the rigors of winter above ground, holding over not-quite-hardy herbs or perennials, or for cold-treating spring bulbs potted up for forcing. Some models are also very useful for

rooting cuttings of woody plants or perennials. Furthermore, cold frames and hotbeds—both of which are often referred to as frames for convenience—are inexpensive to build and easy to maintain.

PICKING A DESIGN

The type of frame you decide to build will depend on how you want to use it, as well as the space and site you have available. Your design can be as simple or elaborate as you wish; many cold frames and hotbeds are designed around materials on hand or ones that can be easily salvaged. Depending on the type of gardening you do, you may decide on a combination of cold frames and hotbeds, as well as permanent and portable models. There are also a variety of ready-made models for sale. Consider the following selection and design factors when making your choice.

Cold frames and hotbeds are basically rectangular, boxlike structures with glass sash on top. Most frames are designed with slanting sash roofs, with the high end toward the north, so that the sun's rays strike the glass at nearly a 90-degree angle in late winter and water and snow slide off the lids easily. Most frames are designed with lids sloping at an angle between 35 degrees and 45 degrees, which, for a 3-foot-deep model, translates to a frame that is 9 to 12 inches lower in front than in back. A slope of 35 degrees is most efficient for catching the late winter to early spring sun; a 55-degree slope catches more autumn sun, which is at a lower angle. It's possible to fine-tune your frame to catch more autumn sun by designing wedge-shaped inserts that change the angle of the glass.

The inside of the frame is usually painted white to increase the amount of light reflected onto the plants. You'll also need blocks or other props for holding the lids open to ventilate the frames.

Hot or Cold?

From a structural point of view, hotbeds and cold frames are identical, with the exception that hotbeds are supplied with some form of artificial heat. Traditionally, rotting manure served as the heat source, but today, electric heating cables are commonly used. Because hotbeds have a regular source of heat, they can be put into use earlier in the season than most cold frames and provide ideal conditions for starting most types of seeds. Also, they can be easily converted to cold frames during times of the year when heating isn't necessary.

Permanent or Portable?

There are two basic types of frames: permanent structures or portable ones. Permanent models are built over a foundation, either dug in the ground or constructed on the surface. Above-ground models provide less frost protection than ones built over a dug foundation, but both provide more reliable protection from the cold than portable frames. Permanent frames are generally sturdier and last longer as well.

Portable frames, which are basically bottomless boxes with clear lids, can be used in much the same way as permanent frames, but are not as well insulated and are therefore subject to wider temperature fluctuations. They're most often used for hardening-off seedlings grown indoors in spring, either alone or in combination with permanent frames, to help handle the spring rush of plants being gotten ready for the garden. For gardeners with limited space, one advantage is that they can be collapsed and stored during times when they're not in use. In the vegetable garden, portable frames can be used to extend the season for spring or fall crops such as lettuce or spinach, or to keep frost away from late-ripening crops such as melons that need a few more weeks to mature in autumn. In areas with mild winters, portable frames can be used to grow winter crops of cold-tolerant vegetables. They can be erected over garden beds to protect plants that might not be quite winter-hardy and will provide adequate protection for many perennials and herbs. Use them to keep rain away from plants that dislike "wet feet" in winter. In summer, use portable frames to grow seedlings in a cool, shady part of the garden.

Site Selection

Although site selection is more crucial with permanent frames than portable ones, basic considerations apply to both types of frames. Cold frames are essentially passive solar collectors, and in order to get maximum benefit from the heat and light of the sun, they should face south (southeast or southwest exposures are next best). Ideally, the site should receive full sun from midmorning to midafternoon during the winter and early spring months. Hotbeds, despite their artificial source of heat, need a full-sun exposure as well.

The site should also be fairly level and well drained. Water accumulating around a cold frame will quickly rot and kill plants, as well as damage the foundation or base of the frame. For protection from winter winds, locate your frame with a building, fence, or hedge on the north side. Although frames built right against the foundation of a house will receive some escaping heat, leaving a foot or two between frame and foundation is a good idea. That way, you can easily get behind the frame to remove the sashes. Mount a hook on the wall behind the frame for holding the lids completely open.

For the sake of convenience, select a site near a water supply and somewhere that's easy to keep an eye on all year long. Deciduous trees overhead aren't necessarily a liability; they'll provide summer shade without blocking winter sun.

Materials

Use the best materials available, especially when constructing a permanent frame. For permanent frames, a concrete block foundation topped with a frame made of decay-resistant wood painted with a nontoxic wood preservative such as Cuprinol is ideal. For portable frames, you'll need to weigh both the

Continued →

life expectancy of the materials and their weight. Try to use rustproof hardware in construction whenever possible.

Glass window sash are most often used to cover frames, but fiberglass, Plexiglas, or heavyweight polyethylene can be substituted. A layer of polyethylene on the underside of the glass sash can be added for extra insulation.

Proper drainage is essential, especially for permanent frames, so plan on placing at least a 6-inch layer of coarse gravel in the bottom of the frame for drainage. Incorporating drain tile into the design of the foundation is a good idea on sites where drainage may be a problem. On top of the gravel, you can add 8 inches of builder's sand in which to sink pots and other containers.

Dimensions

The size of most frames is determined by the sizes of standard window sash, and often by the sizes of salvaged or surplus windows on hand. Although 3-by-6-foot sash is traditional, smaller windows such as 2-by-4-foot or 3-by-3-foot are much lighter and easier to handle. With large sash, or in areas of heavy snowfall, plan on rafters or other supports between each sash. A bed width of about 3 feet is convenient, so you can reach the back of the frame without having to step into it. Frames can be of any length, for more than one sash can be mounted side by side. (Separate hotbeds and cold frames can also be constructed side-by-side, by dividing the foundation between heated and unheated sections and mounting a sash over each section.) Hinges at the back of the frame and handles in the front make for easy opening. Be sure the lids extend slightly beyond the frame in front so that water drains off instead of into it.

The depth of the foundation and/or the height of the frame you decide on will depend on the plants your frame is designed to accommodate. When determining how much space you'll need, take into account the maximum height (including pots) of the plants you'll be growing, as well as the distance from the top of the layer of gravel added for drainage to the lowest part of the sash. A foundation dug to a depth of 2½ feet coupled with a cement block foundation that extends 8 inches above the ground will accommodate a wide variety of plant sizes. (Keeping the wooden portion of the frame off the ground also will reduce rot.) A deeper frame will cut out some light, but will accommodate small trees or shrubs.

MANAGING YOUR FRAME

The first step toward learning to use your cold frame or hotbed effectively is to familiarize yourself with its own particular personality. A thermometer mounted inside the frame where the sun will not shine directly on it will provide useful information about temperature. Check it frequently under various weather conditions and at different times of day. A record of temperature extremes, prevailing weather, and other environmental conditions both inside and outside the frame will help you identify trends and establish schedules for your frame. For most effective light transmission, wipe away condensation each time you check the frame. Also, clean the glazing, inside and out, with clear water when it becomes dusty or splashed with mud.

Temperature Control

Controlling the temperature inside a cold frame or hotbed is of vital importance because on a bright, sunny day, whatever the outdoor temperature, inside temperature in an unvented, insulated frame can rise to 100°F or more, quickly killing plants inside. Until recently, the only way to regulate the temperature was manually—by watching it closely, propping the lid open when the temperature began to rise, and lowering the lid when it began to fall. Fortunately for today's two-career families, automatic vent openers are now available.

To control the temperature manually, you'll need to follow daily weather forecasts and use your own knowledge of local weather patterns to judge how much air to give your plants. The object is to keep the plants from cooking without chilling them. For example, if the morning sun is bright and the sky cloudless, promising continued sun, raise the lid and prop it open 4 to 6 inches. If it's windy or a bit cloudy, open the frame only slightly, so cold winds don't chill the plants. By midafternoon in late fall or early spring, or as early as noon in the dead of winter, check the thermometer inside the frame, and close the lid to conserve daytime heat. Temperature should be checked at least twice daily until you are well acquainted with your frame's personality.

If you're away from home during the day and unable to check the frame, a solar-powered automatic opener will do the opening and closing job for you. There are models with preset temperatures and ones that will allow you to select the temperature yourself. These are available through most general mail-order nursery catalogs and from local garden centers. They'll generally lift sashes up to a specified weight limit, but must be disconnected before the sashes can be opened completely. It is still a good idea to check the frame regularly, however, for vent openers will not perform the other essential chores of checking for signs of disease or insect problems.

In unusually cold weather, or if you have an uninsulated, aboveground frame, you can bank leaves, bales of hay, or soil around the frame. Be aware that this may attract unwanted rodents. Bricks or plastic gallon jugs filled with water can be stacked against the north wall to serve as passive solar collectors. You can enhance the heat absorption of either with a coat of black paint. Both will absorb heat during the day and release it slowly at night.

Containers

Although plants can be grown in a soil mixture placed directly on the layer of gravel in the bottom of the frame, using containers has several advantages. Plants grown in pots, seed flats, or other containers can be easily added, moved about,

or removed without disturbing the frame's other inhabitants. Soil mixes can be tailor-made to suit individual plants, as can watering and fertilizing schedules, so the frame can be used for plants with a variety of requirements. Using individual pots also helps control diseases, which can spread quickly in both cold frames and hotbeds. Pots can be set on the layer of gravel at the bottom of the frame, or sunk to the rim in a 4- to 6-inch layer of sand on top of the gravel.

Watering

Until you become familiar with the conditions that prevail in your cold frame or hotbed, you'll need to check plants frequently to be sure they have enough water. This is especially important in warm weather when plants are actively growing. Check the moisture of the soil between 1 inch and ½ inch deep; for most plants, it should remain moist, but not soggy, at all times. Water whenever plants look droopy, but avoid watering on cold, cloudy days. To discourage fungal diseases, water early in the day so plants and surface soil can dry out before nightfall. Use water of approximately the same temperature as the medium in which the plants are growing, because cold water can shock plants and slow their growth. If you're using your frame to store dormant plants over winter, water well before the onset of cold temperatures, and then check every few weeks through the winter. You can tailor a miniature drip system to the size of your cold frame if it's used principally for starting seedlings in spring and summer.

Pests and Diseases

During your regular visits to your frame, carefully check for evidence of disease or insect infestation. In mild climates or during mild seasons, insects, slugs, or other pests will thrive in a cold frame or hotbed if left uncontrolled. Check each pot carefully before placing it in the frame to look for hitchhiking slugs or sowbugs. The moist conditions inside a frame also are ideal for plant diseases, and the warmer the temperatures (up to a point), the greater the danger of diseases. Generous spacing and proper ventilation can help avoid disease problems. Remove and discard infested, diseased, or sick-looking leaves and plants as soon as you spot them, because problems will spread very rapidly. If serious problems develop, remove all the plants and take steps to sterilize the inside of the frame. Pour boiling water into the gravel and/or sand at the bottom of the frame, or leave the glass lids in place and tightly closed during the summer to allow heat to build up inside the frame. If you've chosen to grow plants directly in soil in the bottom of your frame, it can be treated by either method, but it is also a good idea to dig it out completely every two or three years and replace it with fresh soil.

Caring for Your Frame

Although maintenance tasks are minimal, they are essential because the moist, warm environment inside a cold frame or hotbed makes it subject to rot and rapid deterioration. Whenever paint starts flaking, repaint as soon as the frame is free of plants. Allow a newly painted frame to air for several weeks before putting it back into use, because fumes from the paint may harm plants. Recaulk as necessary to maintain airtight conditions. Watch for signs of rusted hardware and nails. Replace caulking and check regularly for places where air could leak into the frames. Keep the glass and inside of the frame clean to increase the amount of light available to plants.

YEAR-ROUND USES

How you use your frame will depend upon not only what types of gardening you enjoy, but also where you live, what exposure you have available, and what type of frame(s) you select. Experiment to discover the best way to use your cold frame and/or hotbed as well as the optimum annual schedule for your area. Keep in mind that cold frames and hotbeds can be used in much the same way, but as a general rule, you can start the season earlier or extend it longer with a hotbed. You can convert your hotbed to a cold frame during the summer or for applications where heat isn't necessary.

Spring

Spring (or late winter for southern gardeners) is the busiest season in both cold frames and hotbeds, for that is the time of year most gardeners are getting ready for the rush of spring planting.

To harden-off seedlings started indoors before transplanting them to the garden, move them to a cold frame a week or two before they're scheduled for transplanting. Gradually open the vent for longer periods each day. Shade the seedlings at first—using wood lath, burlap, or a mixture of clay soil and water painted on the glass—to keep them from burning. Expose them gradually to full sun.

Cold frames are also good places to germinate seeds in early spring—especially those of cold-tolerant vegetables, perennials, and annuals. Sow seed in flats or pots placed directly in the frame about two months before the last spring frost date. For an even earlier start, sow seeds in a hotbed or indoors and move seedlings to a cold frame after their first transplanting. This not only frees up space for more tender plants indoors, it also eliminates the succulent, rank growth that seedlings grown at warm temperatures can produce. Later in the season, more tender annuals can be sown in the frames.

In the North, where the growing season is short, cold frames can be used to start plants that require long growing seasons (such as melons) that otherwise might fail to mature. They can also be used to grow very early spring crops of lettuce or spinach.

Summer

During the summer, the glass sash that cover a cold frame are generally stored away and replaced with screens or other

Continued ➔

coverings to keep out leaves and other debris. Frames shaded with a grid of wood lath over the screens can be used in late summer to start fall crops of heat-sensitive vegetables such as lettuce. Raise seedlings in pots or flats, then transplant to the garden when temperatures begin to cool. Summer-sown perennials or biennials such as foxglove (*Digitalis* spp.) or Canterbury-bells (*Campanula medium*) can be germinated in pots or flats, held over their first winter under the protected conditions offered by a cold frame, and moved to the garden the following year. Cold frames can also be used for rooting cuttings taken any time of the year.

Fall and Winter

As the days shorten and temperatures drop, glass sash are replaced and cold frames become an ideal place to sow seed of hardy annuals, perennials, wildflowers, shrubs, or trees. With seed sown in fall or early winter, the object is not to germinate the seed immediately, but to provide a cold treatment so that it will germinate promptly the following spring. Sow seed just before the ground freezes so it won't germinate before winter arrives.

Cold frames are also ideal for growing a fall crop of lettuce or spinach. Fall is also the time to move perennials, herbs, and container-grown plants that might not be quite hardy outdoors undercover for winter protection. Semihardy herbs such as parsley can be dug from your garden and guarded in a cold frame over winter. Use your cold frame for forcing pots of hardy spring bulbs.

Making and Using a Hotbed

Hotbeds are designed and used much like cold frames, but as their name suggests, they are supplied with a regular source of heat.

Traditionally, hotbeds were heated by a layer of fresh, fermenting manure spread in the bottom of a frame. Temperatures remained high for several weeks and then slowly dropped off. To reheat the bed, the old manure had to be dug out and replaced with a fresh mixture.

Today, most gardeners use hotbeds heated with specially designed electric cables—the high-tech alternative to the manure hotbed—because of the labor involved in a manure hotbed and because fresh manure is not always easy to find and haul. Any cold frame built over a dug foundation can be made into a hotbed by adding an electric heating cable, assuming a source of electricity is available. Portable models can be used as hotbeds, although they don't conserve heat as well as permanent frames do, but a pit at least 1 foot deep needs to be dug underneath the frame to contain the heating cable.

To convert a cold frame to a hotbed, spread a 2-inch layer of vermiculite for insulation on top of the layer of gravel at the bottom of the pit. Spread the cable on the vermiculite, using long loops to provide an even source of heat. Don't allow the heating cable wires to cross, and keep loops at least 8 inches apart and 3 inches away from the edges of the frame. Cover the heating cable with an inch of sand, followed by a layer of screen or hardware cloth to keep it from being dug up accidentally. Cover the heating cable with 4 to 6 inches of coarse builder's sand in which to sink pots. A 30-foot heating cable is sufficient to heat a 3-by-6-foot frame. Cables with built-in thermostats provide an extra measure of control. Tender plants prefer a medium temperature of between 60° and 75°F; temperatures between 50° and 60°F are sufficient for more cold-tolerant annuals and perennials. Disconnect the cable during seasons when heat isn't necessary, and convert back to a conventional cold frame. To make a manure-fueled hotbed, start with a pit 2 to 2½ feet or more deep and slightly larger than the bed that sits on top of it. Mix the manure with straw, and spread it in a 6- to 8-inch layer at the bottom of the frame. Water it lightly and cover it with soil or sand. Within a few days, the fermenting mixture will raise the temperature in the frame to 70° or 80°F. The temperature will remain high for several weeks, then drop off. To reheat, remove the old manure and straw and replace with a fresh mixture.

Gardeners who heat their homes (or a greenhouse) with steam or hot water have another option for heating a hotbed, provided it is located next to the house. A pipe system connected to the heating system in the house can be used to heat a hotbed. A single loop of pipe can be run around the inside perimeter of the bed on the surface of the soil, about 2 inches from the outside wall, or several lengths of pipe can be buried under the soil, about 16 to 18 inches apart and 8 to 10 inches from the outside wall.

Using Cloches and Row Covers

Stretching the growing season is an age-old goal of gardeners. The quest for the earliest lettuce or the first ripe tomato is universal. Like portable cold frames, cloches and row covers are designed to help extend the season by protecting plants right in the garden. You can use them to get a head start on spring by protecting germinating seedlings or young transplants from spring frost. They're also perfect for protecting maturing crops from autumn cold snaps.

Forms of these portable coverings, sometimes called season extenders, have been used for centuries to protect individual plants or shelter entire rows. In fact, nearly every gardener has devised some sort of temporary season extender when faced with an unusually late spring frost that threatens newly transplanted tomatoes or tender annuals. Everything from cardboard boxes to blankets to paper bags has been pressed into service. Today, season extenders are made from new types of plastic and other materials, which make them versatile, easy-to-use, and inexpensive. The terms portable cold frames and cloches are often used interchangeably when referring to such structures as the double-glass frames used to cover entire rows, for example. Here, however, we've distinguished between the two by calling the heavier, mostly glass-glazed structures portable cold frames.

The light, plastic- or other fabric-covered season extenders are called cloches or row covers.

The basic principle of cloches and row covers relies on the greenhouse effect. Short ultraviolet rays from the sun pass through the glass and warm the soil and the air inside. The soil collects and stores the heat, then releases it slowly. This creates a greenhouselike atmosphere and provides frost protection to plants. The warmer conditions under a cloche or row cover increase the growth rate.

By using these coverings, you can plant seed or transplants—especially of cool-weather-loving crops such as broccoli, peas, cabbage, cauliflower, lettuce, spinach, and radishes—earlier than normal. You'll need to consider how much frost protection the type you're using provides, however, especially for cold-sensitive plants like tomatoes. Generally, row covers only provide protection from 1° or 2°F of frost.

Cloches and row covers can also be used to extend your fall growing season. They can provide warmth and frost protection to melons and other crops that need a long growing season to ripen. Or, use them to protect a late sowing of such cool weather crops as lettuce or spinach.

In spring or fall, cloches and row covers can easily be moved from crop to crop. In spring, for example, when cool-loving vegetables are well established, use them to protect tomatoes, melons, or other warm-weather vegetables.

CLOCHES

The first cloches (*cloche* means bells in French) were glass bell jars. They were heavy, unventilated, and breakable, but nevertheless useful in extending the growing season. Today, there are many different types of cloches, ranging from those for individual plants to those for rows. Glass models are still occasionally available, but most used today are made of plastic or fiberglass. You can make your own or buy them ready-made. You'll have to determine for yourself if the time and expense you put into buying or building cloches is worthwhile.

No matter what kind of cloche you buy or make, there are a few basic guidelines to keep in mind. Like cold frames, cloches must be ventilated to prevent overheating, so you need to pay careful attention to the temperature inside the cloche. A thermometer is helpful for keeping track of how much the area under the covers warms up. In sunny weather, you'll need to partially vent or completely remove the covers during the day. Be aware that small cloches placed over individual plants will heat up fastest. Since cloches remain in place for several weeks, be sure plants have enough elbowroom to grow. Finally, make sure the cloches are securely anchored so they don't blow away.

Homemade Cloches

The possibilities for homemade cloches for individual plants are endless. You can use plastic milk jugs with the bottoms cut out. Remove the cap to prevent overheating. To make sure they do not blow away, dig the edges of the bottoms into the soil or weight them down by tying stones or fishing weights to the jug handles. You can use wood, fiberglass, wire, or any other material to construct round, conical, or square frames to protect individual plants or entire beds. Cover them with plastic or fiberglass. Tomato cages can also be covered with plastic—even just on the sides, with the top open—to provide wind protection and a warm atmosphere. Whatever you do, be sure to anchor everything so it won't blow away, and make sure you have ventilation so the plants don't overheat.

You can use wire fencing to form a Quonset-hut-type tunnel to shelter an entire row and cover it with 4-mil polyethylene. Fiberglass also can be made into a similar structure. Take a panel of translucent corrugated fiberglass and bend it into a semicircle. Wrap stiff wire (#8 or #9 gauge) around it, making a wicket that will secure the fiberglass, and stake the wire into the ground. If you make these in 4-foot segments, you can handle them easily.

If you have glass sash left over from a house renovation project, consider making a portable cold frame/glass cloche. Glass frames provide more frost protection than plastic ones, but they're heavier and harder to move around.

With any cloche that covers an entire row, be sure to close up each end or the row will become a mini wind tunnel. On warm days, you can open the ends to provide ventilation. Make sure plant leaves don't touch the sides of glass cloches in cold weather.

Commercial Cloches

There is a wide variety of commercial cloches available, both for covering individual plants or for sheltering entire rows. Commercial coverings for individual plants include cone-shaped "hats," mini hothouses, and a plastic cylinder that uses water for insulation called Wall O' Water. Kits for plastic tunnel cloches are sold at most garden centers and garden supply mail-order companies. They are easy to erect. Generally you need only to set wire hoops 6 or 8 inches into the ground at about 4-foot intervals along the row. Then dig trenches 6 inches deep along the edges of the row. Lay the plastic over the wires with its edges in the trenches and weigh them down with dirt or stones. Close the ends of the tunnel by tying them to stakes. Make uniform slits in the plastic for ventilation. (You can water plants without removing plastic if you have slits.)

ROW COVERS

Row covers are made of light permeable material, usually polypropylene or polyester, loosely laid right on top of plants or supported above them with wire hoops. They are anchored in place with stones or soil to keep them from blowing away. Sometimes called "floating" row covers because they are so light, polypropylene or polyester covers block out about 20 percent of the sun's rays, but are permeable and let in rain and air. They

Continued →

can be used to extend your season and protect your crops from frost damage, but they provide only a few degrees of protection from frost. On the plus side, they "breathe," thus making overheating during the day somewhat less of a problem. (In hot, sunny weather, temperatures can rise 10° to 30°F underneath row covers, so you still need to watch for overheating.)

Row covers also can be used to protect plants from insects and birds, because they don't need to be slitted or vented unless the weather is warm. If you know from experience that an insect will start munching on your crops at a certain time, you can anticipate this and protect your plants with a row cover. Unfortunately, insects in the soil may also benefit from the nice growing environment under the cover. Crop rotation will help prevent them from attacking the same crop each year.

There are several brands of row covers made from different materials. Polyester row covers, popularly known by the brand name Reemay, were the first to be released. They are very light and permeable, but break down rather rapidly when exposed to ultraviolet light, so much so that they can only be used for one season. They are also abrasive and can damage tender plant parts. Polypropylene covers, such as Agronet, Agryl P17, and Kimberly Farms, are less abrasive to plants and last longer—from two to three seasons. All are delicate and can be ripped by the wind or torn by growing plants. Generally, they're used for about a month in spring and again in fall, then cleaned and stored until the following season.

Fern Marshall Bradley

Every organic gardener should be a mulch expert. Mulching is one of the best ways to fight weeds. It also improves the garden's appearance, reduces water loss, and protects soil from compaction and erosion. If you use an organic mulch, the icing on the cake is improved soil quality as the mulch decays.

Clear the Way with Cardboard

You can get a new site ready for planting without weeding the area and even without digging, says Susan Sides, a North Carolina garden writer. The key: cardboard.

Instead of hacking weeds away from a site and then digging or tilling, just put a layer of cardboard over the ground. Sides gets cardboard from her local recycling center. She says that chicken-feed or dog-food bags also fill the bill, as will newspaper. Once you've covered the ground, wet the cardboard and spread a layer of organic mulch, such as grass clippings, on top. Allow at least two weeks for the grass and weeds underneath to decompose.

"I learned this trick from a woman who runs a plant nursery in Florida," says Sides. "Down there, grass and weeds are especially tough, and soil dries out quickly. But this technique takes care of both problems."

When you're ready to plant, just push a trowel through the mulch and cardboard into the moist soil, and set your seedlings in place. "After that, you can throw more mulch on top whenever you want or need to," says Sides. "The cardboard breaks down pretty quickly; worms seem to love the stuff. It only takes a few months to a year, depending on your climate, for the cardboard to decompose completely. But because weeds haven't had any chance to grow during that time, the area stays pretty much weed-free as long as you keep adding mulch."

Sour Mulch: Beautiful, But Deadly

Wood chips and shredded bark make attractive mulch, but in some cases they can spell death to your plants. Improperly stored organic mulch materials can decompose anaerobically—without oxygen—and produce chemicals including methane and ammonia gas that are toxic to plants. "Soured" mulch also tends to lower soil pH, making nutrients less available. Symptoms of mulch toxicity include yellowing of leaf margins, loss of leaves, and even dead plants.

The key to avoiding the problem, says Donald Rakow, Ph.D., an associate professor of landscape horticulture at Cornell University, is to make sure mulch gets plenty of fresh air. Mulch stored in bins or in overly large piles can't "breathe." "Mulch piles should be turned and mixed at least once a month," says Dr. Rakow. "And the pile shouldn't be higher than 8 feet or wider than 10 to 12 feet." It's also important not to let moisture accumulate in the pile.

Keep Dr. Rakow's mulch-care principles in mind not only when storing the materials but also when shopping for them at garden centers. Ask yourself these questions: If it's sold in bulk, is the mulch kept in properly managed piles? And if it comes in bags, are those bags intact, or has rainwater seeped in through rips and tears?

One sure sign of soured mulch is its odor. According to Dr. Rakow, anaerobic decomposition results in mulch that has a pungent, astringent smell, instead of its usual pleasant, woodsy aroma.

It's also important, says Dr. Rakow, to limit the layer of mulch around landscape plants to just 3 or 4 inches. "A very

deep mulch increases the chance of anaerobic decomposition," says Dr. Rakow. Instead of routinely adding several inches of new mulch around shrubs and flowers each year, fluff up the material that's already there. And when you do need to add a top layer of fresh mulch, limit it to just an inch or so.

Chunky Mulch for Healthier Soil

Choose mulches for permanent plantings with extra care. "The best mulch to use is a large-chunk bark," says Jim Borland, a Colorado garden writer and consultant. According to Borland, large-chunk bark is the optimum size for allowing air to reach the soil, while still retaining soil moisture. Air is essential for soil life, such as earthworms, soil bacteria, and many other too-small-to-see creatures. Plant roots, too, need oxygen.

A mulch with small pieces can prevent oxygen from moving down into the soil. And a mulch with much larger pieces allows for air spaces that are too big, drying out the soil faster. The thickness of each particle and the way they lay together in a chunk-size mulch provides optimum air spaces. A large-chunk pine bark mulch, says Borland, is just the right size for healthy soil, and it lasts at least two or three years.

Make an Island with Mulch

One great way to boost tree health and reduce yard maintenance in one step is to link groups of trees and shrubs with a groundcover of organic mulch. "A groundcover of mulch is ideal for trees because it doesn't disturb roots and doesn't compete for nutrients and water in the soil as planted ground covers would," says Jack Siebenthaler, a registered landscape architect from Florida. The idea is to use spreads of mulch to create an "island" within a landscape, linking trees together visually the same way you would if you were planting the area with a groundcover. This is a popular solution on new building lots with a small grove of trees that were carved from existing woods.

The mulch also means no mowing or plant maintenance—just occasional weed control and remulching once or twice yearly. Bark is a handsome mulching material available throughout most of the country, while pine straw and other neat mulches are regional options. A layer about 3 inches deep is adequate for most sites.

The Lawn and Short of Grass Mulch

Generally, you should leave your grass clippings where they lie—they're an excellent source of nitrogen for your lawn, and (contrary to long-held belief) they don't contribute to excessive thatch buildup.

On the other hand, you may want to use some of those nutrient-rich clippings to mulch your vegetables and ornamentals. Eileen Weinsteiger, the garden project manager at the Rodale Institute Research Center in Pennsylvania, does just that to keep weeds down in the Research Center's growing beds. What's more, she uses a living grass mulch between the beds to smother weeds—and to provide a steady supply of clippings.

"Our growing beds are 5 x 12 feet," says Weinsteiger, "and they're separated by 2-foot-wide pathways planted in ordinary turfgrass." Nutrient runoff from compost applied to the beds in the spring helps the grass pathways thrive.

The grass pathways need weekly mowing. After the soil has warmed, in late May or June, Weinsteiger applies 4 inches of fresh, green grass clippings to the beds every six weeks. The mulch heats up as it decomposes, so she's careful not to put it too close to seedlings. "I like the idea of using something that's generated in the garden to mulch the garden," says Weinsteiger, "and the grass does an excellent job of suppressing weeds."

Matthew Cheever, the owner of Evergreen, a landscape design and maintenance company in Wisconsin, recommends grass clippings as a weed-smothering mulch for ornamentals, too—but admits the material isn't especially attractive. His solution: Apply the clippings, then top them with a layer of decorative bark mulch.

Stone Mulch Annual Beds

Most gardeners find they never have enough organic mulch to go around—particularly after they've already generously mulched the perennial beds and vegetable patch. If you still want to put in some colorful annual flowers, but you're completely out of compost, leaves, pine straw, and wood chips, what do you do?

Use stones Pat Williams, a copublisher of *HortIdeas* newsletter from Kentucky, says, "By the time I get around to planting annuals, there's never enough 'real' mulch left, so I use flat stones instead. I just arrange them around the plants, and lay them close together so there are only small cracks between them. The stones keep most of the weeds out and stabilize the soil temperature, too. As the flowers grow, they more or less cover up the mulch, and the stone that's still visible blends nicely with the foliage and blossoms. And when I go to plant annuals the following year, I just lift the stones up and dig."

Mulching the Low-Maintenance Way

Barbara W. Ellis, Joan Benjamin, and Deborah L. Martin

Mulch is something of a miracle—it's a one-step way to get rid of some of the most tiresome garden chores and make time for the fun stuff. But it doesn't stop there; mulch can provide you with other benefits as well.

Organic mulches, for example, add humus to your soil as they decompose and encourage beneficial organisms and worms to grow and work in your garden. Some mulches can actually repel pests, while other unconventional mulches can save your plants from winter winds and heaving.

Continued ➔

The materials you can round up around your home or buy locally will save you the most labor and expense. You won't have far to haul them and they're usually free (or really cheap). Take a look at everything mulch can do for you, then pick and use the materials that make your life easiest.

Haste Makes Waste with Tree and Shrub Mulching

Mulching trees and shrubs is a simple, once-a-year (or less) chore—if you take time to do it right the first time. If you get in a hurry and dump mulch around your plants any old way, you'll soon be back rearranging it to fix pest and weed problems. Here's a simple list of dos and don'ts to keep in mind.

1. **Don't heap it too high.** Deep mulch layers don't let air or water reach the soil easily, so roots suffer. Four inches of mulch is plenty for good weed control, so don't strain your back or budget applying deeper amounts.
2. **Don't touch plant parts.** Keep mulch 4 inches away from tree bark and plant stems or you'll create a moist hiding place for insects and bark-eating mice and voles.
3. **Do stretch mulch to the drip line.** You'll protect your trees and shrubs best with wide mulch rings that keep lawn grass, mowers, and weeds far away from trunks and stems.

What Can Mulch Do for You?

Mulch may look pretty passive lying there in your garden, but it's constantly working to save you time and effort. Mulch offers innumerable benefits and can save you hours of time spent doing unpleasant garden chores.

Organic mulches are the most useful. They're made from once-living materials like bark, leaves, or grass clippings that eventually decompose and improve the soil. Inorganic or man-made mulches are long-lasting but don't add humus or nutrients to your garden.

Whichever material you choose, mulching will give you more benefits than any other single gardening chore. Here's what you can expect.

Low-work weed control. To control a minor weed problem, pull or hoe out existing weeds and bring on the mulch—at least a 4-inch-deep layer of organic matter. You won't have to weed again unless seeds blow in and root. If you're coping with tough perennial weeds, see "Fight the Toughest Weeds with Ease with 'Super Mulch'" on page 210.

Fewer watering chores. A 3- to 4-inch layer of organic mulch throughout your garden can reduce the amount of water lost to evaporation by at least one-half. That means more water for your plants and less watering for you. Mulch also keeps roots cool so plants need less water.

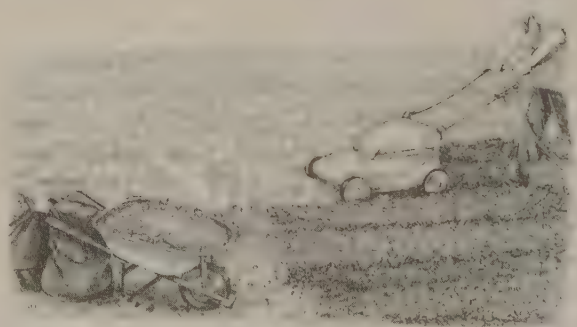
Simple disease prevention. Rain and water droplets from sprinklers splash soil and the spores that cause fungal diseases

Top 10 Reasons to Use Organic Mulch in Your Garden

Vicki Mattern

By applying an organic mulch to your vegetable garden or flowerbed, you'll save hours of time each year. You should spread a thin layer of wood chips, grass clippings, shredded bark, sawdust, or pine needles on your garden for the following reasons:

1. Mulch prevents most weed seeds from germinating and even makes it easier to pull those that do pop through.
2. It will hold down dirt and keep it from splashing on flowers and vegetables.
3. It will allow you to water less often because mulch keeps the soil cool and moist.
4. It decomposes slowly, releasing nutrients into the soil throughout the process.
5. Mulch encourages beneficial earthworm activity by improving the soil tilth and nutrient content.
6. It will help prevent alternate freezing and thawing of the soil in winter, which can heave plants out of the soil.
7. Mulching helps to prevent diseases by keeping water and soil from splashing onto plant leaves.
8. Compost mulches can help prevent soil erosion. Because soil that contains a lot of humus (finished compost) holds together better, rainwater permeates the soil, moving easily through the spaces between granules rather than running off the soil surface.
9. Most of the ingredients for organic mulches can already be found in your home or backyard.
10. Many types of mulch are attractive additions to the garden site.



Use your lawnmower on the mulching setting to chop leaves. Then use the bagging attachment to collect them. Store the leaves in plastic bags or use them right away as mulch.

Choose Your Mulch

The following are some of the best mulches to consider for your garden. Some are suitable for vegetables; others are best used in ornamental plantings. We've distinguished between biodegradable ones, which will add organic matter to the soil, and synthetic mulches like black plastic, which won't.

Material	Primary Benefits	When to Apply	How to Apply
Biodegradable Mulches			
Chopped leaves	Suppresses weeds well. Modulates soil temperature.	At planting time and as needed throughout the season.	Apply in 3-inch layers; best if chopped and composted, then allowed to sit outside for several months.
Compost	Builds tilth. Suppresses weeds. Fertilizes. Warms soil.	At planting time and as needed throughout the season.	Spread 1 or more inches as a topdressing around plants or along rows.
Grass clippings	Builds tilth. Modulates soil temperature.	At planting time and as needed throughout the season.	Apply a 1-4-inch layer around plantings. Make sure clippings are herbicide-free. May burn tender seedlings if placed too close.
Horticultural paper	Permeable to water and air. May warm soil.	At planting time.	Comes in various types, such as black or with peat. Some types may crust in wet climates. Lay down in sections and anchor with soil or stones.
Newspaper	Suppresses weeds well. Retains moisture.	At planting time.	Lay down whole sections of the paper and anchor with soil or stones, or shred paper and apply 4-6-inch layers. Good to use under more attractive mulches. Do not use colored newspaper; some inks can be toxic.
Pine needles	Builds tilth. Suppresses weeds well. Some control of fungal diseases.	At planting time and as needed throughout the season.	Apply in 2-4-inch layers. Needles tend to acidify soil; don't use around non-acid-loving plants.
Shredded bark, wood chips	Retains moisture. Suppresses weeds well.	As needed around established plantings or at planting time.	Apply a 2-4-inch layer around established plantings of trees or perennials. Can tie up nitrogen in soil, so not for vegetable garden. Composted bark or wood chips are best.
Straw	Builds tilth. Suppresses weeds well. Cools soil.	At planting time and as needed throughout the season.	Lay down 8-inch layers of material around but not touching plants. Mulch heavily between rows to keep weeds at bay. May tie up nitrogen in soil; oat straw best.
Inorganic Mulches			
Aluminized paper	Suppresses weeds well. Modulates soil temperature; cools soil but warms air. May repel aphids and squash borer moths.	At planting time.	Lay down single sheets and cut slits to plant through. Make sure mulch extends at least 6 inches out from plants.
Black plastic	Warms soil. Suppresses weeds well.	At or before planting time.	Lay down single sheets of 4-6-mil plastic over whole planting area or between rows of plants. Anchor with soil or stones. Cut slits to plant through.
Clear plastic	Warms soil.	At or before planting time.	Lay down single sheets of plastic. Anchor with soil or stones. Cut slits to plant through. Weeds will grow beneath plastic.
Geotextile mulch	Suppresses weeds well. Permeable to water and air.	At or before planting time.	Difficult to cut. Lay down in single sheets and anchor with soil or stones. Cut slits to plant through.
Pebbles and stones	Suppresses weeds well. Modulates soil temperature. Retains moisture.	At planting time and as needed.	Put down pebbles (such as marble mulching chips, shrubs, and rock chips) in 1-inch layers. Good for gardens.

Continued

onto plant leaves. A cushion of mulch will keep the fungal spores and the soil off your plants.

One-step soil protection. A layer of organic mulch protects the soil from beating raindrops, which prevents crusting and soil compaction. It will also stop heavy rains from washing away valuable topsoil and plants. Mulch can also protect soil from foot traffic.

No-dig soil improvement. When organic mulches break down, they add nutrients to the soil. This gives plants a boost and saves you from fertilizing chores.

Cleaner produce. Surround vegetables and berries with mulch to keep them—and you—free of mud. You'll be able to harvest crops without lots of cleaning fuss, even in wet weather.

Protection from mower blight. A ring of mulch around the base of trees or shrubs keeps you from getting too close with your lawn mower—no more tedious trimming or bark wounds.

Safety from winter's wrath. Plants can heave out of the ground and die when temperatures alternate between freezing and thawing. Mulching after the ground freezes with loose straw or chopped leaves moderates soil temperatures and stops harmful expanding and contracting.

Fight the Toughest Weeds with Ease with "Super Mulch"

When tough perennial weeds like thistles and burdock take over your garden, fight back with "super mulch." First, mow or break off tall weeds, then cover the area with a layer of cardboard (boxes that are broken down and cut open work well) or a 1-inch layer of newspaper. Place 8 to 10 inches of spoiled hay or straw over the top. Apply the mulch in summer or fall and you'll smother the weeds in time for planting the following year. The mulch will break down into humus after a couple of seasons and make a fine planting bed.

If you're battling a particularly crafty weed like poison ivy or an invasive plant like spreading bamboo, leave the area covered for one or two years. Keep 8 to 10 inches of mulch over the area at all times, adding new mulch as the older material breaks down. Don't let the weeds get any light, and they'll give up when their food stores run out.

Mulch and Grow Better Soil

Mulch and compost can turn your poor soil into fertile ground while you grow flowers and vegetables. Follow the simple steps below in late spring, and you'll be able to plant immediately, even on clay or sandy soil.

1. Cut down any weeds or grass in your garden area with a mower and leave the clippings where they fall.
2. Cover the site with a layer of newspaper, 4 or 5 sheets deep.
3. Place 8 to 10 inches of spoiled hay or straw over the paper.
4. Top the hay with 2 inches of compost.
5. Dig some earthworms from a good garden spot and place 5 or 10 of them in 3 or 4 spots under the mulch.
6. Plant seeds of strongly rooted annual flowers or vegetables in the compost and you'll be picking flowers or harvesting crops by summer. Meanwhile, the roots and worms will break up and improve the soil texture, and the mulch and compost will break down and improve your soil's health. Try cleome, cosmos, sunflowers, amaranth, beans, and grains for the best results the first year.

Annual Flowers Make the Mulch

Does your newly planted perennial garden have more bare spots than plants? Fill in the blanks with quick-spreading annual flowers. They'll keep your planting weed-free until slower-growing perennials fill in.

Trailing annuals like sweet alyssum and Madagascar periwinkle (*Catharanthus roseus*) shade out weed seedlings before they can get a foothold. Even annuals that grow upright can lend a helping hand if you space them close enough so that they touch each other when they're mature.

Buy inexpensive flats of impatiens to cover bare spots in shade gardens; use French marigolds, melampodium (*Melampodium paludosum*), or narrowleaf zinnias (*Zinnia angustifolia*) as fillers in sunny areas.

Grow Your Own Mulch

Are you short on mulch materials or tired of replacing mulches every year? Instead of hauling more organic matter out to your garden, grow a living mulch. Live plants can be as effective as compost or hay at conserving moisture and reducing weeds. Living mulches are particularly good at preventing soil erosion too: They don't just protect the ground from heavy rains, they hold it in place with their roots. For tips on using plants as mulch in the flower garden, see "Annual Flowers Make the Mulch" on page 211 and "Plant Once, Mulch Forever with Permanent Perennials." For vegetable gardens, read on.

Crowd out weeds with vegetables. Plant beans, cabbage-family crops, salad greens, and peas in wide rows spaced close enough so leaves touch when plants are grown. The dense growth will shade the soil so moisture doesn't evaporate. Cover bare areas so weeds can't get a toehold.

Fill in open areas with cover crops. To protect your soil over winter with very little effort, plug the bare spots in your garden with cover crops in late summer.

To plant cover crops on this schedule, as soon as you're done harvesting vegetables, cut off and compost the tops of plants. Broadcast oat, purple vetch, or hairy vetch seeds over the entire garden area for a quick protective blanket. They'll sprout, grow through the fall, and get killed back in winter.

In spring, plant right through the cover crops; they make a good mulch even when they're dead. In warm areas where cover

crops survive winter temperatures, till them into the soil before planting.

Plant Once, Mulch Forever with Permanent Perennials

If you've got bare or weedy patches around trees or shrubs, plant groundcovers or other spreading perennials. They're the easiest mulch of all since they don't need refurbishing each year. They'll shade the soil, keep out weeds, and need almost no maintenance once established.

Plant daylilies, ajuga, lily-turf, and English ivy in sun or shade. For shady spots, try hostas, epimediums, lilies-of-the-valley, pachysandra, or sweet woodruff.

Weird Mulches That Work

Lots of great but unusual mulch materials are hidden away waiting for you in your house, yard, and community. See if you're overlooking any of these handy resources.

Carpet. If you just tore out some cotton or wool carpeting, take it to the vegetable garden instead of the dump. Lay strips down between the rows for a long-lasting, weedproof mulch. Only use all-cotton or all-wool carpet since synthetic ones may contain harmful chemicals.

Christmas trees. Evergreen boughs make great plant covers in winter, and you can find a plentiful supply around the holidays. Let neighbors know you'd like their discards, or just collect them from the curb before sanitation workers do. Lop off the limbs and pile them around any perennial plants or shrubs that need protection from winter winds and freezing and thawing temperatures.

Herbs. Lots of gardeners think of herbs like mint and perilla as invasive pest plants. If you've got a large patch of rampant herbs, why fight it? Cut the plants back with hedge shears whenever you need some mulch and place the stems and leaves around your plants. You'll have fragrant weed control that helps repel insects. Other vigorous herbs for mulch include artemesia (*Artemisia* spp.), velvet sage (*Salvia leucantha*), and yarrow.

Snow. If you live in the North, don't overlook the benefits of snow mulch for winter protection. A heavy blanket of the white stuff keeps plants safe from drying winter winds and frigid temperatures. Nature often does all the work for you, but in years with little snow, you can help out by piling it up to cover perennial plants and shrubs.

Weeds. It's hard to believe, but weeds make good mulch if you're selective about what you use. For a low-maintenance living mulch, leave noninvasive weeds like chickweed in your garden if they spring up between vegetables or around trees and shrubs.

Dead weeds. You can use dead weeds as mulch, too, as long as they haven't gone to seed. Use them to anchor newspaper mulch instead of laying them on bare ground: Pulled weeds have been known to reroot in especially rainy seasons. Common weeds that make good mulches include lamb's-quarters, jewelweed, plantain, pigweed, and pokeweed. Avoid Bermuda grass, bindweed, crabgrass, nutsedge, purslane, or any other weed that can reproduce from root sections.

Wool. Nonwoven, feltlike mats made of wool and other natural fibers make a long-lasting (2 years or more) but biodegradable mulch. They're convenient (but expensive) to use since they come in squares or rolls that can be cut with scissors or a knife.

Water the soil first, then cut mats to fit, and place a single layer around but not touching plants. Or apply a layer with holes cut for plants. Anchor with soil, another mulch, wire pins, or rocks.

Look to Your Trees for Mulching Materials

Leaves make great mulch—especially if they're chopped and don't blow around like whole leaves. They're easy to come by: Just mow your yard in fall and collect the chopped leaves in a mower bag. If you don't have enough, collect bags of leaves from neighbors and put them in windrows at home to mow, too. Some municipalities offer free leaves, and you can also check with lawn-care companies and your local parks department.

Move Mulch with Ease

If you're adding 4 inches of mulch to a large vegetable garden, you're in for some work. You can choose lightweight mulches, but even they can be cumbersome if you have to move large quantities around. Try these tips for getting mulch to your garden and placing it around your plants with the least effort.

Bag it or blow it. Collect grass clippings and leaves with a lawn mower bag and you'll save time raking. Dump the mulch materials directly in your garden or in a compost pile that's in or beside your garden. If you don't have a bagging mower, dump leaves in windrows near your garden. Run your mower over the leaves to chop them, then mow in a single direction to blow the leaves into your garden or into a single row.

Get some wheels. A pickup truck or lawn tractor with a trailer makes it easy to move bulky materials like bales of straw and hay. If they aren't available, carts, wheelbarrows, and even little red wagons can save your back and make mulching easier. You can load mulch directly into these vehicles, push or pull them to your garden, then dump the materials exactly where you need them. To load up extra mulch and keep it from blowing around, fill large plastic garbage barrels, plastic bags, or washtubs, load them into a wheeled vehicle, and drop them off where they're needed.

Rob the laundry. If you don't have wheels, put plastic bags of mulch into a laundry basket. You can slide the basket over your lawn without risking a plastic bag break.

Try a tarp or stuff a sheet. It's easy to drag grass clippings or leaves to your garden if you throw them on a plastic tarp or old bedsheet.

Get double duty from mix-and-match mulches. When you're short on mulch or money, try a mixture of materials to cover

Continued →

your planting beds. For example, use a beautiful, decorative mulch like cocoa beans on top of an uglier, but inexpensive, mulch like grass clippings. Or sprinkle attractive shredded bark over newspaper or straw, or mix several kinds of mulch together, and top with a thin layer of decorative mulch. No one will know the difference but you and your pocketbook.

Fertilizing the Low-Maintenance Way

Barbara W. Ellis, Joan Benjamin, and Deborah L. Martin

Fertilizing is certainly not on the top-ten list of favorite gardening activities. The good news: If you've been managing your soil organically by adding compost and other organic amendments regularly, your plants probably won't need very much fertilizer. Soil that's rich in organic matter generally contains plenty of nutrients that are readily available to plants. Rich soil also is biologically active, so trillions of soil organisms are hard at work breaking down even more nutrients for plants all during the growing season.

In this section, you'll learn ways to make the most of fertilizers and also cut the time and effort you spend applying them. You'll also find an explanation of what soil pH means to your plants and how to manage it efficiently.

Just the Facts: What You Need to Know about Feeding Your Plants

Nitrogen, phosphorus, and potassium (N, P, and K) are the primary nutrients plants need to grow. In addition to these three macronutrients, plants also need smaller amounts of calcium, magnesium, and sulfur—the secondary nutrients. Plants also use trace elements, also called micronutrients, in minute amounts. Trace elements include boron, chlorine, copper, iron, manganese, molybdenum, and zinc.

The good news is healthy soil that's rich in organic matter generally contains enough of all of these nutrients to keep plants healthy and growing. Fertilizing becomes necessary either when there aren't enough nutrients in the soil or when nutrients are present but are in forms plants can't take up through their roots. (A pH imbalance, for instance, will cause nutrients to be unavailable.) Of course, gardeners also fertilize to boost plant performance—to produce a bigger crop of tomatoes, for example.

KNOW HOW FOOD WILL MAKE THEM GROW

Whatever plants you want to feed, it's helpful to know how nutrients will affect them. In general, nitrogen promotes growth of leaves and stems, phosphorus encourages production of flowers and fruits, and potassium boosts root growth. Although plants need all three of these nutrients to grow, the amount of each varies according to their stage of development.

Fertilizers with different amounts of most nutrients allow you to fine-tune your feeding program. For example, plants putting out new growth benefit from fertilizers with higher ratios of nitrogen relative to the other nutrients. Plants that are flowering and setting fruits do better with an increase in phosphorus. You can make sure your plants have everything they need by applying complete fertilizers—those containing all three major nutrients—with varying ratios of nitrogen, phosphorus, and potassium. You can mix your own fertilizers by combining single-nutrient fertilizers, but if your goal is reducing the time you spend fertilizing, buying complete commercial mixes is most efficient.

KEEP FEEDING SIMPLE

You could easily devote all your time to formulating the right combination of macronutrients, secondary nutrients, and trace elements to satisfy the needs of each and every plant you grow. Fortunately, this is as unnecessary as it is undesirable. Use the following information about the needs of certain plant groups to help you choose the best fertilizers to use.

Leafy crops, foliage plants, trees, and shrubs, grasses. A steady supply of nitrogen gives these plants what they need to build lush, green, healthy stems and foliage. Look for products that supply from two to four times as much nitrogen as they do phosphorus or potassium.

Fruits, flowers. Phosphorus enhances the floral display in ornamental plantings and improves blossom and fruit set in fruit-producing plants, including vegetable fruits such as tomatoes, beans, and squash. A complete fertilizer for these plants has twice as much phosphorus as it does nitrogen, with an equal or lesser amount of potassium.

Root crops. As mentioned above, potassium plays a critical role in healthy root growth, so it stands to reason that root crops such as carrots, beets, and potatoes would benefit from a fertilizer ratio that's twice as high in potassium as it is in nitrogen.

Vegetables. Since a vegetable garden contains a mix of crops—root, leafy, and fruit-bearing—it's easier to supply a balanced fertilizer to all crops than to cater to a variety of different nutrient needs. To feed your whole garden, select a fertilizer in which the macronutrients are in equal ratio to each other; use single-nutrient sources to satisfy specific crop needs.

GET WHAT YOU AND YOUR PLANTS NEED—READ THE BAG

When shopping for fertilizers, it's important to take time to read the bag. The label on all commercial fertilizers features a three-number NPK ratio, and also the guaranteed analysis. Some, but not all, products provide ingredient information.

The amount of macronutrients a package of fertilizer contains is expressed as a three-number ratio. The first number

Organic Fertilizers Catalog

Organic Fertilizer	Nutrients Supplied	Rate of Application	Uses and Comments
Bloodmeal, dried blood	Bloodmeal: 15% nitrogen, 1.3% phosphorus, 0.7% potassium. Dried blood: 12% nitrogen, 3% phosphorus, 0% potassium.	Up to 3 lbs. per 100 sq. ft. (more will burn plants)	Source of readily available nitrogen. Add to compost pile to speed decomposition. Repels deer and rabbits. Lasts 3-4 months.
Bonemeal	3% nitrogen, 20% phosphorus, 0% potassium, 24-30% calcium.	Up to 5 lbs. per 100 sq. ft.	Excellent source of phosphorus. Raises pH. Best on fruit trees, bulbs, and flower beds. Lasts 6 to 12 months.
Cottonseed meal	6% nitrogen, 2-3% phosphorus, 2% potassium.	2-5 lbs. per 100 sq. ft. (For trees, apply 2-4 cups around drip line for each in. of trunk size.)	Acidifies soil, so it's best for crops that prefer low pH, such as azaleas, blueberries, citrus, dogwoods, hollies, and strawberries. Lasts 4-6 months.
Dolomite	90-100% $MgCa(CO_3)_2$ (51% calcium carbonate, 40% magnesium carbonate).	To raise pH one point, use 7 lbs. per 100 sq. ft. on clay or sandy loam, 5½ lbs. on sand, and 10 lbs. on loam soil.	Raises pH and adds magnesium, which is needed for chlorophyll production and photosynthesis. Repeated use may cause magnesium excess. Also sold as Hi-Mag or dolomite limestone.
Fish meal, fish emulsion	Fish meal: 10% nitrogen, 4-6% phosphorus, 0% potassium. Fish emulsion: 4% nitrogen, 4% phosphorus, 1% potassium.	Fish meal: up to 5 lbs. per 100 sq. ft. Fish emulsion: dilute 20:1 water to emulsion.	Fish meal: Use in early spring, at transplanting, and any time plants need a boost. Lasts 6-8 months. Fish emulsion: Apply as a foliar spray in early morning or evening. Also sold as fish solubles.
Granite dust	0% nitrogen, 0% phosphorus, 3-5% potassium, 67% silica; 19 trace minerals.	Up to 10 lbs. per 100 sq. ft.	Very slowly available. Releases potash more slowly than greensand, but lasts up to 10 years. Improves soil structure. Use mica-rich type only. Also sold as granite meal or crushed granite.
Greensand	0% nitrogen, 1% phosphorus, 5-7% potassium, 50% silica, 18-23% iron oxide; 22 trace minerals.	Up to 10 lbs. per 100 sq. ft.	Slowly available. Lasts up to 10 years. Loosens clay soils. Apply in fall for benefits next season. Also sold as glauconite or Jersey greensand.
Guano, bat	8% nitrogen, 4% phosphorus, 2% potassium average, but varies widely; 24 trace minerals.	Up to 5 lbs. per 100 sq. ft.; 2 T. per pint of potting soil; 1 lb. per 5 gal. water for manure tea.	Caves protect guano from leaching, so nutrients are conserved.
Guano, bird	13% nitrogen, 8% phosphorus, 2% potassium; 11 trace minerals.	3 lbs. per 100 sq. ft. Fruit trees: 3-6 oz. per inch of trunk diameter. Houseplants: 1-2 oz. per gallon of water.	Especially good for roses, bulbs, azaleas, and houseplants. Also sold as Plantjoy.
Gypsum (calcium sulfate)	23-57% calcium, 17.7% sulfur.	Up to 4 lbs. per 100 sq. ft.	Use when both calcium and sulfur are needed and soil pH is already high. Sulfur will tie up excess magnesium. Helps loosen clay soils.
Hoof and horn meal	14% nitrogen, 2% phosphorus, 0% potassium.	Up to 4 lbs. per 100 sq. ft.	High nitrogen source, but more slowly available than bloodmeal. Odorous. Takes 4-6 weeks to start releasing nitrogen; lasts 12 months.
Kelp meal, liquid seaweed	1% nitrogen, 0% phosphorus, 12% potassium; 33% trace minerals, including more than 1% of calcium, sodium, chlorine, and sulfur, and about 50 other minerals in trace amounts.	Meal: up to 1 lb. per 100 sq. ft. Liquid: dilute 25:1 water to seaweed for transplanting and rooting cuttings; 40:1 as booster and for fruit crops.	Contains natural growth hormones, so use sparingly. Best source of trace minerals. Lasts 6-12 months. Also sold as Thorvin Kelp, FoliaGro, Sea Life, Maxicrop, Norwegian SeaWeed, liquid kelp.
Langneinite	0% nitrogen, 0% phosphorus, 22% potassium, 22% sulfur, 11% magnesium.	Up to 1 lb. per 100 sq. ft.	Will not alter pH. Use when there is abundant calcium and sulfur. Magnesium and potassium are needed. Also sold as Sul-Po-Mag or K-Mag.
Leatherdust	5.5-12% nitrogen, 0% phosphorus, 0% potassium.	½ lb. per 100 sq. ft.	2% nitrogen is immediately available; rest releases slowly over growing season. Does not burn or leach.
Manure, composted cow	2% nitrogen, 1% phosphorus, 1% potassium.	40 lbs. per 50-100 sq. ft. as soil conditioner; 2 parts to 6-8 parts loam as potting mix.	Low level of nutrients and slow release make it most valuable as a soil conditioner. Use as winter fertilizer for houseplants.
Phosphate, colloidal	0% nitrogen, 18-22% phosphorus, 0% potassium, 27% calcium, 1.7% iron; silicas and 14 other trace minerals.	Up to 10 lbs. per 100 sq. ft.	More effective than rock phosphate on neutral soils. Phosphorus availability higher (2% available immediately) than rock phosphate because of small particle size of colloidal clay base. Half the pH-raising value of ground limestone. Lasts 2-3 years.
Phosphate, rock	0% nitrogen, 33% phosphorus, 0% potassium, 30% calcium, 2.8% iron, 10% silica; 10 other trace minerals.	Up to 10 lbs. per 100 sq. ft.	Releases phosphorus best in acid soils below pH 6.2. Slower release than colloidal phosphate. Will slowly raise pH one point or more. Also sold as phosphate rock.
Sulfur	100% sulfur.	1 lb. per 100 sq. ft. will lower pH one point. As fungicide: dilute at 3 T. per gallon of water.	Lowers pH in alkaline soil. Increases crop protein. Ties up excess magnesium. Also sold as Dispersul.
Wood ashes	0% nitrogen, 0-7% phosphorus, 6-20% potassium, 20-53% calcium carbonate; trace minerals such as copper, zinc, manganese, iron, sodium, sulfur, and boron.	1-2 lbs. per 100 sq. ft.	Nutrient amounts highly variable. Minerals highest in young hardwoods. Will raise soil pH. Put on soil in spring, and dig under. Do not use near young stems or roots. Protects ashes from leaching in winter. Lasts 12 or more months.

is the percentage of nitrogen; the second, the percentage of phosphate (the form of phosphorus plants use); and the third, the percentage of potash (the form of potassium plants use).

Commercial fertilizers—both synthetic and organic—supply one, two, or all three of the macronutrients. Some contain secondary nutrients; a few, such as seaweed and compost, also supply all of the micronutrients.

Look for fertilizers that are labeled "Certified Organic," or carefully check the ingredients to make sure all the ingredients are safe and natural. Be wary of any products labeled organic that have an NPK ratio that adds up to more than 15; these products probably have ingredients that aren't organically acceptable.

Don't Have a Feeding Frenzy

One of the best ways to save time fertilizing is not to fertilize. If you're feeding your soil regularly with compost and keeping it covered with organic mulch, most of your plants won't need any supplemental feedings. So before you haul out the fertilizer, take time to think about which plants truly need to be fertilized. Perennials, trees, shrubs, and vines that are growing well will probably continue to do fine without feeding. If they just need a boost, an annual mulching with compost will help control weeds, hold moisture in the soil, *and* feed.

Even in a well-managed organic garden, there are plants that do better when fertilized. Fast-growing vegetables tend to be more productive when they receive added nutrients. Beds of annual flowers may bloom more as well. Perennials that have been in place for a few years also benefit from fertilization to replenish the nutrients they've removed from the soil. And container plants that rely on the soil in their pots will thank you for an occasional boost. By comparison, you may choose not to fertilize your lawn. Not fertilizing has an added benefit: The grass grows more slowly and you have to mow less.

Exercise Your Application Options

Different forms of fertilizer lend themselves to different application methods. Dry fertilizers may be powdered, granular, or palletized—such products are easily applied over the soil surface. Liquid fertilizers give you the option of spraying nutrients directly on your plants as a foliar feed or watering them into the soil around plants.

1. **Foliar application.** Spray liquid fertilizer or compost tea onto plant leaves to give them a boost any time during the growing season.
2. **Side-dressing.** Apply dry fertilizer or compost in a ring around established plants or in a band next to a row of plants.
3. **Top-dressing.** A drop-type spreader lets you apply dry fertilizer or screened compost over the top of your lawn.
4. **Broadcasting.** To prepare soil for planting, you can broadcast dry fertilizer with a spreader or by hand, then rake it in.

Let Your Irrigation System Do Double Duty

If you have an irrigation system, let it fertilize for you—add a siphon attachment between the tap and the hose. Put the uptake tube into a bucket of concentrated liquid fertilizer and let the system do the rest.

With a drip system, you'll need a proportioner or fertilizer injector that will work with its lower water flow rate. To prevent clogging, filter fertilizer solutions before adding them to your irrigation system, and avoid fish emulsion. After fertilizing, flush your system with clear water for a few minutes.

Siphon attachments, proportioners, and injectors are available at well-stocked garden centers and by mail.

Cut Fertilizer Needs with Compost

If you keep only one fertilizer on hand, make it compost. The nutrient content of compost is low when compared to synthetic fertilizers (compost's NPK ratio can range from 0.5-0.5-0.5 to 4-4-4), but it does much more than just add nutrients to the soil. It promotes microorganism populations that increase the availability of nutrients to your plants. As a source of organic matter, it also helps improve soil quality, drainage, and water-holding capacity.

Once you start using compost, you'll understand why good gardeners know you can never have too much of it. See below for some of the best ways to save time and still feed your plants with compost. If you feel like you could never make enough compost to perform all these different functions, check with the agency in your local government that oversees waste collection. Chances are your municipal government, township, or local parks department has a yard waste composting facility where residents can get compost at little or no cost.

Compost mulch. Mulching perennial beds and mixed plantings with compost is enough to adequately feed most established plants. It also reduces the need to water and weed.

Top your vegetable garden in fall. Spreading a 1- to 2-inch layer of compost over your vegetable garden in late fall will protect the soil from the elements through winter and leave it ready for planting when spring arrives.

Side-dress with compost. During the growing season, you can side-dress vegetable crops with compost or use it as a mulch for the garden.

Feed your lawn. If you open your drop-type spreader to its widest setting, you can nourish your lawn with a top-dressing of compost.

Make compost tea. To make a batch of compost tea, put one or two shovelfuls of compost into a coarsely woven or burlap sack. Tie the sack shut, and steep your "tea bag" in a 5-gallon bucket of water for 1 to 7 days. Dilute the resulting liquid to a weak-tea color and use it to water your plants; strain it through cheesecloth to apply as a foliar spray or via drip irrigation. Any

plants in need of a boost will respond well to a foliar application of compost tea.

Be Practical about pH

A soil's pH—the measure of its acidity or alkalinity—is important because it affects whether plants can take up the nutrients in the soil through their roots.

Soil pH varies by region and fluctuates with the previous uses of soil, such as cultivation or development. It is expressed as a number from 1.0 to 14.0: 1 is acid, 7 is neutral, and 14 is alkaline.

While some of your plants may have specific pH preferences, most tolerate a fairly wide range of soil pH. And plants that are finicky are simply expressing their need for the nutrients that are unavailable to them when the pH is "wrong."

The easiest thing to do about soil pH is nothing—as long as it's not seriously inhibiting your gardening success, leave it alone. Follow the steps below to do as little as possible about soil pH, while understanding how it affects your plants.

Know your soil's pH. Have a soil test done by a professional, or buy a home pH test kit and find out what your soil's pH is.

Know a little about pH and nutrient availability. Most nutrients plants need are available when the soil pH is between 6.0 and 7.5. When the pH is below 6.0, some nutrients, including nitrogen, phosphorus, and potassium, are less available to the plants. When the pH exceeds 7.5, iron, manganese, and phosphorus availability drop.

Know a little about plants and pH. Most cultivated plants grow best in soils with a pH in the range of 6.0 to 7.0. Common exceptions to this rule include blueberries, potatoes, and rhododendrons, all of which prefer more acidic conditions.

Choose plants accordingly. When you choose landscape plants, take pH into account. You can adjust soil pH by applying soil amendments. However, you'll be more successful if you select plants that are adapted to your soil's pH. Keep in mind that it's easier to amend cultivated soils, such as in vegetable gardens, than sodded or planted areas of the landscape.

Allow time for change. If you find your soil's pH is seriously out of kilter, or if you want to amend a limited area to make way for vegetable crops that won't tolerate existing conditions, start the amendment process early. Many factors, including soil type, organic matter content, and the type of amendment you use, will contribute to how quickly or slowly you can alter soil pH. Follow the specific recommendations you'll get with a complete soil test, and allow time for them to take effect before you plant.

Discover compost. Among its many attributes, compost also includes help for gardeners struggling with unfavorable soil pH. Because compost enhances soil microorganism activity (and because soil microorganisms help make nutrients available to plants), compost serves as sort of a soil pH buffer, reducing plants' dependence on a particular pH range.

Enjoy Your Present pH

The best way to cope with soil pH is to make good use of the pH you already have. A 250-square-foot garden will produce healthy crops of vegetables (pH 7.2) and luscious blueberries (pH 5.0) with very little extra work. However, to grow blueberries in a soil where you can easily grow vegetables, and vegetables where you can grow blueberries, is another matter altogether. It takes an enormous amount of work, time, and amendments to alter soil pH. In this example, it would take 16.5 pounds of sulfur to lower the pH of the 7.2 garden to 5.0 and 30 pounds of lime to raise the 5.0 garden to 7.2. Plus, substantial pH changes must be made slowly—by amending the soil over two years or more—to avoid severely upsetting the balance of life in the soil. Few soils are in need of such dramatic amendment—be happy with what you have.

More Food Isn't Better!

Many gardeners, especially those who take a casual approach to measuring things, subscribe to the theory that if a little is good, a lot must be better. When it comes to fertilizers, they couldn't be further from the truth. With few exceptions, plants rarely take up more fertilizer than they need; the nutrients they don't use remain in the soil. Some cause imbalances in soil biology, while other more soluble products end up washing into the groundwater. So don't waste your money or your time: When you apply fertilizer, follow the label's recommendations for how much to use. If you estimate how much you need, err on the low side.

For Easy Applications, Make a Master Measure

Fertilizing your garden is easier if you don't have to spend time weighing and measuring fertilizers each time you feed. Making a master measure for the fertilizers and soil amendments you use most often will allow you to just scoop and spread—without overfeeding. To make one, first weigh the materials to determine the volume of a pound. Then pour each into a clean, dry plastic container—recycle whatever's handy; an old deli container or a modified milk jug works fine. Then mark the volume with a permanent marking pen on the outside of the container. One good general mix is 3 pounds of alfalfa meal, 2 pounds of bonemeal, and 1 pound of kelp meal for every 100 square feet of growing area.

Making and Using Organic Fertilizers

Barbara W. Ellis

What happens when you push a spading fork into your soil? Does the fork sink easily into rich-smelling earth populated by a host of well-fed earthworms? Or is your ground hard to penetrate, dry and unyielding? If the latter is true, making and using

Continued

organic fertilizers is one way to turn your soil into a plant lover's dream.

The most important goal of any soil improvement program is the promotion of microbial activity, because it's the activity of microorganisms in the soil that makes nutrients available to plants. That's why adding organic matter to the soil in the form of compost or green manure is so important to fertility. Fertilizers not only feed plants, they also feed generations of bacteria and fungi that help break down organic matter and make it available to plants. Organic fertilizers differ from chemical ones in that they tend to release nutrients more slowly and in lower concentrations than chemical fertilizers. They also tend to leach out of the soil more slowly than chemical ones. Unlike their chemical counterparts, many organic fertilizers add organic matter to the soil as well.

Whether you make them yourself or buy them prebagged at your local nursery or garden center, organic fertilizers benefit your soil and plants by slowly and gradually releasing nutrients. The organic matter present in many types of organic fertilizer also improves soil structure and tilth, as well as nutrient- and water-holding ability.

No matter what kind you choose, though, remember that fertilizers can't make up for basically poor soil. Like vitamin supplements for the body, they can help supply missing nutrients, but they can't compensate for gross deficiencies such as lack of organic matter and poor drainage. To improve poor soil, you'll need to add compost and other organic matter to the soil. Then you can count on organic fertilizers to fill in the gaps.

Selecting Organic Fertilizers

Your first goal is to supply the soil with the three major plant nutrients: nitrogen (N), phosphorus (P), and potassium (K). A soil test will tell you the amounts of each element your soil needs. Different fertilizers contain different ratios of these three basic nutrients. Choose one basic type to correct a particular deficiency or mix your own blends to suit your particular needs.

Sources of Nitrogen

ANIMAL MANURE.

Manure is a good source of nitrogen and other soil nutrients. Because of the organic matter it contains, it's also a real boon to soil structure. There are three basic ways manure is sold: fresh, composted, and air-dried. Fresh is cheapest; dried most expensive because the percentage of nutrients and humus per pound is correspondingly higher. Bagged, dried cow manure is available at any garden supply store. Some suppliers may also carry such exotic preparations as bird and bat guano.

In addition, gardeners distinguish between hot and cold manures. Although to some, hot manure means relatively fresh manure, normally the term refers to manure that contains a relatively high percentage of nitrogen. Poultry and sheep manures are examples of hot manure. Cold manures contain relatively low percentages of nitrogen. Cow and horse manure are examples of cold manures.

If you have access to a source of fresh manure, it's best to compost it for three to six months before using it near plants. Composting also kills weed seeds in manure and allows salt, which is often fed to livestock, to leach away. Applied directly to growing plants, fresh manure can burn plant tissue and even kill seedlings. The best time to apply fresh manure to your garden is in the fall, after the growing season is over. Or you can work it into the soil in spring, no less than a month before planting. You can also use it to side-dress planting rows. Never apply it directly to plants. Dried or well-rotted manure can be worked into the soil at planting time or when you're preparing your beds.

FISH EMULSION.

Fish emulsion fertilizer is a by-product of the processing of menhaden, a small, oily, bony fish related to herring. The nitrogen it contains is in the form of amino acids, which plants can take up directly. Fish emulsion isn't a complete fertilizer, though. It is low in calcium, and gardeners with soil naturally low in calcium who depend on fish emulsion exclusively may end up with deficiency disorders such as blossom end rot on tomatoes or tip bum on lettuce. Fish emulsion can be applied diluted to the soil at planting time, as a side dressing, or sprayed on as a foliar feed.

OTHER SOURCES OF NITROGEN.

Dried blood or bloodmeal and cottonseed meal are two other good sources of nitrogen. Cottonseed meal lowers soil pH as well, making it especially suitable for acid-lovers like blueberries and azaleas. Both can be added to the soil at planting time or worked into the soil during the growing season.

Leaves and grass clippings are two other free sources of nitrogen, and both also provide valuable organic matter to the soil. Chopped or whole leaves can be composted or worked directly into the soil in the fall or several weeks before planting in spring. Adding leaves directly to the soil will slightly reduce yields the first year, but as you add leaves each season, the amount of organic matter in your soil rises along with yields. Grass clippings can be composted, used as a mulch, or worked into the soil in the fall or several weeks before planting.

Sources of Phosphorus

BONEMEAL.

Bonemeal is a good slow-release source of phosphorus, which is vital for flowering, fruiting, and root development. It should be worked into the soil at planting time to get it close to the root

zone. (Although it also supplies a small amount of nitrogen, bonemeal is best applied as a supplement to manure or compost, which are less expensive sources of nitrogen.) Bonemeal will raise soil pH and shouldn't be used on acid-lovers like blueberries.

Several factors influence the availability of phosphorus from bonemeal to plants. Commercial bonemeal has been steamed and crushed. The more finely ground the product, the easier it is for plants to use. The microorganisms in soil break the particles down and make the phosphorus available to plants. For this reason, bonemeal breaks down faster in a healthy soil with lots of microbial activity than in poor soil. Work bonemeal into the soil in spring when the soil is warming and microorganisms are active and can begin to break it down. Finally, soil pH affects availability, for if soil is too acid or too alkaline, phosphorus combines with other elements and becomes unavailable to plants. Phosphorus is most available in slightly acid soil, with a pH between 6.2 and 6.5.

Bonemeal can be used as a top-dressing or worked into the soil at planting time. It tends to be expensive and is probably best used in small applications. Add a handful to the hole when planting roses, shrubs, or trees, and a sprinkling to the holes for perennials or large bulbs such as tulips, daffodils, and lilies. Scientists have recently found that bulbs need more nitrogen than phosphorus, so be sure to provide a source of nitrogen as well.

PHOSPHATE.

Phosphate is available in two forms: colloidal phosphate and rock phosphate. Both are considerably cheaper sources of phosphorus than bonemeal. Colloidal phosphate, also called soft phosphate, is the residue left after phosphate-containing limestone has been washed. The washed, crushed limestone is then sold as rock phosphate or converted into one of the enhanced chemical phosphate fertilizers. The phosphorus in colloidal phosphate is more readily available to plants than rock phosphate, but the latter works well over the long haul.

Sources of Potassium

LANGBEINITE.

A mineral mined in New Mexico, langbeinite is an excellent source of potassium. It contains much more potassium than greensand and granite dust, which are the two most common organic sources of this essential nutrient. It's also a more readily available source of potassium than greensand, a mineral-rich sediment, and granite dust, both of which break down very slowly. Langbeinite can be worked into the soil at planting time or used as a side dressing.

OTHER SOURCES OF POTASSIUM.

In addition to langbemite, greensand, and granite dust, seaweed is also a good source of potassium. It is most commonly available in liquid form, and in addition to potassium also contains a large percentage of essential trace minerals. It can be applied as a liquid directly to the soil or as a foliar spray. Wood ashes also contain potassium and can be mixed with other fertilizers, worked into the soil at planting time, added to the compost heap, or used as a side-dressing. Ashes tend to raise soil pH and shouldn't be used on acid-loving plants.

Applying Fertilizers

There are several different ways to apply fertilizers, and the best method will depend on what type you're using and what plants you are growing. Obviously, liquid and dry fertilizers are applied differently, and the methods and applications suitable for an intensively managed vegetable garden wouldn't be appropriate for a lawn.

How often to fertilize depends on the plants you are growing. A vegetable garden where crops are harvested and plants are removed one or more times a year will have a much greater need for fertilizer than a perennial border, for example. As a general rule plants are fertilized when they are first planted. Heavy feeders can be given supplemental feedings approximately once a month throughout the growing season. With hardy plants such as perennials, trees, and shrubs, it's important to taper off toward fall so the plant can become dormant. Fertilizing late in the growing season can trigger lush growth, which is susceptible to frost damage.

DRY FERTILIZERS

Many organic fertilizers are best applied by digging them into the soil when beds are being prepared for planting in fall or early spring. Dry fertilizers such as manure, colloidal phosphate, langbeinite, bonemeal, dried blood, and wood ashes, as well as compost, can all be incorporated into the soil in this manner. If you're preparing an entire vegetable garden, spread the fertilizer evenly over the whole bed—either by broadcasting or shoveling and raking—into an even layer. Then rake or dig it into the soil. Another alternative, especially useful with expensive materials like bonemeal, is to amend the soil along rows where the plants will be growing.

When planting perennials, shrubs, or trees, fertilizers can be added to the individual holes at planting time or worked into the soil surface around plants.

You might want to use a lawn spreader to apply rock powders over a large area. Simply put the powder into the hopper and the machine does the spreading for you. Hand-held spreaders are available for small jobs. Spreaders have the advantage of producing a consistent, even layer.

Side-dressing is an effective way to apply fertilizer, especially for supplemental feedings during the season or alongside new rows of plants. Work the fertilizer into the soil in a shallow furrow beside a row or work it into the surface around plants just outside the root zone. Plant roots grow toward the

Continued →

fertilizer and take it up gradually. Side-dressing is also a safe way to apply "hot" fertilizers such as fresh manure, which can burn plant roots if applied directly.

LIQUID FERTILIZERS

One of the easiest ways to apply liquid fertilizers such as manure tea or fish emulsion is to use a watering can with a perforated sprinkler head, called a rose, attached. You can also deliver liquids by means of drip irrigation systems (make sure to filter the liquid to prevent it from plugging up the system).

Foliar feeding is a quick and safe way to apply liquid fertilizer. It's nothing more than spraying dilute liquid fertilizer onto the leaves of plants, which take it up readily. Use a dilute solution of fish emulsion, liquid seaweed, or compost or manure tea, and spray it directly on the leaves of a plant. You can use a commercial sprayer of the type used to apply insecticides, but be sure to filter the liquid before spraying. You can also use a watering can with a perforated sprinkler head to do foliar feeding.

Jeff Cox

Learning to propagate plants—to make new plants from existing ones in your home and garden—is one of the most exciting and rewarding aspects of gardening. Many of the methods are easy, and you don't need fancy or expensive tools. Propagation is cheaper than buying large numbers of plants, so with a little time and effort you can fill your garden quickly at minimal cost. Propagating new plants will keep your house and garden full of vigorous specimens, and you'll probably have plenty to give away, too!

You can reproduce most plants by several methods. There are two major types of propagation: sexual and asexual. Sexual propagation involves seeds, which are produced by the fusion of male and female reproductive cells. Growing from seed is an inexpensive way to produce large numbers of plants. Annuals, biennials, and vegetables are almost always reproduced by seed. You can also grow perennials, shrubs, and trees from seed.

Asexual propagation methods use the vegetative parts of a plant: roots, stems, buds, and leaves. Division, cuttings, and layering are all asexual methods.

With division, you split entire plants into sections; for cuttings, you remove stem tips and root them; and in layering, you root a stem while it is still attached to the parent plant.

Select a technique by considering the plant you are working with, the materials you have, the season, and the amount of time you are willing to wait for a new plant.

Division

Division is a quick and reliable way to propagate many types of multi-stemmed plants with almost guaranteed success. Dividing—separating a plant into several smaller new plants—works well for increasing groundcovers, clump-forming perennials, bulbs, and tubers. You can also divide ornamental grasses and suckering shrubs, as well as houseplants and herbs.

The best time to divide garden plants is when they are dormant. In general, divide spring- and summer-blooming plants in the fall, and fall-blooming plants in the spring. If possible, divide houseplants in the spring as new growth starts. Divide plants with tubers and tuberous roots, such as dahlias and tuberous begonias, before planting in the spring.

The key to division is starting with a vigorous parent plant. If the soil is dry, water the plant thoroughly the day before. Whenever possible, wait for cool, cloudy weather (or at least evening), to reduce moisture loss from the plant during the process.

To divide a hardy plant, lift it from the soil with a fork or spade. Separate small clumps by pulling off the vigorous young plantlets; discard the woody center growth. Use a sharp knife to cut apart small plants. When dividing plants, make sure that each piece you remove has its own root system. Otherwise, new divisions won't grow. Replant divisions as quickly as possible, to the same depth as the original plant, and water them thoroughly. Mulch fall divisions well to protect the developing roots from frost heaving.

DIVIDING HARDY BULBS

The easiest way to propagate hardy bulbs—especially the ones that are good for naturalizing, such as daffodils—is to dig them when the foliage yellows, separate the offsets on each bulb, and replant. You can plant them at the same depth and location as the mature bulbs, but they might reach flowering size sooner if you grow them in a nursery bed for two to three seasons first.

Propagate crocuses and other bulbs that arise from corms in much the same way: Dig them and separate the small new corms, called cormels, that form alongside the parent corm.

There are two ways to propagate lilies: Pick the small bulbils that form along the stem above the leaves or the bulblets that form at the base of the stem. Then plant them in a nursery bed, where they'll need to grow for several years to attain blooming size. You can also scale lily bulbs to propagate them. Remove the scales one at a time, and place them in a shallow flat or pot filled with moist vermiculite or peat moss. Bury the scales about halfway, and keep them moist. Small bulblets, which can be transplanted to a nursery bed, will form at the base of each scale.

Division Step-by-Step

1. To start dividing a clump, cut around the mother plant with a trowel or spade (depending on the size of the plant), or loosen the soil with a garden fork. Then lift the plant from the ground, shaking enough soil from the roots so you can see what you're doing when you divide the plant. If there's still too much soil clinging to the roots, you can hose it off.
2. Use a sharp spade to divide perennials or tough clumps of ornamental grasses. Don't chop at the roots, though; try to make single, clean cuts. Another technique for separating hard-to-divide clumps is to plunge two garden forks back-to-back into the clump, then press the handles together until the clump separates into two parts. Divide each part into halves to quarter the perennial, or pull off sections for smaller divisions.

   For smaller perennials or plants with thick, fleshy roots, use a sharp knife to cut the plant apart.
3. If the center of the plant has become woody and has stopped flowering, divide the clump in half. Cut out and discard the woody center, leaving an outer ring of good plant material. Cut the ring into smaller pieces.

   Replant the divisions quickly, water them in, and cover them with damp newspaper or burlap for the first week. Pot up very small divisions until they're growing strongly, then transplant to the garden.

DIVIDING TENDER BULBS

You can increase your stock of favorite dahlia cultivars in the fall when you've dug the tuberous roots and allowed them to dry, or store the clumps whole and divide them in spring. Use a sharp, sterile knife. Make sure that each division has a piece of stem attached; new shoots sprout only from that part of the plant. Discard any thin or immature roots. Divide tubers such as tuberous begonias and caladiums in spring. Cut them into pieces, making sure each piece has an eye or bud. Let the pieces dry for two days and then plant them. Gladiolus corms produce small cormels, which you can grow to flowering size in two or three years. Dig, cure, and store the cormels the same way you treat the mature corms. In spring, plant the cormels in a nursery bed at the same time you put the mature corms out in the garden.

Cuttings

Plants have the amazing capacity to regenerate from small pieces of tissue, called cuttings. These small portions of stems, leaves, or roots will form new roots and shoots if given the right treatment.

Taking cuttings is the most common way to propagate many types of ornamental plants. Because raising plants from cuttings is an asexual type of reproduction, the new plants will look exactly like the parent.

There are several ways to make cuttings, but all types of cuttings need a medium to support them while they grow roots, plus some type of structure to protect them during the rooting period. It's also important to observe good sanitation to minimize disease problems.

The best media for taking cuttings are moisture-retentive but well drained and free of insects, diseases, and weed seeds. Commonly used media are sand, perlite, vermiculite, and peat moss. No one medium or combination is ideal for all plants, but an equal mixture of peat and sand or perlite is useful in most situations. Soil is not a good propagation medium, especially in containers. Unlike the other materials, soil is not sterile and can compact severely from frequent waterings. Only very hardy cuttings are planted directly into soil.

Some plants, such as African violets, coleus, and willows (*Salix* spp.), will root directly in water. This method is fun to try, but if you want to save the cutting, plant it in potting soil while the roots are still small. Plants may have difficulty adapting to soil if their roots are in water too long.

Cuttings need a protected, high-humidity environment while they root. Cuttings don't have roots to take up water, but they still lose moisture through their leaves. By keeping the surrounding air moist, you minimize water loss and help cuttings survive until they can support themselves.

On a small scale, plastic bags are great for protecting cuttings. Support the bag so the plastic does not rest on the cuttings and encourage rot. Provide ventilation by occasionally opening the bag for an hour or two. In most cases, you won't have to add water until the cuttings form roots. To harden off rooted cuttings, gradually open the bag for longer periods.

For large numbers of cuttings, a cold frame or greenhouse is more practical. You can set pots of cuttings on the soil or plant directly in the soil inside a cold frame. Close the frame and cover the glass with shading material, such as cheesecloth or wooden laths (like snow fencing or lattice); gradually remove the shading when roots form. Ventilate and harden off by gradually opening the cold frame for longer periods.

Use a clean, sharp tool to collect and prepare cuttings. Crushed plant tissue is an invitation to rot. Never propagate from diseased or insect-infested plants. Plant cuttings in fresh, sterile propagation mix that is stored in closed containers. Pots and propagation areas should be scrubbed clean and, if possible, sanitized by rinsing with a 10 percent bleach solution (1 part bleach to 9 parts water). Check plants often during rooting, and remove any fallen leaves or dead cuttings. Don't overwater; do provide adequate ventilation.

When Propagation Isn't a Plus

Roger Yepsen

Certain shrubs will give rise to a wealth of seedlings, more than you can use, so that controlling these freebies is added to your landscaping chores. Look for sterile hybrids of your favorite plants to keep these pets from becoming pests. For example, the Buddleia hybrids 'Lochinch' (with fragrant purple flowers) and 'Sungold' (yellow flowers) will stay politely within their bounds. Sterile Rose of Sharon cultivars, *Hybiscus mutabilis x syriacus*, include 'Tosca' (lavender flowers with a carmine eye) and 'Lohengrin' (white flowers). While winterberry euonymus (*Euonymus fortunei*) can be invasive, you can go with wintercreeper euonymus 'Purpurea' and sterile variegated forms.

SOFTWOOD STEM CUTTINGS

Take softwood cuttings from succulent spring growth of woody plants such as azaleas and magnolias. Treat stem cuttings of herbaceous plants, including geraniums and impatiens, like softwood cuttings. Because these cuttings are taken from young tissue, they form roots easily but need high humidity to prevent them from wilting.

Take softwood cuttings from April through June, when new leaves are fully expanded but stems are still soft. Take houseplant cuttings anytime.

Water the parent plant a day or two before taking cuttings. Fill a container with moist propagation mix.

Collect cuttings in the morning or on a cloudy, cool day, and keep them moist until planting. Cuttings should be 3 to 6 inches long; they usually include a terminal bud. Remove leaves from the lower half of the stem, and apply rooting hormone if desired. Insert the cutting to about one-third its length, firm the medium, and water to settle the cutting. Enclose the container in plastic, or place it under a mist system in a cold frame or greenhouse.

Ventilate plants; water to keep the medium moist but not wet. Softwood and herbaceous cuttings root quickly, often in two to four weeks. When roots appear, harden off the cuttings and plant them in the garden or in a pot.

HARDWOOD STEM CUTTINGS

Take hardwood cuttings from woody plants during their dormant period. Hardwood cuttings don't require high-humidity conditions. This method is effective for some types of woody plants and vines, including grapes, currants, willows, and some roses.

Take cuttings after leaf fall and before new growth begins in spring. Mid-autumn is often the best time to collect and plant cuttings so they can form roots before the buds begin to grow.

For potted cuttings, fill the container with moist propagation mix. If you are planting cuttings outdoors or into a cold frame, prepare a deep, well-drained nursery bed.

Collect 4- to 8-inch cuttings from vigorous, one-year-old wood, a few inches below the terminal bud. Make a straight cut at the top, slightly above a bud, and a sloping cut at the base, slightly below a bud. Stick cuttings 2 to 4 inches apart in the medium, with the top bud about 1 inch above the surface. Be sure the cuttings point upward: Double-check that you've stuck the ends with sloping cuts into the medium. Plant fall cuttings soon after they are taken, or store them upside down in moist peat moss or perlite and plant right-side up in spring. Cover fall-planted cuttings with 6 to 8 inches of mulch to prevent frost heaving; remove mulch in spring. Plant late-winter cuttings directly into pots or soil.

Best Bets for Division

Dividing established perennials is a fast and sure way to fill your yard with flowers. Plants with more than one tall stem, especially clump-forming ones like garden phlox or asters, are good candidates for dividing, says Dave Bowman, who grows over 1,000 perennials as a co-owner of Crownsville Nursery in Maryland. Or keep your eye open for ones that root as they wander along the ground, such as snow-in-summer (*Cerastium tomentosum*) and creeping phlox (*Phlox stolonifera*).

The plants listed below are easy to divide by digging up a clump and separating the roots into smaller sections. Some will pull apart by hand with a bit of gentle teasing; for others, you may need a sharp knife or trowel. Replant as soon as possible, and water well. Protect from direct sun for a few days until the roots recover.

- Avens (*Geum* spp.)
- Bee balm (*Monarda didyma*)
- Candytufts (*Iberis* spp.)
- Daylilies (*Hemerocallis* spp.)
- Evening primroses (*Oenothera* spp.)
- Hardy ageratum (*Eupatorium coelestinum*)
- Hostas (*Hosta* spp.)
- Irises (*Iris* spp.)
- Obedient plants (*Physostegia* spp.)
- Peonies (*Paeonia* spp.)
- Perennial sunflowers (*Helianthus* spp.)
- Soapworts (*Saponaria* spp.)
- Tansies (*Tanacetum* spp.)
- Yarrows (*Achillea* spp.)

Keep cuttings moist. They usually root rapidly in spring, but it is best to leave them at least until fall. Transplant rooted cuttings to the garden or into pots.

EVERGREEN CUTTINGS

Broad-leaved and needled evergreens are often propagated by stem cuttings. Try this method on plants such as arborvitae, hollies, and boxwood.

Collect broad-leaved cuttings in late summer. Take needled cuttings in fall or winter; yew and juniper cuttings should have had some frost.

Fill a container with moist propagation mix, or prepare a well-drained bed in the base of a cold frame.

Collect 4- to 6-inch tip cuttings in the proper season. Some cuttings benefit from a piece of older wood—a heel—left at the base of the stem. To take a heel, pull sharply downward on the base of a sideshoot as you remove it from the parent plant; trim the excess with a knife.

Wounding is another way to encourage the rooting of difficult plants. Create a wound by cutting a shallow sliver on the side of the cutting near the base. This process stimulates cell division and enhances water uptake but also increases the chance of disease problems.

Before planting, remove lower leaves and sideshoots. To save space with large broadleaved cuttings, cut each remaining leaf in half. Apply rooting hormone if desired. Plant cuttings about one inch deep, firm the soil, and water to settle the cuttings. Place potted cuttings indoors in a plastic bag or in a greenhouse; alternatively, set pots in a cold frame, or plant into the frame.

Ventilate and water if necessary. Once roots appear, gradually harden off the cuttings. The new plants are best left in place until fall and then planted in the garden or in a pot.

LEAF CUTTINGS

Some plants with thick or fleshy leaves can produce roots and shoots directly from leaf pieces. This is a popular propagation method for houseplants such as African violets and snake plants.

Take cuttings any time of year. Use healthy leaves that are young but fully expanded. Thoroughly water the parent plant a day or so before collecting cuttings. Fill a container with moist propagation medium.

Cut snake plant and streptocarpus leaves into 2-inch-long pieces. Plant the pieces right-side up, about 1 inch deep. Peperomias and African violets are reproduced by leaf-petiole cuttings. Detach a leaf along with 1½ to 2 inches of its petiole. Plant vertically or at a slight angle, so the petiole is buried up to the leaf blade. After planting, water the cuttings to settle them in the soil.

If excessive condensation occurs, ventilate the cuttings. When new leaves appear in six to eight weeks, gradually harden them off. Sever plantlets from the parent leaf if it has not already withered away; transfer rooted plants to pots.

Division Dos and Don'ts

No matter which method of division you use, there are some basics that apply. Remember that division shocks your plants—treat them like the postoperative patients that they are, and follow these guidelines:

- **Do** prepare the site for your new divisions before you divide your perennials.
- **Do** take plants out of the ground before you divide them.
- **Do** make sure your tools are sharp. Sharp knives, trowels, or other tools cause fewer open wounds. Since they damage the roots less, plants are less susceptible to disease.
- **Do** card or compost the dead, woody centers of plants. Cut the remaining section of healthy plant into smaller pieces and replant.
- **Do** remove one-half to two-thirds of the foliage on your divisions so it won't wick water away from the plant, but **don't** cut off more than that or you'll slow growth and invite rot.
- **Do** replant divisions as soon as possible. Divisions are vulnerable—**don't** leave them lying in the sun.
- **Do** plant divisions ½ inch higher than they were planted originally; they'll sink a little as the soil settles. The goal is for them to end up at the same level as the original plants were growing.
- **Do** water your divisions well. Give them a good soaking as soon as you plant them, and continue to water them regularly until they're established.
- **Do** shade newly planted divisions to protect them. Cover the plants with moist newspaper or burlap held down with rocks or soil for the first week after planting.
- **Do** give divided perennials and ornamental grasses a foliar feed of liquid seaweed or fish emulsion to provide trace elements and speed establishment.
- **Do** heavily mulch plants divided in fall when the soil cools, to prevent shallow freezing and frost heaving.
- **Don't** divide perennials after early October, since the roots need time to establish themselves while the soil is warm.
- **Don't** divide taprooted perennials—start them from stem cuttings or seed. These include plants such as butterfly weed (*Asclepias tuberose*), gas plants (*Dictamnus* spp.), and rues (*Ruta* spp.).

ROOT CUTTINGS

Root cuttings are a reliable way to propagate plants with thick, fleshy roots. Slice off pencil-thick roots, and cut them into 2-inch pieces. Use a diagonal cut at the bottom of each piece so that you'll know which end is up. (They won't grow if you plant them upside down.) Pot up root cuttings in pots or cell packs filled with sterile, porous potting medium, such as half seed-starting mix and half perlite. Keep the cuttings barely moist, put them in a cold frame or an unheated room, and give them bottom heat, if possible.

These plants propagate well from cuttings of their thick, fleshy roots. Dig deep to lift the mother plant, then cut roots into 2-inch pieces for propagating.

Adam's-needle (*Yucca filamentosa*)

Baby's-breath (*Gypsophila paniculata*)

Bear's-breeches (*Acanthus* spp.)

Bugloss (*Anchusa* spp.)

Butterfly weed (*Asclepias tuberosa*)

Common bleeding heart (*Dicentra spectabilis*)

Cranesbills (*Geranium* spp.)

Mulleins (*Verbascum* spp.)

Oriental poppy (*Papaver orientale*)

Perennial salvias (*Salvia* spp.)

If you have a cold frame, unheated room, or greenhouse, you can also propagate perennials from root cuttings. The best perennials for root cuttings have fleshy roots, like Japanese anemone (*Anemone x hybrida*), grape leaf anemone (*A. vitifolia*), snowdrop anemone (*A. sylvestris*), bleeding hearts (*Dicentra* spp.), cranesbills (*Geranium* spp.), garden phlox (*Phlox paniculata*), great coneflower (*Rudbeckia maxima*), ligularias (*Ligularia* spp.), and Siberian bugloss (*Brunnera macrophylla*). Take root cuttings in the fall or winter when plants are dormant, grow them in the greenhouse or cold frame, and plant them out in a nursery bed when they are growing strongly.

Layering

Layering is a way of propagating plants by encouraging sections of stems to sprout new roots, which are cut from the mother plant and planted. This simple method produces good-sized new plants in a relatively short time.

SIMPLE LAYERING

Simple layering involves bending a low-growing branch to the ground and burying several inches of stem. It is used to propagate many types of vines and woody plants, including grapes and magnolias.

Spring is the best time to start simple layers. Choose flexible, vigorous one-year-old shoots about as thick as a pencil.

Thoroughly water the soil around the plant. The next day, bend a shoot down to the soil. Measure back 9 to 12 inches from the tip of the shoot, and mark the spot where that point on the stem touches the ground. Release the shoot, and dig a 4-inch hole at the marked point. The hole should have one side sloping toward the parent plant. Work in several handfuls of finished compost.

Remove leaves and sideshoots along the chosen stem from 6 to 15 inches behind the stem tip. Wound the stem by making a shallow 2-inch-long cut at a point about 9 inches behind the tip. Insert a toothpick or small pebble in the cut to keep it open. Dust the cut with rooting hormone. Bend the stem down into the hole, and use a wire pin to keep the wounded area in contact with the soil. Stake the stem tip if it doesn't stay upright by itself. Cover the pinned stem with soil and water thoroughly.

Keep the layered area moist and weeded. The stem may root by fall; check by uncovering the stem, removing the wire pin, and tugging lightly. If the stem feels firmly anchored, it has rooted. Sever it from the parent plant, but leave it in place until spring. Then pot it up or transplant it. If the stem is not well rooted, replace the soil and wait a year before checking again for roots.

TIP LAYERING

Shoot tips of certain plants such as black and purple raspberries root when they touch the ground. Plant tip layers in late summer, using the ends of the current season's growth. Make sure you use healthy, vigorous canes. Prepare a hole as you would for simple layers; judge the placement of the hole by the tip of the stem.

Bend the stem tip down to the prepared planting hole. Lay the cane against the sloping side and place the tip against the farthest edge of the hole. Replace the soil, and water well.

By early fall, shoots will appear and roots will have formed; cut the original cane where it enters the soil. In mid-fall or the following spring, carefully dig up the rooted tip, and plant it in its new position.

AIR LAYERING

Air layering is similar to simple layering, but the stem is covered with long-fibered (unmilled) sphagnum moss rather than soil. You can air-layer upright stems of trees, shrubs, and indoor plants such as philodendrons.

Outdoors, start air layers in early fall with young wood, or in spring with the previous season's growth. Indoors, air layers can be done any time, but it's best to start when plants begin growing actively in spring.

Soak the sphagnum moss in water for a few hours or overnight. Before using, wring the excess water out of the moss, so it is moist but not dripping wet.

Start with a healthy, vigorous stem. Decide where you want the roots of the new plant to be, anywhere from 6 to 18 inches behind the tip. Remove all leaves and sideshoots for 3 inches on either side of that point. Wound the stem by making a shallow 2-inch-long cut into it. Dust the wounded area with rooting hormone. Wrap the ball of moist sphagnum moss around the wound and tie it with string. Next, cover the moss ball with a piece of clear plastic about 6 inches square. For indoor plants, tie the plastic at both ends with string or twist ties. Use waterproof tape to secure the ends on outdoor air layers; make sure the ends are completely sealed. For outdoor plants, also cover the plastic wrap with foil or black plastic and tie or tape it to the stem; this will keep the layered area from getting too hot in the sun.

Indoor plants can produce roots in a few months; outdoor plants may take one or two growing seasons. You'll be able to see the roots growing in the moss. Cut off the top of the plant below the new roots and remove the plastic. Soak the root ball for three to four hours, pot it up, and place it in a sheltered spot for a few days. Let outdoor plants grow in their pots for a few months before planting them out.

Propagating Plants

Barbara W. Ellis

One of the easiest and most economical ways to increase your plant collection is to learn how to propagate them yourself. You can start new plants in a variety of different ways—sow seed, root cuttings, layer, or divide them. Propagating plants is a fascinating hobby that requires little in the way of supplies or equipment, and the techniques involved are straightforward and relatively easy to master. Best of all, creating new plants is fun and rewarding and provides an opportunity not just to create but to share plants with other gardeners.

There are two types of propagation techniques: sexual and asexual propagation. Plants grown from seed or spores have been sexually propagated, because most seed is the result of cross-pollination and contains genetic information from two different parents. Vegetative propagation is the term used for the many different asexual ways plants can be propagated, such as division, cuttings, or layering. All vegetative techniques involve removing sections of stems, roots, or leaves from a parent and inducing them to develop into new plants by providing conditions that encourage the production of roots and shoots. Plants propagated vegetatively are genetically identical to the parent plant. For this reason, vegetative propagation is used to make exact copies of plants that have special features such as taste, color, disease resistance, size, or form. Since many cultivars do not come true from seed (because seeds resulting from cross-pollination are not genetically uniform), and others do not produce seed at all, vegetative propagation is an important way to perpetuate valuable cultivars. For example, 'Bartlett' pear was created in 1770 and is enjoyed today only because of vegetative propagation. Another benefit of vegetative propagation techniques is that they generally yield much quicker results than growing plants from seed.

Vegetative Propagation

What makes it possible for individual plant parts to transform themselves into complete plants with roots, stems, foliage, and flowers of their own? All plants have specialized clusters of cells that can divide very quickly and differentiate into all the structures a plant needs to grow. These clusters of cells, called meristem or meristematic tissue, are found in the growing tips of roots, stems, and branches. As the plant grows, it is the meristematic cells that differentiate into new stems, roots, foliage, and flowers. Meristematic tissue also lies dormant in the plant, most notably in dormant buds, which will begin to grow if given the proper stimulus. For example, the moist, humid conditions needed to root a cutting will awaken the meristem in dormant buds and cause it to begin producing roots and shoots. Plants such as orchids propagated by a specialized technique called meristem or tissue culture are grown from single cells of meristem tissue. Certain types of plant cells can also turn into meristemlike tissue, causing roots to arise on the cut surface of a stem even if dormant buds are not present.

SUPPLIES

The first task is to assemble the tools and supplies you'll need. You'll probably need the following items:

- **Propagation knife.** For taking cuttings or making cuts to encourage roots to form on a layer, you'll need knives of various sizes and shapes. Specially designed propagation

Continued ➔

knives usually have a thin, straight blade. They must be kept very sharp.

- **Pruning shears.** You'll also need one or several different sizes of pruning shears and/or scissors for cutting stems, leaves, or other plant parts.
- **Containers.** In some cases, new plants can be propagated and planted directly into the garden, but you'll need containers for rooting cuttings or potting up new plants. Many different sizes and shapes of containers will work, as long as they are deep enough to hold the base of the cuttings, provide drainage, and can be covered in some manner to maintain humidity. At least 2 inches deep is best. Try using plastic garden flats and pots or plastic food containers. Plastic shoe or sweater boxes also are very useful because cuttings can be stuck in rooting medium spread in the bottom, and with the top in place they provide the humid conditions cuttings need.
- **Rooting medium.** A good rooting medium provides enough support to hold the cutting firmly and also retains moisture, but is porous enough to drain well and allow roots to penetrate. Many mixtures will work, but a mixture of equal parts sterile, coarse sand (not builder's or beach sand) and vermiculite or perlite are recommended as the initial medium. After rooting, cuttings can be transplanted to a medium that is richer in nutrients—a mixture of one or several of the above ingredients with an equal amount of sterile potting soil is fine.

  A container of water will serve as an effective rooting medium for many plants—coleus or philodendrons, for example—but this approach has drawbacks. Roots that are produced in water tend to lack the structure and strength of roots produced in other media, and they do not transplant to soil well since they tangle together and are easily damaged.
- **Dibble.** This is a pencil-like instrument that is used to make a cylindrical hole into the rooting medium for the cutting. Making a hole with a dibble (or the end of a pencil) prevents the cut end of the cutting from being damaged when it is stuck into the soil. It also prevents rooting hormone from rubbing off.
- **Atomizer.** A simple atomizer or spray bottle will make the task of increasing humidity around the cuttings quick and easy.
- **Disinfectant.** Bleach or alcohol are excellent disinfectants for cleaning pruning shears and knives. Make a solution of 3 parts water to 1 part bleach or alcohol. Dip implements into a container of this disinfectant after taking each cutting to avoid transporting fungi, bacteria, or other diseases from plant to plant.
- **Heating cable.** Although this piece of equipment is optional, many kinds of cuttings will root more quickly if provided with bottom heat. You can provide bottom heat by setting propagation containers on heated surfaces, such as the top of a radiator, refrigerator, or hot water heater. Or invest in a commercial heating cable like the ones sold for speeding the germination of seeds. These are available from most mail-order nurseries or well-stocked local garden centers. They will generally keep the temperature of the medium about 5° to 10°F above the temperature of the surrounding air, and can be easily positioned along the bottom of a propagation box beneath the soil.
- **Rooting hormones.** Rooting hormones are very useful in encouraging hardwood and other difficult-to-root cuttings to form roots, but they must be used sparingly and carefully. Generally, only the tip of the cutting is dipped into the powder; in this case, more is not necessarily better. It's also important to realize that these hormones can be contaminated with fungi and other organisms. When using them, pour a small amount into a separate container, use it to treat the cuttings you're planting on a given day, then throw away the excess. It's best to store rooting hormones in the refrigerator to extend the shelf life, which ranges from six months to a year. Some formulations include chemical fungicide, but you can purchase ones that don't and use sulfur to control fungal diseases.
- **Antitranspirants.** Often used to protect evergreen foliage from water loss and windburn in winter, antitranspirants will reduce the amount of moisture lost through foliage. For this reason, they help prevent a cutting from drying out before roots have a chance to form. Antitranspirants are also quite useful when transplanting cuttings to larger pots or to the outdoors, because they reduce water loss and help plants overcome stress.
- **Propagators and mist beds.** If you're serious about getting professional results, you may want to invest in a propagation box, which is much like a miniature greenhouse. It provides uniformly high humidity, and most models come equipped with heating cables. You can also make one yourself with plastic stretched over a wood or wire frame and a heating cable spread under a layer of vermiculite or sand. You can suspend fluorescent lights over the box if necessary. Be sure to provide for ventilation to prevent excessive humidity from building up.

  A mist bed is a more sophisticated piece of equipment, which is relatively expensive and is generally used in a greenhouse. A heating cable regulates bottom heat while a timer and a series of small mist nozzles spray the cuttings with a fine mist of water at intervals throughout the day. A mist bed isn't enclosed, because the frequent misting provides all the humidity the cuttings require.

Rooting Cuttings

Rooting cuttings is one of the easiest, most popular ways to propagate plants. Although there are several different types of cuttings, two basic concerns apply to all types. First, since cuttings are removed from the parent plant before roots develop, they dry out easily. To root them successfully, you'll need to provide a rooting medium that is well drained but remains moist at all times. They also require high humidity to reduce water loss. Second, it's important to provide as antiseptic conditions as possible to discourage disease organisms and fungal spores from invading the wound(s) made when taking the cutting.

Propagation Datebook

With so many options for propagating plants, it can be hard to decide what to do when. Layering can be done anytime in spring, summer, or fall. In general, divide plants either in early spring, just as new growth begins, or in summer after bloom. Take cuttings after the flush of new spring growth is over. Propagate houseplants anytime. Here are some propagation suggestions to mark on your calendar:

- In early spring, divide asters, yarrows, and other perennials. In early to midsummer, take softwood cuttings of ornamental shrubs.
- In July, take root cuttings of oriental poppies (*Papaver orientale*), bleeding hearts (*Dicentra* spp.), bugloss (*Anchusa* spp.), and other plants with thick, fleshy roots.
- In August, divide peonies (*Paeonia* spp.), digging carefully so you don't damage any more eyes than necessary. Replant with eyes not more than 2 inches below surface.
- In August, start cuttings of wax begonias, coleus, and geraniums for winter bloom indoors.
- In August, propagate groundcovers such as pachysandra and periwinkles (*Vinca* spp.) in cold frames.
- In August, start cuttings of subshrubs like lavender, santolina, sage, and thyme.
- In late summer, take cuttings of broadleaved evergreens, such as boxwoods (*Buxus* spp.), arborvitaes (*Thuja* spp.), and hollies (*Ilex* spp.).

Taking Stem Cuttings

Regardless of the type of stem cutting you're taking, it's best to start with short ones, between 3 and 6 inches in length. Remove all flowers and flower buds so that the plant's energy will go toward root rather than flower production. Also remove the bottom leaf or set of leaves so that the foliage won't touch the rooting medium.

It's important to make a clean cut without crushing the stem. Use a knife on soft and semihardwood cuttings; shears on thick stems or for hardwood cuttings. Make the cut at a 45-degree angle, so that the cut has more surface area from which the roots will grow. The top of the angled cut should be between ¼ and ½-inch below a leaf node (where leaves emerge from the stem). Be sure to sterilize your knife or shears with disinfectant between cuttings to avoid transporting fungi or disease organisms from plant to plant.

Fill the containers you'll be using with rooting medium, water thoroughly, and allow excess water to drain away before sticking in the cuttings. Use a dibble or the end of a pencil to make holes to insert the cuttings, spacing the holes 2 to 4 inches apart depending on the size of the cuttings. Insert the cuttings at least 1 inch into the medium, and make sure the bottom set of leaves is not in contact with the medium.

After planting the cuttings, don't let the rooting medium dry out. There are several different ways to water the cuttings. You can gently water the surface of the medium using a watering can with a fine-spray nozzle. Another method is to water from below by setting containers in a pan or tray of water and allowing water to seep upward through the drainage holes. Either way, be sure to allow the containers to drain after watering because they should not be left sitting in water. A third method is to set the propagation container atop a water-filled pebble tray, with one or several wicks running from the medium, through drainage holes in the bottom of the container, into the water. (Strips of nylon stockings work fine as wicks.) Be sure the bottom of the container doesn't make direct contact with the water.

Cuttings require high humidity (near 100 percent) in order to root without drying out. You can place a plastic bag over a single pot or group of pots and support it with thin strips of wood or heavy gauge wire to keep it from touching the foliage. Or use garden flats with clear plastic covers, sweater boxes, a cold frame or hotbed, a propagation box, or a mist bed to maintain humidity.

Ideally, the air temperature within the propagation container should be 70°F or less. Within the rooting medium, between 60° and 70°F is best. Adequate light is important, but bright light will literally cook the cuttings. Either natural, indirect sunlight or light from fluorescent fixtures is fine. Make sure fluorescent lights are suspended approximately 6 to 10 inches above the propagation container.

Types of Cuttings

HERBACEOUS CUTTINGS.
These are stem cuttings taken from herbaceous plants, meaning plants that do not develop woody tissue. Many houseplants, annuals, perennials, herbs, and vegetables can be propagated by this type of cutting. Herbaceous cuttings can be taken at any time of the year, but late spring and early summer are probably

Continued ➔

best. Most plants are in active growth at this time of year and actively growing shoots that will yield the best results.

SOFTWOOD CUTTINGS.
Similar to herbaceous cuttings, softwood cuttings are taken from woody plants such as ornamental shrubs, small-fruit bushes, and many trees. Softwood cuttings should be taken from actively growing shoots in late spring or early summer. These cuttings should be 2 to 4 inches in length.

SEMIHARDWOOD CUTTINGS.
This type of cutting is similar to softwood cuttings but is taken later in the year, when active growth has slowed down and no new leaves are being produced. The stems are becoming woody (hard) at the base, but the stem tips are still soft. Also called semiripe cuttings, these should be between 4 and 6 inches long and should be taken in late summer. They will usually require the addition of a rooting hormone for best results.

HARDWOOD CUTTINGS.
These are stem cuttings taken from outdoor deciduous trees and shrubs after the leaves have dropped. They are taken from new wood that is thoroughly ripe or woody and dormant. These are taken in late fall to early spring and should be between 5 and 12 inches long.

Because they are dormant, hardwood cuttings are treated quite differently than softwood or semihardwood cuttings. Place them singly (or in bundles of the same species or cultivar) in a large container filled with moist sand or vermiculite. Place the container in a cool (35° to 45°F), dark location for the winter months. When lifted in spring, the cuttings will have developed a protective callus over the cutting wound, from which roots will emerge upon planting. Dust the callus with rooting hormone and root the cuttings in a manner similar to that recommended for the other types of cuttings listed above. Bottom heat is often effective at this stage. Once rooted, cuttings will be ready for transplanting to individual pots or outdoors.

Leaf Cuttings

Not many plants will propagate from leaves, but those that do (primarily a limited number of houseplants) provide a quick and easy way to increase numbers. Like stem cuttings, described earlier in the section, leaf cuttings require as sterile conditions as possible to discourage fungi and other disease organisms. They also need high humidity and a rooting medium that remains evenly moist.

The simplest type of leaf cutting consists of the leaf alone, without the petiole, or leaf stalk, attached. The base of the leaf is placed in the medium, which is kept evenly moist until one or more plantlets appear. Once the new plants have produced an adequate root system, the leaf can be removed and they can be potted and grown on. Jade plants (*Crassula* spp.) and piggyback plants (*Tolmiea menziesii*) are easy to propagate by simple leaf cuttings. There are several other types of leaf cuttings, which are described below.

LEAF AND PETIOLE CUTTINGS.
These consist of an entire leaf with at least ½ to 1½ inches of the petiole (leaf stalk) attached. Place the petiole into the rooting medium of a propagation container, and follow the standard procedures listed above for stem cuttings. One or more new plantlets will develop from the petiole, at which time the original leaf can be removed and the plantlets grown on in the propagation container until ready for transplanting. African violets are often propagated this way.

LEAF-BUD CUTTINGS.
As the name suggests, this type of cutting consists of a mature leaf, a dormant bud in the leaf axil, and a small amount of stem tissue (¼ to ½ inch in length) to which the leaf is attached. Place the base of the leaf into the rooting medium, covering the bud and the stem. The stem may be softwood, semihardwood, or hardwood. Then follow the same procedures described earlier in this section for leaf and petiole cuttings. The new plant will develop from the dormant bud. English ivy (*Hedera helix*) is especially easy to propagate in this manner.

SPLIT VEIN CUTTINGS.
The leaves of some plants will produce new plantlets anywhere along their undersurface where a cut vein is in contact with rooting medium. For these, remove a leaf from the plant and make slits across individual veins—one slit per vein, effectively severing a vein with each cut. Lay the leaf flat on the surface of the medium, right side up, with the underside in direct contact with the medium. You may need to tack down the leaf with hairpins or bent pieces of wire to be sure the leaf is touching the medium. Rex begonias are often propagated in this manner.

LEAF SECTIONS.
Some plants can even be propagated from small pieces of a leaf, as long as each piece includes a section of a large vein. For these, simply cut the desired number of leaf sections and place them vertically into the rooting medium. Be sure to place them right side up—with the end that was closest to the base of the plant in the medium. New plantlets will develop from the base of the primary vein. Sansevieria trifasciata, commonly called snake plant, is the plant most often propagated in this manner.

Cane Cuttings

Plants that produce canelike stems can be propagated by softwood cuttings, but one of the most productive approaches is to cut the cane into 2-inch-long sections, each of which must have a node (an old leaf scar and a dormant bud). Place each cutting horizontally into the rooting medium, with about

Proper Propagation

Plant propagation has its own special vocabulary. It's helpful to understand the meanings of certain terms as you read about how to propagate. Here are some of the basics:

Cutting. A cutting is part of a stem, leaf, or root that is removed from a plant and forms a new plant that looks like its parent. You can take cuttings from a wide variety of herbaceous and woody plants.

Division. Division is the separation of a multi-stemmed plant into smaller plants. It's a common way of propagating bulbs, tubers, groundcovers, and clump-forming perennials.

Layering. Layering is a technique that encourages root growth on stems that are still attached to the parent plant. Tip layering and air layering are variations on the basic layering method.

Grafting. Grafting is a method for joining a stem piece, called a scion, to a compatible plant supplying the root system, called the rootstock. The technique brings the cambium (actively growing tissue between the bark and wood) of the scion and the rootstock into close contact so that the plants will grow together as one. There are several ways to graft, including whip-and-tongue and bud grafts.

⅓ of the cutting (including the dormant bud) located above the surface of the medium. Use bottom heat to promote rooting, and follow the same procedures recommended for other stem cuttings. Dieffenbachias (*Dieffenbachia* spp.) and dracaenas (*Dracaena* spp.) can be propagated in this manner.

Root Cuttings

Many fleshy-rooted plants can be propagated from the simple technique known as root cuttings. Root cuttings are taken once the plants have become dormant at the end of the growing season. Lift the parent plant and root; prune it by severing several of the large, fleshy roots. Then replant the parent plant. This root pruning will not harm the plant, provided you don't remove too many roots.

Cut each root into 2- or 3-inch sections (4 to 6 inches long for trees). It's important to keep track of polarity, which end of the root was closest to the parent plant (up) and which was farthest from the plant (down). That's because the oldest part of a root cutting (generally the widest end) must be placed at the surface of the propagation medium with the youngest part of the cutting placed into the medium. They won't root upside down. One easy way to keep track is to make the cut at the "top" or oldest end of the root horizontal and the "bottom" cut at a 45-degree angle. That way, each cutting will have a recognizable top and bottom for planting.

To plant root cuttings, fill a container with equal amounts of peat and ordinary sterilized potting soil. Thoroughly moisten the soil and let the water drain away. Then dust the bottom of each cutting with powdered sulfur to control fungi. Use a dibble to make insertion holes, allowing no less than 1½ inches between holes, and place the cuttings into the holes. Again, make sure that the cuttings are oriented with the oldest or top part nearest the surface. Cover the container with ¼ to ½ inch of pea gravel or coarse sand.

Crop Harvesting Schedule

When to Harvest	Crops
Daily	Beans, green and filet
	Beets
	Blackberries
	Corn
	Cucumbers
	Peas
	Raspberries
	Zucchini
Weekly	Eggplants
	Leeks
	Melons
	Peppers
	Tomatoes
As Needed	Beans, dry
	Carrots
	Brussels sprouts
	Kale
	Parsnips
	Potatoes
	Winter squash

If you are propagating hardy plants, you can place the container in a cold frame. Keep cuttings of tender plants in a frost-free place. Water only when the medium begins to become dry; too much moisture can promote the growth of fungi, which is the prime cause for loss of root cuttings. When new shoots appear, provide a mild dose of fertilizer such as manure tea. Once the plants have become established, they can be transplanted to individual pots or moved to the garden.

Division

One of the easiest ways to propagate clump-forming plants is to divide them; that not only serves to propagate, but also helps rejuvenate clumps that have spread and left an old, overcrowded center that has ceased blooming. Plants propagated

Continued ➔

in this manner are dug, separated into individual plantlets, each with its own shoot(s) and roots, and then replanted. Many perennials are divided in early spring, when plants are just beginning to awaken from winter dormancy and begin actively growing. However, spring-blooming plants are best divided in early summer, just after bloom in the case of irises, or in late summer or early fall as they approach dormancy, as in the case of such plants as peonies or hostas.

To divide a plant, dig the parent plant and either gently pull or cut apart sections of the crown. You can cut with pruners or use the sharp edge of a spade or trowel. Replant the divisions as soon as possible, and keep them well watered both until you get them back into the ground and until they become established.

A number of plants such as raspberries and lilacs produce suckers or offsets that root either before or after they are cut away from the parent plant. Use a knife to cut them away from the parent plant or use a shovel and dig the sucker or offset if it has already rooted. Make sure the cut is as close to the parent stem as possible. Replant at the same depth as when attached to the parent plant.

Bulbs can also be propagated by yet another form of division; bulbs such as daffodils that produce offsets at the base of the main bulb can be dug and separated. Once the bulb has finished blooming and the foliage is turning brown, it's a simple matter to lift the parent bulb, remove the offsets, and replant. Offsets will generally take one to several years to reach blooming size.

Layering

Most plants that have long, flexible stems are candidates for another propagation technique called layering. Layering is a method to encourage roots to develop on a section of a plant where they would not normally grow (such as on aboveground stems) while the stem is still attached to the parent plant. This process can occur naturally, such as when a forsythia branch arches downward, touches the soil and roots. It's also easy to induce the process.

To layer a plant, start with a young, vigorously growing outer stem. In mid- to late spring, dig a small, shallow hole or trench (1 to 3 inches deep) several feet from the center of the parent plant. Arch the young stem downward so that its tip or a portion near the tip can be placed into the hole. Then fasten it down with a wire wicket or a rock if necessary and cover it with soil. Keep the soil evenly moist, and by the end of fall a complete root system should have formed at the base of the buried portion of the stem. The offspring plant can then be severed from the parent plant, either that fall or the next spring, and planted elsewhere. Some stems will root more readily if a slanting cut is made partway through the stem at the point where it touches the soil.

Serpentine layering is a very similar technique used to produce many plants from a single, flexible stem. In this case, make a slanting cut every 8 to 10 inches along the length of the stem. Then bury the stem along the ground, fastening the cut portions into the soil in holes dug at intervals away from the plant. Leaf nodes buried underground will generate roots; those left above will grow shoots. When lifted in spring or fall, a root system should exist at each point along the stem where it was cut, and each new plant can be severed from the original parent stem and replanted.

AIR LAYERING

Some plants that do not have flexible stems can be layered in yet another way, through a technique called air layering. To air layer a plant, cut a small horizontal wedge on one side of a healthy stem, partway through the stem just below an old leaf scar (node). Dust the wound with rooting hormone, and pack a ball of moist sphagnum around the stem, thickly covering the wound. Hold the sphagnum in place by wrapping black plastic around the stem and securing it with twist ties or tape. Keep the sphagnum evenly moist until roots develop. Once the roots begin to emerge from the sphagnum, you can sever the offspring from the parent and replant. Air layering is often used to root the tops of houseplants such as dieffenbachia (*Dieffenbachia* spp.) that have lost their lower leaves. The parent plant will usually resprout below the cut.

STOOLING.

Another form of layering, called stooling or mound layering, involves wounding each stem of a multistemmed plant about 6 inches above ground level, and then mounding soil over the base of the plant and the wounds. This is usually performed in spring. By fall, each stem will have developed its own root system from the point of the wound and can be severed from the parent plant and replanted.

Propagating Tips

Fern Marshall Bradley

Propagating is one of those gardening skills that seem a bit intimidating at first—until you try it. Once you see how easy it is to grow your own, you'll be taking snips and cuttings from plants all over your yard.

There's a method of propagating to suit any gardener's personality. You can start new plants in a downright lazy way, letting Mother Nature do the work for you through a technique called layering. Or you can experiment with soil mixes and rooting aids—even rig up a homemade fog propagator using a room humidifier.

Our experts offer innovative tips along with time-proven techniques for increasing your stock of flowers, shrubs, and fruits. If you're a beginner, start with the simple methods and the easiest plants.

Enjoy Success with Cuttings

Cut a leafy stem off of a plant, and chances are you've got a cutting to root. Taking stem cuttings can be one of the simplest ways to propagate. Rooting woody cuttings can be a little trickier, but still easy enough that nearly everyone can succeed. Try the following tips for the best results with cuttings from every type of plant from houseplants to shrubs and trees.

A SIMPLE SHORTCUT FOR MORE PERENNIALS

Save money on perennials by growing your own from cuttings. "Take cuttings of soft but not too young growth, down to about the third leaf, in early to midsummer," recommends Dave Bowman, a co-owner of Crownsville Nursery in Maryland, which specializes in perennial flowers. Put them in a nursery bed or flat, and keep them out of direct sun until they develop their own root systems. You can cover the cuttings with plastic strawberry baskets or push leafy branches into the ground around them for temporary shade.

Cuttings may show new top growth without being rooted. To be sure new roots have formed, give your cuttings a slight tug, says Bowman. If they don't let go easily, they have rooted.

REVIVE GRANDMA'S ROSE JARS

Many old-time gardeners have successfully propagated rose cuttings with nothing more than an old canning jar. "I remember, when I was a child, my grandparents used to start roses readily. They'd just snip off a piece, stick it in the ground, and cover it with a fruit jar," says Dave Dunbar, a Penn State extension agent.

In the spring, take cuttings of succulent new growth. Push a cutting a few inches deep directly into good garden soil, then cover it with an upside-down glass jar. The jar acts as a mini-greenhouse, keeping the cutting moist and humid. A spot between other plants in the garden makes a good nursery. You won't forget about your cuttings when you see them frequently, they'll be watered along with the rest of the garden, and the taller plants will shade the sensitive cuttings from the sun. Your success rate won't be as high as with more advanced techniques, but it requires no special equipment and can be done on the spur of the moment—just like in Grandma's garden.

KEEP IT CLEAN

Diseases are hard to control in the warm, moist environment that cuttings need. To cut your losses, "start with sterile soil and sterile water," advises Steve Reynolds, a sales manager at Furney's Nursery in Washington State. "Boil the water and cool it before moistening your growing medium."

Be alert for the first signs of problems, such as curled or spotted leaves or visible fungal growth. Move quickly to remove the affected cuttings as well as neighboring cuttings. Air the flat, and try again. Reynolds takes the hard line if disease gets a toehold. "Once fungus is present, you may as well ditch it," Reynolds says. Start from the beginning with fresh medium, new cuttings, and a sterilized container. Be sure to make clean cuts to avoid ragged tissue that will decay and may cause disease problems.

TAKE CUTTINGS FROM MORE-WILLING WOOD

For the best success with cuttings, take them from young growth. "Cuttings of juvenile plants of any species root much more easily than cuttings of mature plants," states Kenneth W. Mudge, Ph.D., an associate professor of horticultural physiology at Cornell University in New York. How do you know if your forsythia or other parent plant is juvenile or mature? Flowers are the tip-off: Flowering growth is mature growth. Flowering, mature wood is usually found at the top or outside of the plant, while suckers and other low growth on the same plant are usually nonflowering, juvenile wood. As much as 90 percent of your cuttings should root if you take them from younger growth, says Dr. Mudge.

CUT 'EM LOW

Sprawling shrubs or trailing plants are usually easy to start from cuttings, but plants with a strong upright growth habit, like many shrubs and trees, can be a little trickier. That's because these plants are hormonally programmed for top growth. "Upright growers like rhododendrons and photinias are easier to root from cuttings if you take clippings from lower branches, where the 'straight-up' hormone isn't as concentrated," notes Steve Reynolds, a sales manager at Furney's Nursery in Washington State.

GET THE TIMING RIGHT

Most softwood cuttings are easier to root if they're made in late spring or summer, after the first flush of growth. As Steve Reynolds, a sales manager at Furney's Nursery in Washington State, explains, "Spring growth is most vigorous, but at that time a plant's hormones are geared for new top growth, not for rooting."

Individual species have their own quirks regarding timing, which you may have to discover through trial and error. For example, cuttings of bearberry (*Arctostaphylos uva-ursi*) taken in spring won't root, Reynolds says. He suggests starting bearberry cuttings in July or August.

On the other hand, cuttings of burning bush (*Euonymus alata*) taken too late aren't successful. "As long as the leaves are green, it roots readily," says Kenneth W. Mudge, Ph.D., an associate professor of horticultural physiology at Cornell University in New York. "If you take cuttings when the leaves have turned pink, the cuttings will defoliate and will be hard to root."

MAKE A MINIATURE GREENHOUSE

Looking for ways to reuse clear-plastic soda bottles? You can turn them into miniature greenhouses for cuttings. John

Continued ➔

L. Creech, Ph.D., the former director of the U.S. National Arboretum, uses the improvised greenhouses to root azaleas and other plants. He cuts the bottom off of two bottles. He fills one bottom with moist sand, removes the colored-plastic bottom-rest from the other, and fits the two bottoms together.

"In July, I insert eight to ten cuttings, put the 'greenhouse' in a shady place, and keep the sand moist. It takes about six weeks for the plants to root," Dr. Creech explains. He then transplants the baby shrubs to pots filled with soil, keeps them in a protected place, and puts them out in the garden the following year.

KEEP CUTTINGS IN A FOG

Bathing cuttings in humid air is an essential step in getting them to take root. "The whole key to starting a softwood cutting," says Steve Reynolds, a sales manager at Furney's Nursery in Washington State, "is to keep the top of the cutting humid enough so it can live until the roots get established. Keep the humidity close to 100 percent."

Commercial growers use sophisticated fogging machines to supply humidity. Home gardeners can apply the same idea on a small scale, says Kenneth W. Mudge, Ph.D., an associate professor of horticultural physiology at Cornell University in New York. Dr. Mudge suggests using an ultrasonic cool-mist humidifier as part of a home fog propagator. (See the directions below for building a home fog propagator.) You can set up a fog propagator in a cool garage, on a shaded porch, or inside a greenhouse. Be sure that the propagator box isn't exposed to bright sunlight. "Shade is vitally important anytime you're rooting cuttings," Dr. Mudge points out.

You can find the materials to build the fog propagator at any lumberyard. Nails will work fine for fastening the parts together, although construction will be a little easier and a little sturdier (as well as slightly more expensive) if you use deck screws driven with a Phillips bit in your electric drill. Galvanized screws or nails are best because they won't rust in the propagator's humid environment. Also, galvanized nails grip better than "bright" nails. You can use untreated pine to build the frame, but it's best to coat it with flat black paint.

Here's how to construct the propagator frame:

1. **Make the base.** Cut 2 of the base sides to 34½ inches long. Cut the other 2 base sides to 21 inches long. Nail the longer pieces into the ends of the shorter pieces.
2. **Make and install the uprights.** Cut the uprights to 23¼ inches long. The key to making a sturdy propagator is to make all of the upright joints overlap the base joints. In other words, the seam where two uprights meet should never line up with the seam where two base pieces meet. Nail the uprights to the bases and then to their mating uprights. Make sure the uprights are square to the bases.
3. **Make and install the top rails.** Cut 1 top rail to 33 inches long, 1 top rail to 36 inches long, and 2 top rails to 22½ inches long. Again, you want to tie the top of the box together with joints that overlap the upright joints.

You'll need to set up the propagator frame on a tray or greenhouse bench containing several inches of gravel for good drainage. Set the humidifier inside the frame, and fill the remaining area of the frame with several inches of a thoroughly moistened fifty-fifty mix of peat and perlite. Add the cuttings, and cover the frame with heavy-gauge polyethylene. Be sure the plastic hangs down past the top of the base sides to create a closed chamber.

Reap the Dividends of Division

Dividing one large plant into several smaller ones is another easy technique for creating new plants. We most commonly think of dividing perennials, but you can also divide bulbs and ornamental grasses.

MUM'S THE WORD

"You can easily make 100 plants out of 1 chrysanthemum," says Dave Bowman, a co-owner of Crownsville Nursery in Maryland. "And for best growth, it's actually better to divide them every year." Go out to the garden in spring, he advises, and start pulling up shoots. Replant directly in the garden, or set out in a nursery bed until later in the season.

You can also take cuttings from potted chrysanthemums. Cut back the plant after flowering, and wait for new growth. Then make as many cuttings as you can, clipping them off at

the third set of leaves. Start the cuttings in a flat, cold frame, or nursery bed.

MAKE 100 DAYLILIES IN A DAY

If an established clump of daylilies is thriving in your garden, all you need is a sharp knife and a shovel to make a whole bed of these appealing perennials. "Do you know what a Ginsu knife is?" asks Chick Wasitis, laughing. Once ubiquitous on late-night television, those hard-working knives "make a terrific tool for slicing up clumps of daylilies," says Wasitis, a co-owner of Crownsville Nursery in Maryland, where he grows more than 1,000 kinds of perennials.

To divide an established daylily, lift the plant after it blooms, in mid- to late summer. Cut foliage back to 4 to 5 inches. Use a Ginsu knife, a handyman's razor-knife, or a butcher knife to separate the clump into divisions of at least a single fan with some roots attached. (Watch those fingers!)

GROW A HOST OF DAFFODILS

Shallow planting is the key to encouraging daffodils to divide. Brent Heath, a co-owner of the Daffodil Mart in Virginia, says that planting the bulbs 4 inches deep will spur bulb division. "But you're taking a risk with winter cold," Heath points out. "In winter, you may lose them."

Heath prefers to plant deep and let hybrid daffodils multiply naturally. In good growing conditions, daffodil bulbs planted deep will often double naturally in size each year, producing twice as many flowers the following season. "When you get up to 16, 32, or 64 flowers in a clump, the bulbs tend to stop multiplying. What you have is a big clump of little bulbs," Heath explains. This is the time to replant. In late May or early June, about eight to ten weeks after bloom, lift the clump, and gently shake off the dirt. Let the bulbs come apart naturally—don't pull them. Then plug the bulbs back into the soil. Plant the big bulbs 6 inches apart.

It's best to put small bulbs, called offsets, in a nursery bed until they reach maturity. Keep in mind that even under optimum conditions it will take three years until these offsets come into bloom, says Bill Kennedy, a customer representative for Van Engelen, a Dutch bulb nursery in Connecticut. Label the cultivars so it will be easy to move them into the garden as they mature. In fall of the following year, lift the bulbs, and move them to their homes in the bed or border.

SCALE A LILY BULB

If you love lilies, the good news is you can easily propagate enough of them to fill your yard. Bob and Diana Gibson, co-owners of B & D Lilies in Washington State, grow lilies by the acre, and they propagate many of their lilies by using scales from the mother bulb. "We sacrifice our bulbs, taking off the scales down to the pit," notes Bob Gibson. "But you can make four or five new bulbs every year by taking just the outer ring of scales. That way, you won't hurt the mother bulb at all."

Dig up the lily bulbs in fall after the foliage has nourished the bulb and died back. Mix up a bucket of potting medium for your scales. The Gibsons suggest 5 pounds of vermiculite, lightly moistened with 1 cup of water. Keep the mix barely moist so that a handful doesn't stick together. Remove the outer ring of scales from each bulb. Set the bulbs aside, and replant them in the garden as soon as possible, positioning them so that the top of the bulb is at least 6 inches below the soil surface. Let the scales dry in a shady place for one day so that a callus forms. Fill plastic sandwich-size bags with the moistened vermiculite, and use a pencil to poke several holes for ventilation in each bag. Add several scales to each bag, then store the bags in a warm (70° to 72°F), dark place.

At the end of three months, bulblets the size of green peas will have formed on each scale. Put the scales with bulblets in the refrigerator for 10 to 12 weeks, then plant out in a nursery bed, in light shade. In 3 to 4 weeks, the bulblets will put up a single leaf. By the end of the season, each plant will have three to four leaves. In another season, they'll grow a tall stem but no flowers. In fall, move them into the garden where they are to grow. At the end of the following year, they'll flower.

DON'T FEAR BOUNTIFUL BULBLETS

Lily bulbs form bulblets naturally in the garden. "A common panic of people who grow lilies in their garden," says Diana Gibson, a co-owner of B & D Lilies in Washington State, "is the sight of 'suckers' coming up around the bottom of the plant, which they fear will sap the lily's strength." But lily suckers are really young plants growing from bulblets that form on the underground part of the stem. They will do just fine left where they are and will gradually mature into full-size bulbs, expanding the clump.

Let Your Plants Layer

Layering takes advantage of the natural tendency that many plants have to sprout roots along their stems. Try our experts' suggestions for using this technique to multiply herbs and shrubs or to regenerate a leggy houseplant.

BURY A BRANCH TO MAKE NEW PLANTS

Simple layering is one technique that really lives up to its name. You can propagate many of your favorites anytime during the growing season with this easy trick. "My lavender hedge all started with one plant," says Sally Roth, a garden writer from Indiana. "All I did was push a bit of soil over a low branch here and there in the spring. By the time I had the bed ready, a dozen new lavenders were rooted and ready to be snipped away from the mother plants."

Roth says she likes the fun of experimenting to see what will root. She merely bends a low branch to the ground and scoops a handful of soil over a short section of the stem, patting it down and sometimes weighting it with a stone if the branch is inclined to spring upward.

Continued →

The herb garden is a good place to start experimenting, suggests Roth. Many herbs, including absinthe, anise hyssop, artemisias, bee balm, clary sage, culinary sage, lemon balm, rosemary, scented geraniums, and thymes of all types, are especially easy to propagate just by scuffing a bit of soil over a low stem.

The perennial border, too, is full of likely candidates, such as candy tuft (*Iberis* spp.); catmint (*Nepeta X faassenii*); chrysanthemums; goldenrods (*Solidago* spp.); perennial asters; sweet William (*Dianthus barbatus*); thread-leaved coreopsis (*Coreopsis verticillata*), including the popular 'Moonbeam'; and periwinkles (*Vinca major* and *V. minor*). Vines such as English ivy, honeysuckle, jasmine, trumpet vine (*Campsis radicans*), and Virginia creeper (*Parthenocissus quinquefolia*) are also gratifyingly easy to propagate.

Herbs, perennials, and vines will usually root within several weeks, depending on the species. Even some woody shrubs can be propagated with this no-fuss method, though it may take a year or even two before they're ready to transplant. Try your hand with barberries (*Berberis* spp.), border forsythia (*Forsythia X intermedia*), rhododendrons and azaleas (*Rhododendron* spp.), rose-of-Sharon (*Hibiscus syriacus*), common lilac (*Syringa vulgaris*), pussy willows, willows (*Salix* spp.), viburnums, and weigelas (*Weigela* spp.). But don't limit yourself to these suggestions—experiment with whatever you like.

"Starting new plants this way appeals to the skinflint in me," admits Roth. "There's no investment in supplies, and it only takes a minute. If the plant doesn't root, I haven't lost a thing. And if it does . . . well, there's always room for one more."

SHORTEN YOUR HOUSEPLANTS

You can rejuvenate some overgrown, leggy houseplants by air layering, a layering technique that encourages roots to form on aboveground stems wrapped in sphagnum moss. This technique works well for tall houseplants such as schefflera (*Brassaia actinophylla*), croton (*Codiaeum variegatum*), dracaenas (*Cordyline* spp.), dumb canes (*Dieffenbachia* spp.), fatsias (*Fatsia* spp.), rubber plant (*Ficus elastica*) and other Ficus species, and Swiss-cheese plant (*Monstera deliciosa*). "This is a good way to make two shorter plants from one tall plant," notes Dave Dunbar, a Penn State extension agent. Dunbar uses air layering to keep his rubber plants and scheffleras in bounds. You can also experiment with air layering on plants outdoors that don't respond well to other types of propagation. Be sure you choose a healthy, vigorous stem for air-layering. Follow this technique:

1. Using a razor blade or small, sharp knife, make a shallow, 2-inch-long slit in the stem anywhere from 6 to 18 inches behind the growing tip.
2. Sprinkle some rooting hormone on the cut, insert a wooden matchstick to keep the cut open, and then wrap with damp, long-fibered (unmilled) sphagnum moss.
3. Cover the moss with clear plastic, and secure the bundle at its top and bottom with masking tape.
4. When you see roots poking through the moss, cut off the new plant just below the new roots, and remove the tape and plastic. Soak the root ball of the new plant for 3 to 4 hours, and pot it up.

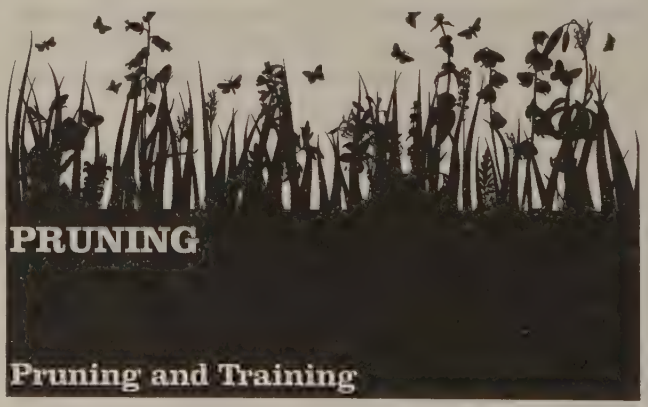
The Craft of Grafting

Many gardeners never venture to try grafting. It seems mysterious and tricky, and indeed it can be. If you'd like to try grafting, refer to a book on propagation for details on the technique. Here we've included a few hints from the experts for gardeners who have taken the plunge.

NAIL GRAFTING SUCCESS WITH PRACTICE

"Grafting is easy," says Doug Merkle, the operations manager for Indian Wells Orchard in Washington State, "but practice is the key." Merkle often uses a drywall nail to hold a graft on an apple tree together, then tightly wraps it with masking tape. Be sure that the two stems are joined cambium-to-cambium. (Cambium is a thin layer of actively growing tissue between the bark and the wood.)

"It takes manual dexterity to make good grafting cuts," says Juanita Popenoe, Ph.D., an assistant professor of plant and soil sciences at West Virginia University, "plus a lot of practice. The more you do it, the better you are at it." Inspired gardeners who are all thumbs may want to invest in a professional top-working tool, which is available from A. M. Leonard Nursery Supply Company. It's expensive, notes Dr. Popenoe, but very precise. The tool makes a V-cut in the rootstock and an exactly matching cut in the scion.



Fern Marshall Bradley

Pruning may seem like a mysterious art. The good news is that once you become familiar with pruning, it loses its baffling quality. If you learn how to make two basic pruning cuts—called heading cuts and thinning cuts—and understand how plants respond to those cuts, you can change pruning from a chore to a creative outlet.

Whenever you prune, evaluate which kind of pruning cuts will help control size or direction of growth, or produce better

flowering or fruit production. These tips from top arborists and garden designers will get you started on a new, enlightened pruning routine.

Controlling Plant Size

We all love watching our landscape plants slowly grow and change with time. But sometimes growth can get out of hand. With regular pruning, you can prevent shrubs from turning the front walk into an obstacle course and keep that luscious fruit in the home orchard within easy reach.

PRACTICE SAFE PRUNING

With sharp shears, loppers, and a pruning saw, you can control the size and shape of most shrubs and small trees. But don't try to take on too much. Alex L. Shigo, the author of *Tree Pruning*, sets the following limits:

- If a branch is over 2 inches in diameter, don't try to cut through it.
- If you must use a ladder, the tree is too big for you to prune yourself.
- Never use a chain saw.
- Never prune near a utility line.

For limbs of large diameter or for tall trees, you can call upon another tool—a professional arborist. "If trees are of any size, the liability and safety issues are such that you'll want to have someone with experience handle the pruning," recommends Dan Neely, Ph.D., the editor of the *Journal of Arboriculture*.

RIGHT TOOL, RIGHT TASK

You wouldn't use a butcher knife to slice a loaf of bread or a paring knife to cut a watermelon in two. Likewise, you shouldn't cut tiny twigs with a pruning saw or large limbs with pruning shears. Pruning tools, like knives, come in graduated sizes and strengths for different diameters of wood. Pick the right model for whatever task lies ahead. Doing this allows you to make a clean cut every time and leave behind healthy, intact wood. Here are some suggestions on tools to choose and how to use them:

Hand-held pruners. Pruners are best for heading back or thinning out medium-size branches.

Hedge shears. Use these for manicuring formal hedges.

Long-handled loppers. These work well for pruning branches up to 1½ inches in diameter.

Pruning saws. These saws are good for cutting off limbs up to 2 inches in diameter. "Look for new Japanese blades on pole saws, which have revolutionized pruning," says Alex L. Shigo, the author of *Tree Pruning*. "The cut they make looks like it has been shaved with a razor."

Even if your pruning tools are not high-tech, they will work well if you keep the cutting blades sharp. "They must slice, not tear the wood," says Dan Neely, Ph.D., the editor of the *Journal of Arboriculture*.

SELECT STRATEGIC STEMS

The key to creating a sound strategy for pruning a deciduous or broad-leaved evergreen shrub is to first figure out how the plant is constructed. Just as a person's ankle bone is connected to the knee bone, which is connected to the leg bone, shrubs are networks of interconnected pieces. Each piece of the plant can have a unique reaction to pruning.

Some parts of a plant are better targets for pruning than others. Ken Miller, a principal of Ken Miller Horticultural Consultants in Missouri, looks for medium-size stems. They resprout new growth readily, unlike larger branches or trunks. They aren't prone to producing an excess of surplus shoots, which is a common result when you shear small twigs. Usually, the best stems for pruning range from about ¼ to ⅝ inch in diameter. "They are slightly thinner than a fat Magic Marker," Miller says.

Once you find stems of the appropriate size, begin removing them one at a time. Look especially for long or overcrowded stems: Your goal is a compact shrub that maintains the original integrity and plant form of the species.

CORNER THE COLLAR

One cardinal rule in pruning woody plants is to not mess with the branch collar—the natural bulge at the base of the branch. This defies common practice of past decades, when pruning professionals routinely recommended cutting off limbs flush with the trunk. More recent research shows that cutting off the branch collar eliminates a natural barrier that keeps pests and diseases from infiltrating the core of the tree.

"Every woody plant has a collar," says Alex L. Shigo, the author of *Tree Pruning*. "This is true of shrubs, trees, even roses. Some people believe you can hack at will. Then cankers or other fungal diseases move in. People blame it on something else when the culprit is poor pruning."

Thus, when you see that a branch must go, prune carefully to keep the rest of the tree walled off from potential problems. Remove the bulk of the branch, leaving only a stub. Then carefully remove the stub, but leave the entire branch collar.

The branch collar swells slightly broader than the branch. It rings the branch base and protrudes slightly from the trunk. If you are in doubt about where the collar begins and ends, study wild trees that have lost branches. All that remains is the collar, perhaps enveloped in new wood or sealed with a complete, round doughnut of bark callus.

You want to achieve the same results after you prune. Cut just outside where the collar balloons out from the branch. The angle you take will vary with each tree, even with each branch. Proper cuts will heal round, not oval, and should seal by the following growing season.

Continued ➔

TOPPING DOESN'T DO THE TRICK

One top tip that many tree professionals push is this: Don't top your trees. "A tree may respond vigorously when you whack off its head," says urban forester Dennis Lueck. "But it's an unhealthy choice for the tree and a hazard to the people beneath it."

The big cuts made when a tree is topped, Lueck explains, are an open invitation to invasion by fungi and bacteria. Rot starts at the cuts, then extends down the trunk and enters the root system, debilitating the tree. Although the flush of new growth may be vigorous, most of it grows straight up. This results in a very weak branch union, creating a joint that is likely to snap when the branches get large and heavy or when a forceful wind or load of snow comes along.

"If you do top a tree," says Lueck, "top it at ground level." Then replace the "too big" tree with a species better suited to the location. And spread the word about topping. Too many homeowners—and arborists—still resort to this tactic to reduce tree size.

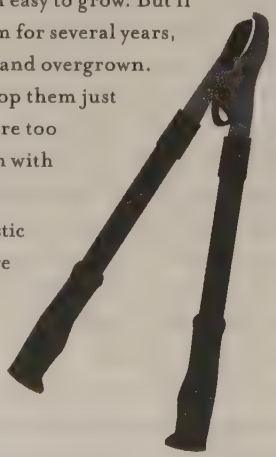
Maintaining Plant Form

Pruning also helps maintain and improve plant form. Plants need shaping and thinning to help light and air penetrate to all parts of the plant. This promotes good growth and helps minimize disease problems.

Radical Pruning

Roger Yepsen

When it comes to certain shrubs, it's easy to have too much of a good thing. Buddleia, caryopteris, forsythia, kolkwitzia (beauty bush), lilac, and mock orange have an exuberance that makes them easy to grow. But if you've skipped pruning them for several years, they may have become leggy and overgrown. When plants are dormant, lop them just above the ground. If stems are too thick for lopping, go at them with a saw.



This may seem like a drastic step, but it will hurt you more than it hurts the plants. Come next spring, they will sprout new growth and quickly revive.

SELECTIVE PRUNING SIMPLIFIED

There's an art to directing the shape of trees and shrubs. Vaughn Banting, a Louisiana landscape designer and bonsai artist, has mastered that art while crafting exquisite miniature bonsai trees. He applies the same techniques to shape lush landscape plants. Simply put, he cuts stems back to a bud that will grow in the direction he wishes.

"At the base of every leaf and stem on deciduous trees and broad-leaved evergreens, there is a dormant axillary bud. If you cut the stem just beyond that area, the leaf will give rise to an axillary shoot. If the leaf points left, so will the new shoot," says Banting.

Likewise, if the leaf is under the stem, the new branch will point down. If on the top, the shoot will point up. If the plant has opposite leaves like a maple, dogwood, or viburnum, you can't predict which bud will grow after pruning. Decide which bud you want to grow out, and damage the other bud with your thumbnail.

"This kind of attention to detail is the difference between training plants and just chopping them off," says Banting.

SHAPE TREES FROM THE START

For a young tree, the leader is the core of strength that supports lesser limbs. If a second branch arises that grows strongly upright, the union of that branch with the trunk could be weak. Years later, when the upright branch has grown large and heavy or when it is weighted down by ice or snow, the union may split. Take steps while trees are young to prevent this problem, advises Richard W. Harris, Ph.D., a professor emeritus of landscape horticulture at the University of California at Davis. "There is a key to keeping attractive and safe-structured trees. On any fork in the tree structure, one side should be smaller to prevent the danger of future splitting," says Dr. Harris.

For up to five years after you plant a young tree, keep a close eye on the branches that arise from the leader. You can manipulate them to keep the tree strong and healthy for decades. Here are a few factors to juggle:

Maintain the leader. If several upright shoots arise near the top of the main trunk, encourage the strongest to become the leader by leaving it unpruned. Discourage others by removing their side branches and pinching off the top 2 inches of new growth or by heading the entire branch back by about one-quarter.

Develop strong attachments. Check all future side branches that emerge from the trunk. They should be one-half of the main limb's diameter or smaller.

Establish a branching framework. Lower on the trunk, you can pick the main framework of branches. Select branches that emerge from the trunk with a 45-degree or wider angle and radiate outward in different directions so they do not shade branches below. Be sure they are separated by 1 to 1½

feet of trunk. You can temporarily leave on other branches to strengthen the young tree, but retard their growth as detailed in "Maintain the Leader." Once the tree has a sturdy trunk and enough branches to keep the trunk shaded, begin pruning away these temporary branches. Start with the largest, and remove a few each year for a two- to three-year period to reveal the finished structure of the tree.

PRUNE A PICTURESQUE PINE

Instead of relegating pines to their usual roles as screens or green backdrops, sculpt them into focal points with character. "You can prune and pinch young pines to give them a much older look, a sense of timelessness. You can reveal their inherent beauty and character," says David Slawson, Ph.D., an independent landscape designer from Kentucky who specializes in Japanese garden design.

Pinch soft new growth on pines with your fingers rather than with pruning tools. Grasp a candle—an infant branch tipped with buds—at the point you want to pinch. (Dr. Slawson usually leaves between one-third to one-half of the total length.) Bend until the end snaps off. Thin off unnecessary candles by grasping the base between your thumb and forefinger and snapping them off. If you must remove a branch, don't just head it back—you'll be left with an ugly stump that won't regrow. Make the cut at a point where two branches join, or where the branch emerges from a main stem—this kind of cut will be much less noticeable.

When pruning pines, your window of opportunity is limited. If you want new buds to form on a candle, you must pinch it while it is immature, before the needles form. This means you must pinch during a one- to two-week period in spring. If you pinch later, the candle will develop into a single branch, but it will not sprout sideshoots.

Watch for candle-break so you don't miss your chance to prune. The downy tan candles will emerge from the end of each branch and stretch out 3 to 6 inches long, or longer near the top of the tree. Pinch before the candle tissue hardens and begins to flush green with young needles. If you cut candles with pruning shears, you will remove the tips of the needles and the ends will turn brown. Which candles you remove or thin will vary according to your goals, which might include one or more of the following:

Size control. Use candling (pruning candles) to keep a pine compact without shearing. This is more subtle than shearing, because you are shaping individual branches, Dr. Slawson explains. To maintain a pine at a constant height, remove one or two of the longest candles on each branch. Then pinch the side candles back to one-third of their full height, or about ½ to 1 inch long.

More height. If you want more height, leave the longest candle on each branch tip and thin out the others. Don't pinch the remaining candles back until the tree reaches the height you want. However, continue to thin for shape.

An aged effect. If you want a gnarled tree with character, find a young tree in a nursery that has an interesting twist or S-curve to the trunk and branches. After planting, remove up to one-third of the branches to reveal the trunk line. On each remaining branch, remove the largest center candle if it emerges straight out of the branch. This will stimulate development of a zigzag branching pattern. Also remove some side candles, leaving two to three candles that point outward and one or two that point inward. Pinch those candles to create feathery clouds of foliage on the end one-third of the limb.

AN EASY ESPALIER

If you want to get double-duty out of a narrow space, you can train dwarf fruit trees to spread lengthwise along a trellis or a series of horizontal wires. The espalier can be freestanding or against a wall or fence. You will prune and direct the trees to drench the fruit with sunlight and shape the limbs in a bold geometric design. Espalier specialist Henry P. Leuthardt says a Belgian fence, a lattice-like series of foliage-framed diamonds, is the simplest espalier to make. In this pattern, the key is to consistently secure the branches to the trellis as they grow. "The key word here is support," says Leuthardt. "Just because the branches start growing on an angle doesn't mean they won't go back to the vertical if left to their own devices."

Creating an espalier does take some attention and persistence. If you're up to the challenge, follow Leuthardt's recommended procedure:

1. Select three to five 1-year-old whips (unbranched nursery trees) of a spur-forming tree fruit like apples and pears. Plant them 2 feet apart along your trellis or other framework.
2. Head each tree back to 15 to 18 inches. This will encourage new branches to sprout just below the cut.
3. After new branches have appeared, prune off all but two strong branches. The two you keep should be on opposite sides of the tree. Train them to a 45-degree angle as soon as they need support. As the limbs continue to grow, tie each to the trellis at 1-foot intervals using either a flexible tie or something like cloth or raffia that will rot before cutting into the swelling branch. The limbs will cross neighboring tree limbs and create a latticework pattern.
4. From the second through the fourth year, the trees will sprout vertical branches. Head them back to 4 to 6 inches long so they don't compete with the main branch. They become short spur branches.
5. After about three years, the branches will stretch diagonally to the top of the trellis. At this point, cut back upright-growing branches and thin out excess growth to maintain the open diamonds between the branches.

Continued ➔

6. To maintain your espalier, prune at least twice a year. After the first lush growth of the growing season, thin the new green growth as necessary. You may have to prune again during the growing season if the weather encourages abundant growth, Leuthardt warns. "However, don't prune after Labor Day so you won't encourage late growth that could freeze during winter," Leuthardt says. Wait until the dormant season to clear out late summer and fall growth or to heavily prune an older espalier.

Come To Terms With Pruning

Don't prune blindly. Pruning instructions often include directions to make specific types of cuts. Be sure you know what they are before you tackle that plant!

Heading. Heading is cutting a branch back to a side bud or shoot. This makes plants shorter and bushier.

Thinning. Thinning is cutting a limb off at the base, either at ground level or at a branch collar. This technique opens the plant to air and light, and it directs growth.

Skirting or limbing up. These both mean pruning off the lower limbs of trees. Skirting or limbing up is usually done for easy passage underneath.

Shearing. Shearing is making a series of heading cuts along one plane, as when shaping hedges. When you shear, you slice through small twigs, leaving stubbed-off ends. This releases droves of dormant buds below the cut. They awaken, emerge, and flush outward in a mass of new growth.

Pinching. When you pinch, you are heading by nipping out the end bud or a short section of a twig or stem with your fingertips to make the plant more compact and bushy.

Deadheading. Deadheading is removing spent flowers, by pinching or cutting, to encourage formation of new buds. Some plants, like baptisias, won't rebloom after deadheading; others, like delphiniums, will. If you're saving seed or want the seed heads for decoration, don't deadhead.

Figuring Out the Timing

Once you've figured out *how* to prune properly, there's still the question of *when* to prune. In the sections below, our pruning specialists explain that removing part of the plant top stimulates growth at certain times of year and stifles it in other seasons.

THE WHYS AND WHENS OF PRUNING WELL

For most landscape plants, except conifers and disease-susceptible species, you have an almost endless choice of pruning times. You can juggle your pruning schedule to make your pruning most effective. See "Prune a Picturesque Pine" on page 235 for special instructions on timing and method for pruning pines and other conifers.

"Many errors are made in timing today," says Alex L. Shigo, the author of *Tree Pruning*. "A decade ago, correct pruning meant making a flush cut and a large trunk wound. We had to set the timing to minimize injury to a tree, not to doing the best job." Now, pruning experts recommend making a collar cut, which doesn't injure the tree. So timing considerations are different. "You should know why you are pruning, and start there," says Shigo. These are Shigo's timing guidelines:

- To stunt a tree, prune it in midsummer.
- For spring-flowering shrubs or trees, prune after the floral show is over. This group includes rhododendrons and azaleas (*Rhododendrum* spp.), forsythias (*Forsythia* spp.), lilacs (*Syringa* spp.), and big-leaved hydrangea (*Hydrangea macrophylla*).
- Plants that flower on new growth should be pruned while they are dormant in early spring. This group includes most summer-flowering shrubs, everbearing raspberries, and floribunda and hybrid tea roses.
- To avoid leaving dead spots, shear a hedge after growth begins.

TO PRUNE OR NOT TO PRUNE

There are certain exceptions to your newfound pruning freedoms. Here are ways to avoid some pruning pitfalls:

Don't prune in the fall. "Avoid pruning living wood as a tree goes into dormancy. It's not equipped to produce callus until it reemerges from dormancy. The cut will remain open and susceptible much longer," says Alex L. Shigo, the author of *Tree Pruning.*

Watch slippery spring bark. "When trees are first breaking dormancy in spring, many have bark that is prone to slipping for a week or so. Avoid pruning at this time so you don't tear off more bark than you intended," advises Dan Neely, Ph.D., the editor of the *Journal of Arboriculture.*

Skip spring and early-summer pruning on disease-susceptible trees. If you grow American elms (*Ulmus Americana*), which are prone to Dutch elm disease; oaks (*Quercus* spp.), which are susceptible to oak wilt; honey locusts (*Gleditsia* spp.) that are smitten with canker; or pears, apples, quinces, crab apples, pyracanthas (*Pyracantha* spp.), and cotoneasters (*Cotoneaster* spp.), all of which can get fire blight; avoid pruning during peak infection times.

"A lot of pathogens can enter wounds, but most diseases are limited to reproducing and infecting plants during a certain time period. If the wounds are fresh during that time, there could be big trouble," Dr. Neely says. Conditions in late spring and early summer often are favorable for infection to occur.

"The temperature and humidity are relatively moderate and favor fungus sporing and bacterial division. Thus, the weather encourages their spread," says Dr. Neely.

Dr. Neely suggests pruning disease-susceptible trees in late winter, just before they emerge from dormancy. You can also prune trees in late summer, he says, but you risk having trees die back if dry weather follows pruning.

Pruning the Low-Maintenance Way

Barbara W. Ellis, Joan Benjamin, and Deborah L. Martin

The absolute best way to cut down on the time and labor you spend on pruning is to avoid it altogether. And the secret to that is choosing plants that grow only as tall and wide as your space. Looking for dwarf trees and shrubs is a good start. Also keep your eye out for well-behaved fruit trees and berry bushes—there are new ones being introduced every day. Although buying on impulse is fun and easy, choosing the right plants from the start is worth the extra time it takes: It will save you pruning time and effort for the life of your plants.

But uprooting all the plants in your yard and replacing them isn't often an option. And extreme age, high winds, lightning, or diseases can also ravage plantings. What to do? Haul out the pruning saw and shears. But never fear, with the information that follows you can complete your pruning chores quickly and with confidence.

Pick Your Cuts to Prune Plants Right the First Time

Random hacking takes a lot more effort than proper pruning, and it costs a lot. These cuts come back to haunt you as rotted or diseased areas and lush, uncontrolled growth. As a first step toward reforming your pruning practices, always make proper pruning cuts that will shape your plant the way you want it to grow.

When you prune, cut just above a bud. But don't just select any bud—cut to one that's pointed in the direction you want a branch or stem to grow. Unless your plant has a bare spot in the middle, choose a bud growing away from the center to avoid crowded, crossing branches. If you're removing damaged stems or branches during the growing season, cut just above a healthy leaf to help hide the wound.

Cut Out Labor

There are two ways to prune trees and shrubs. You can thin them and save time and effort, or head them back and create more work. It's not hard to decide which technique is best for you—or your plants.

Thinning cuts. Prune selectively by cutting branches back to the next larger limb or by removing entire limbs or stems. You'll shape the plant by reducing its height and improve air circulation by opening it up. The result is a healthy, attractive plant that won't need follow-up pruning.

Heading cuts. When you cut the ends off branches, they send up a dense growth of side shoots. This type of pruning makes formal hedges look tidy and full but creates problems. It reduces air circulation and light inside the plants so inner branches are susceptible to insects or diseases; they may even get shaded out completely.

If you can't give up your formal hedge, prune it so the top is slightly narrower than the bottom so the entire plant gets light.

Use Handy Helpers to Make Pruning a Breeze

All you really need for painless pruning are a few good tools. High-quality stainless steel or forged steel blades won't snap under stress, so you'll avoid lots of wasted time and frustration. But even they have limits; treat your tools right and only tackle jobs they're designed for. If it takes lots of effort to cut, you're pruning a branch that's too big for your tool.

A set of hand pruners and a handheld pruning saw should see you through most pruning situations you're likely to encounter. If you have hedges or large plantings of flowers or brambles, a pair of hedge clippers and a pair of loppers will come in handy, too. Pick out tools that feel comfortable in your hand and are lightweight enough so pruning won't exhaust you. Clean the blades after each use, using steel wool if necessary; then wipe them with an oily cloth and they'll last a lifetime. Here's what to look for:

Hand pruners. Bypass hand pruners are kinder to fragile stems than anvil types, which tend to crush tender stems as the blade comes to rest on a flat plate. Pointed blades let you reach into tight spots and give a clean cut on stems and twigs under ½ inch thick. Ergonomic models have handles that are set at an angle to the blades so you won't have to bend your wrist as much.

Anvil pruners will cut wood with less effort than bypass pruners, though, and are a good choice if you have limited hand strength.

Pruning saws. A curved pruning saw can cut through wood with ease, especially if you select one that cuts on the push *and* pull strokes. Many models only cut on the pull stroke, so there's less pressure on the narrow blade. They're just as useful but not quite as fast. Try out models you see in local hardware stores or garden centers to find one that feels and cuts comfortably. You may find the best selection in mail-order catalogs.

Chain saws. Most people do not need a chain saw. A handsaw can handle the majority of pruning tasks with finesse. Unless you're dealing with a forest, hire a professional when you need to remove large limbs or trees. They'll have the protective gear and training to do the job safely.

Hedge shears. Nothing beats sharp hedge shears for deadheading flower plantings with great speed. They'll trim

Continued ➔

formal hedges efficiently, too—try electric models for extremely large plantings—but if you really want low-maintenance, convert your formal hedges to an informal style.

Loppers. A good pair of loppers will make short work of pruning chores for branches that are ½ to 1½ inches in diameter. The long handles give you plenty of leverage for cutting tough limbs. Ratchet-style loppers hold the blades in place while you get a better grip. Several small pulls on the handles is all it takes to slice through a stem, so you won't need Herculean strength.

Pole pruners. You'll rarely have to use a pole pruner unless you're growing fruit trees. They'll extend your reach but are awkward; it takes practice to balance and cut without injuring nearby limbs. Rent one unless you have lots of trees.

Pruning Dos and Don'ts

The way you prune plants makes a huge difference in your workload. Cut limbs correctly, and they'll recover quickly and you won't have any follow-up work to do. Cut them incorrectly, using a misguided technique like topping, and you'll create an ongoing nightmare of yearly corrective pruning. Use the dos and don'ts shown here to make your pruning jobs this year—and every year thereafter—a breeze.

1. **DO line up your pruning cuts and use three-step branch removal.** Cuts should mirror the angle of the branch bark ridge—that furrow of bark where branch and trunk meet. Your cut should closely parallel the branch collar; but not cut into it. This type of cut gives your tree the best chance to cover over the wound and keep out insects and diseases.

   Remove medium and large branches in three easy steps. First, cut part of the branch off to reduce the weight. Holding up a heavy branch while you prune it off the trunk will break your back, your pruning saw, and tear the bark. Then, undercut the remaining stub so the trunk bark won't rip when the stub falls free. Last, make the final cut from the top, beside (but not cutting into) the branch collar.

2. **DON'T make pruning cuts that are too deep or leave branch stubs.** Flush cuts injure trees so badly they can't grow over the wound; enter rot and insects. Stubs rot and give insects and diseases an opening to destroy healthy tissue.

3. **DO prune branches selectively.** Open up or lower the size of a mature tree by removing overcrowded or long branches at the point where they meet the trunk or a larger branch.

4. **DON'T top trees, ever!** This so-called method destroys a plant's natural shape and results in unhealthy, malformed trees. A host of new, weak sprouts will rise from the cuts, and they'll need constant pruning to keep them under control. Insects and diseases will find the cut wood inviting.

Pruning Tips for Poorly Placed Plants

Plants always let you know if they're in the wrong spot by growing out of control. Get them back in shape with pruning, then take the steps necessary for a permanent cure; otherwise, you'll be doing fix-it pruning forevermore. Look for these symptoms to identify poorly placed plants.

First Aid for Trees

When a tree is pruned or wounded, there's a natural instinct to apply a bandage to the wound in the form of pruning paint. However, studies by Alex L. Shigo, the author of *Tree Pruning*, and others show that such paints are unnecessary. In fact, applying pruning paint to already-infected wood will seal in microorganisms and actually promote decat.

It's better, Shigo says, to help a wound seal naturally by encouraging callus tissue to form around its edge. To do this, use a sharp knife to remove any dead or injured bark from around the wound. Enlarge the wound as little as possible, making rounded edges. Cut any loose bark away to form a clean, smooth surface. The bark should be tight around the wound, so fasten it with small nails if necessary.

Do You Really Need a Chain Saw?

Sure, chain saws are fast—and great for cutting wood—but they're not so great for pruning. Before you buy, rent, or use one, consider the following:

- Unless you have lots of practice, it's hard to make a proper pruning cut without slicing into healthy tree trunks or branches.
- The only place it's really safe to use a chain saw is when both feet are planted firmly on the ground. Don't be tempted to violate this rule by climbing ladders; it's too easy to injure yourself and the tree.
- A chain saw is incredibly powerful and quick; don't give it a chance to get away from you by raising it above your head.
- Protective gear is a must when using chain saws. You'll need safety goggles, gloves, a helmet, steel-toe boots, earplugs, and heavy-duty trousers. Make it easy on yourself and hire a professional arborist with the proper gear.

Weak, spindly growth. Poor soil and insufficient light can cause weak, spindly growth. If you suspect poor soil, prune to reshape the plant, then use compost and organic fertilizer to restore soil fertility.

Evaluate light conditions, too; the plant may be getting too much shade. If so, prune back by one-third and transplant to a sunnier spot. Choose a shade-tolerant plant for a replacement.

Awkward shape or branching. Incorrect pruning, storm damage, and winds are just some of the reasons a plant may have an ugly or awkward shape. To correct it, lightly shape the plant by pruning out individual branches. Do not give it a "haircut" with hedge shears; you will only cause lots of additional scraggly growth and make the problem worse.

Determine why the plant grew strangely. Was it injured? Is it in an area with high winds? Storm damage probably won't recur, so pruning is a good cure. Constant, severe winds are another story; provide a windbreak or move the plant to a sheltered area. If a lawn mower caused the damage by bashing away at the base of stems, prune away the injured area and surround the plant with a wide mulch ring.

Wildly vigorous growth. Plants that smother your house or neighboring plants are definitely in the wrong place. Prune them back by one-third (more if you're dealing with an out-of-control vine) so they are manageable. Then move them to a more appropriate spot or the compost bin.

Choosing the Best Arborist

Any time you have to climb a tree or use a chain saw to prune a branch, think twice. An arborist can save you a lot of time, aggravation, and possible injury. Good ones have the training, equipment, and protective gear to do the job quickly and safely. Remember, one small slip in a tree can mean permanent injury.

Check credentials. Look for a certified arborist; they've had to pass a rigorous exam on tree care and selection. Call or write the International Society of Arboriculture, P.O. Box GG, Savoy, IL 61874; (217) 355-9411.

Consult local experts. Contact nearby botanical gardens to see if they can recommend good arborists. Extension agents, horticulture or forestry professors, or the staff at your local department of conservation may also have ideas.

Beware of incredible deals. Bargain-rate tree-pruning deals are usually a sign of inferior or incompetent work.

Check references. Ask for the names of recent clients. Call them up to see if they were pleased with the work.

Pick the Right Size and Shape to Escape Pruning Chores

Have you brought home gorgeous plants, then discovered after they engulfed your house that they were too big when full- or even half-grown? To avoid this problem, measure your planting space before you buy. That way you'll know if a 6-foot-tall, 5-foot-wide shrub will fit under your picture window. You'll save hours and hours of futile labor trying to prune oversize plants to fit. Here's how to tell what size plants will eventually reach.

Read the label. Plant labels are a great help since most list mature size and some growing hints. Double-check the label information with garden center personnel before you buy; occasionally, labels get switched with other plants.

Check several sources. For reliable plant sizes and growth habits, head for your local library and ask for good tree and shrub books.

Cutting Dos and Don'ts

Fungal problems are the major threat to cuttings. Here are some dos and don'ts for avoiding rots and other fungal disasters:

- **Do** sterilize your knife with alcohol between cuts.
- **Do** treat each cutting with a 5 percent bleach solution (1 part bleach to 19 parts water) if you want an extra guard against fungi. If you plan to put the cuttings in a plastic propagating tent or enclosure, use chamomile tea instead of bleach solution. Dip the entire cutting for a few seconds to a minute.
- **Don't** stick cuttings deeper than 1 inch or they may rot, and **don't** let leaves come in contact with the soil surface.
- **Do** stick cuttings far enough apart so the leaves of adjacent plants don't touch.
- **Don't** let the plastic you use to enclose the flat or pot touch the cuttings.
- **Do** open the plastic on your propagating containers at least once a day—good circulation prevents fungal problems, while stagnant air encourages them.
- **Do** check your cuttings daily for mildewed or dropped leaves. Remove dropped leaves and diseased cuttings as soon as you see them to keep fungi from spreading to healthy cuttings.

The Best Time to Prune Flowering Shrubs Is When You Have the Time

Flowering shrubs aren't as choosy about pruning as you might think. Timing schemes for spring- and summer-flowering shrubs guarantee that you won't miss a season of bloom. But there's no crisis if you don't follow them; you'll still get plenty

Continued →

of blooms the following season. What's most important is that pruning gets done, so schedule when it's most convenient for you.

If you can't stand to miss even one bloom season, all you have to do is follow one simple rule: Prune flowering shrubs after they flower.

Spring-blooming shrubs. Trim forsythias, lilacs, sweet mock orange, and other early bloomers right after flowering. They set next year's flower buds during summer, so if you prune in fall, winter, or the following spring, you'll slice off the next season of bloom. If the plants are severely overgrown, renewal-prune by removing one-third of the stems to ground level each year.

Summer-blooming shrubs. Any time after flowering is fine for pruning hydrangeas, buddleias, rose-of-Sharon, and other summer bloomers. There's no rush as with spring bloomers, though, so take advantage of their foliage through fall and prune in late winter or early spring. Summer bloomers set flower buds on the new season's growth, so hard pruning (cutting stems back to 2 or 3 inches from the ground) will guarantee you the most flowers.

Restyle Your Shrubs to Reduce Maintenance

When it comes to low maintenance, formal, squared-off hedges and closely clipped shrubs don't make the grade. You don't have to be a slave to these maintenance monsters, which need clipping several times a year to look their best. Instead, put your hedge shears away, grab your hand pruners, and help nature rework your plants into beautiful, easy-care informal shapes.

Restyling deciduous shrubs and hedges. Use thinning cuts, not heading cuts, to open up holes in plants to let light in. (This is a good way to rejuvenate an informal hedge, too.) Make the cuts close to the ground or just above low branches; you'll encourage side buds to grow.

Remove one-third of the growth on each plant each year, taking out the most gnarled and woody branches first. Continue the process for three years until all the old growth is gone. Let new growth and suckers form the framework for your informal hedge.

Shrubs that respond well to this treatment include deutzia, forsythia, sweet mock orange, spirea, and old-fashioned weigela.

Restyling evergreen shrubs and hedges. Clean out any dead wood inside the shrubs. Poke holes in the top by reaching inside as far as you can with hand pruners and cutting branches back to larger limbs. You'll end up with an uneven but attractive look if you make sure each cut branch still has some green on it.

Broad-leaved evergreens like hollies and yews will respond to the additional light with new growth, and eventually return to their natural form. Junipers and American arborvitae may not respond at all. In that case, replacing them is the best solution.

Thin for Health

Shrubs, trees, and perennial flowers with overcrowded stems or branches are just the kind of sheltered, humid home insects and diseases like mildew prefer. Remove one-quarter to one-third of shrub or perennial stems from the center of your plants so sunlight and air can reach the inside leaves—diseases and insects hate this! Cut a few limbs out of the center of trees if they're too choked with branches for healthy growth. Take them back to a large branch or the trunk. Repeat each year until the plant has a healthy, open growth habit.

Unusually Effective Pruning Tools

Push mowers and string trimmers make good pruners for large groundcover or perennial plantings. For a fast spring cleanup, set the mower at its highest setting and run it over the plants in early spring before new growth starts. This works on level ground but not on hilly areas or plantings that have heaved out of the ground; they'll get scalped and die.

String trimmers zip through perennials, ornamental grasses, or groundcover foliage on any kind of ground. They'll leave a ragged finish, but new foliage will cover it quickly. You can't beat it when you're short on time.

Pruning and Training Glossary

Branch collar.
The bulge at the base of a branch; this part of the trunk helps hold the branch to the trunk.

Branch crotch.
The angle at which the tree branch meets the trunk or parent stem.

Break bud.
When a latent bud is stimulated into growing out into a leaf or twig.

Cane.
A long and slender branch usually originating from the roots.

Heading cut.
To cut back a branch to a side bud or shoot.

Leader.
The main, primary, or tallest shoot of a trunk. Trees can be single-leadered, such as birch, or multiple-leadered, such as vine maple.

New wood.
A cane of the current year's growth. Some shrubs bloom only on new wood, while others bloom on the previous year's growth.

Old wood.

A cane of the previous year's growth or cane that's older.

Pinching.

To use your fingertips to squeeze off the end bud of a twig or stem to make the plant more compact and bushy.

Skirting or limbing up.

To prune the lower limbs of a tree to increase air circulation, improve visibility, or clear room underneath the tree.

Sucker.

An upright shoot growing from a root or graft union. In common usage, these are straight, rapid-growing shoots or watersprouts that grow in response to poor pruning and wounding.

Thin out.

To cut off a limb at the base, either at ground level or at a branch collar.

Topiary.

Plants sculpted into geometric shapes or likenesses of animals or people.

Jeff Cox

After the planning and planting come the watering, weeding, and tending. While we all realize that gardening is work, it's nice to know that there are ways to make that work more pleasurable so we can spend more time enjoying our gardens rather than taking care of them. Of course, low maintenance gardens start with proper planning.

Good garden care requires the proper tools. Tools not only help you get the job done, but the right tools—used properly—will save time and effort on your part. Next on the garden-care list is weed control. Weeds can drive the most peaceful gardener to herbicidal thoughts. But we'll tell you how to keep weeds from becoming a problem in your garden—and how to control those that do appear—without resorting to dangerous chemicals.

Mulch plays another important role in the garden—it will save you time watering your plants and fighting pests. Along with mulching, you need to know the best ways to feed, stake, trellis, and water your plants. And if you feel as though all this work gets crammed into a very short time span, read on to discover ways to extend the season to get the absolute most from your garden.

Choosing Tools

The notion that a tool is nothing more than a device for doing work stops at the garden gate. Anyone who has worked garden soil with a well-balanced fork or rake, sliced weeds effortlessly with a skillfully sharpened hoe, or pruned effortlessly with a good, sharp pair of shears knows that a high-quality tool not only gets the job done but also adds pleasure to the doing. Little wonder that gardeners come to think of their most effective tools as friends.

HAND TOOLS

Whenever it's practical, use hand tools rather than power tools. Power tools are expensive and contribute to both our air and noise pollution problems. If you keep them sharp, good-quality hand tools will make your garden work go quickly and easily.

Hoes You can use hoes to lay out rows, dig furrows, cultivate around plants to loosen the soil and kill weeds, create hills and raised beds, break up clods, and prepare bare spots in lawns for reseeding.

The standard American pattern hoe is a long-handled tool that allows you to work without too much bending. It has a broad, straight blade, a little larger than 6 inches wide and 4 inches deep. However, many gardeners prefer a nursery hoe, which is lighter and has a 2- to 3-inch-deep blade.

Use an oscillating hoe to slice weeds just below the soil surface. It cuts on both the push and the pull stroke. On modern variations, often called "hula" or action hoes, the slicing blade moves back and forth to cut while being pulled or pushed.

Narrow hoe blades utilize your arm power more efficiently than wider blades. The hoe handle should be at least 4½ feet long so you can work without bending over and straining your lower back muscles. In general, when working with hoes, try to remain standing upright and run the hoe blade below and parallel to the soil surface. Keep your hoe sharp so it will cut through weeds rather than yanking them out.

Shovels A standard American long-handled shovel is good for mixing cement and for scooping up soil, gravel, and sand. You can also use it to pry rocks and root clumps from the soil. You can use a shovel to dig rounded planting holes, but a garden fork or a spade generally works better for most digging.

The standard shovel handle is about 4 feet. The shovel handle should come to shoulder height or higher. Shovels

Continued →

should also have a turned edge or footrest on the shoulders of the blade to protect your feet when you step on the tool.

Spades Spades have a flat, rather than scooped, blade with squared edges. With a spade, you can cut easily through sod and create straight edges in soil. Use a spade for digging planting holes, prying up rocks, dividing and moving perennials, cutting unwanted tree and shrub roots, tamping sod, and digging trenches.

A spade handle is generally shorter than a shovel handle, usually ranging from 28 to 32 inches. Like shovels, spades should have a turned edge or footrest on the shoulders of the blade.

Forks Spading forks cut into soil, usually more easily than solid-bladed tools can. A spading fork is handy for mixing materials into the soil and for harvesting potatoes, carrots, and other root crops. The tines of a standard spading fork are broad and flat; those of the English cultivating fork are thinner and square. The English version is better for cultivating and aerating soil. Remember that forks are used to loosen soil, not to lift it. Use a pitchfork (three tines) or a straw fork (five or six tines) for picking up, turning, and scattering hay mulch, leaf mold, and light compost materials.

The standard handle length for a spading fork is 28 inches. Very tall gardeners may prefer a 32-inch handle. Short gardeners, including children, should use a border fork, which has shorter tines and handle.

Trowels A garden trowel is a miniature version of a shovel. Use it to dig planting holes for small plants and bulbs, for transplanting seedlings, or for weeding beds and borders.

Some trowels are made from forged steel and fitted with hardwood handles; good ones are also available in unbreakable one-piece cast aluminum. Trowels come with a variety of blade widths and lengths. Choose one that feels comfortable in your hand.

Rakes Rakes generally fall into one of two categories: garden rakes and leaf rakes. Garden rakes are essential for leveling ground, creating raised beds, killing emerging weeds, gathering debris from rows, covering furrows, thinning seedlings, working materials shallowly into the soil, erasing footprints, and spreading mulch. Garden rakes come in many widths, with long or short teeth that are widely or closely spaced. The handle should be long (4½ to 5 feet) and the head should be heavy enough to bite into the soil easily. If you have rocky soil, choose a rake with widely spaced teeth.

Lawn or leaf rakes, also called fan rakes, are good for gathering up leaves, grass clippings, weeds, and other debris and for dislodging thatch from the lawn. Metal lawn rakes last longest and are the springiest, although many gardeners prefer the action and feel of bamboo tines, and some prefer plastic or rubber.

Pruning Tools There are two types of pruning shears: the anvil type, with a straight blade that closes down onto an anvil or plate, and the bypass type, which cuts like scissors. Anvil pruners are often easier to use, requiring less hand pressure to make a cut. Bypass shears make a cleaner cut, can work in tighter spaces, and can cut flush against a tree trunk or branch (anvil pruners leave a short stump). Most models of either type will cut hardwood branches up to ½ inch in diameter.

Lopping shears, also called loppers, are heavy-duty pruners with long handles. Both anvil and bypass loppers can cut branches up to 2 inches in diameter. Hedge shears have long blades and relatively short handles. They can cut branches up to ½ inch thick. Pruning saws cut through most branches that are too thick for shears.

Push Mowers Push mowers have several revolving blades that move against a single fixed blade, producing a neat trim. They do a fine job, cutting evenly and quietly. For those with small, level lawns, the push mower is the ideal lawn-cutting instrument. It is inexpensive, not difficult to push, nonpolluting, and quiet, and it produces a neat-looking lawn.

POWER TOOLS

In some cases, you may need the extra power of engine-driven equipment. It's tempting to use these machines on a regular basis because they get the job done quickly. Keep in mind, though, that handwork can be part of the pleasure and relaxation of gardening. If you routinely use power tools to speed through garden chores, you'll miss the opportunity to observe the growth of your plants and to watch for the beginning of disease or insect problems.

Power Mowers Gas-powered rotary mowers have a single blade that revolves at a high speed, literally ripping the tops off grass plants. Unlike push mowers, power mowers can handle rough terrain and knock down high weeds. Mulching mowers blow finely cut grass pieces back into the lawn, building up soil organic matter while removing the need to rake or bag clippings.

Tillers Rotary tillers can make short work of turning and churning garden soil, breaking new ground, cultivating, aerating, weeding, and mixing materials into the soil. The rotary tiller is a gasoline-powered machine equipped with steel blades that rotate on a central spindle.

Chipper/Shredders After a lawn mower and a rotary tiller, the favorite large power tool of gardeners is often a chipper/shredder. This machine, powered with gasoline or electricity, reduces leaves, pruned branches, and plant debris to beautiful mulch or compost material. Shredders are better for chopping up weeds and other soft plant material; chippers can handle heavier, woody materials.

TOOL CARE

After making the considerable investment in good-quality tools, it is wise to spend some time to keep them in good shape.

Routine Care Clean, dry, and put away all hand tools after each use. Keep a large plastic kitchen spoon handy to knock dirt off metal blades. Don't use a trowel or other metal tool, since you could damage the blades of both tools. A 5-gallon bucket of sharp builder's sand in the tool shed or garage is useful for cleaning tools. Dip the metal blade of each tool into the sand and plunge it up and down a few times to work off any clinging soil. Use a wire brush to remove any rust that may have formed. Keep power equipment in good repair and properly adjusted.

Handles Regularly varnish and sand wooden handles to maintain their resilience and good looks. If you buy a good-quality tool second-hand and it has a weather-beaten handle, refresh it with several coats of varnish, sanding between each coat. You can repair split handles temporarily with tape and glue, but replace broken handles as soon as possible.

Sharpening Sharp-bladed hand tools will perform efficiently and with ease only if you keep them sharp. Take the time to study the angle of the bevels on all your tools, then sharpen each, as needed, to keep the proper bevel. If you have tools that are especially difficult to sharpen, take them to a professional for sharpening.

Winter Care At the end of the season, polish all metal parts of hand tools with steel wool, oil them to prevent rust, and store them in a dry place. Lubricate all tools that have moving parts. This is also a good time to take hard-to-sharpen tools to the sharpening shop.

Controlling Weeds

Fast, tough, and common—that's all it takes to earn a plant the name of weed. But any plant growing in the wrong place—especially if it's growing there in abundance—is a weed. Maple tree seedlings that sprout between the lettuce and radishes are weeds. So is the Bermuda grass that keeps invading your perennial beds from the lawn.

The bigger your weeds get, the more difficult they are to control. Get into the habit of a once-a-week weed patrol to cut your weed problem down to size. Using the right tools and techniques also will help to make weeding a manageable—maybe even enjoyable—task.

HAND WEEDING

Hand-pulling weeds is simple and effective. It's good for small areas and young or annual weeds such as purslane and lamb's quarters. Using your hands allows you to weed with precision, an important skill when sorting the weeds from the seedlings. For notorious spreaders like ground ivy, the only choice for control is to patiently hand-pull the tops and sift through the soil to remove as many roots as you can find.

Short-handled tools such as dandelion forks (sometimes known as asparagus knives), pronged cultivators, and mattocks are good for large, stubborn weeds, especially in close quarters such as among perennials. Use these tools to pry up tough perennial weeds. Hand weeders come in all shapes, and everybody has a favorite. If one type feels awkward, try another.

A hoe is the best tool for weeding larger areas quickly and cleanly. Use it to rid the vegetable garden of weeds that spring up between rows. When you hoe, slice or scrape just below the soil surface to sever weed tops from roots. Don't chop into the soil—you'll just bring up more weed seeds to germinate. Keep the hoe blade sharp. Hoeing kills most annual weeds, but many perennial weeds, such as dandelions, will grow back from their roots. Dig out these roots with a garden fork or spade.

USING MULCH

One of the best low-effort ways to beat weeds is to block their access to light and air by mulching bare soil areas. A 3- to 4-inch layer of mulch smothers out many weeds, and weeds that manage to poke through are easier to pull.

Black plastic mulch can practically eliminate weeding in the vegetable garden. Cut slits for plants and water to penetrate. Remove the plastic at the end of the growing season to let the soil breathe. You can use biodegradable materials, such as newspaper or corrugated cardboard, to temporarily suppress weeds, tilling them into the soil at the end of the season. See "Mulching Your Garden" on this page for more information on organic and black plastic mulches.

A living mulch of a low-growing grass or legume crop seeded between rows of plants in your vegetable garden can keep down weeds and improve soil organic matter content at the same time.

Continued ➔

Even tough perennial weeds will succumb eventually to a thick layer of mulch.

Just as weeds compete with your garden and landscape plants for water, food, and growing space, your plants use the same method to crowd out weeds. As your plants grow, they will shade the ground, reducing weed germination and growth. Space vegetable and flower plants closely in beds to decrease the time until the leaves form an effective light-blocking canopy.

Reduce weed growth in your lawn by setting your lawn mower blade a notch or two higher. Taller grass is generally healthier and lets less light reach the soil.

USING HERBICIDES

In some cases, fatty-acid-based herbicides such as Safer SharpShooter can help control weeds. These herbicides provide effective spot control for annual weeds, but perennial weeds will spring up anew from the unharmed roots. Some organic gardeners have traditionally relied on vinegar or salt to kill weeds. However, these substances will affect soil balance and can harm your garden plants as well. Only use them in areas where you don't want any plants to grow, such as between cracks in a patio.

Mulching Your Garden

Every organic gardener should be a mulch expert. Mulching is one of the best ways to fight weeds. It also improves your garden's appearance, reduces water loss, and protects soil from compaction and erosion. If you use an organic mulch, the icing on the cake is improved soil quality as the mulch decays.

There are two basic kinds of mulch: organic and inorganic. Organic mulches include formerly living material such as wood chips, shredded bark, chopped leaves, straw, grass clippings, compost, sawdust, pine needles, and even paper. Inorganic mulches include gravel, stones, black plastic, and geotextiles (landscape fabrics).

Both types discourage weeds, but organic mulches also improve the soil as they decompose. Inorganic mulches don't break down and enrich the soil, but under certain circumstances they're the mulch of choice. For example, black plastic warms the soil and radiates heat during the night, keeping heat-loving vegetables such as eggplant and tomatoes cozy and vigorous.

USING ORGANIC MULCHES

There are two cardinal rules for using organic mulches to combat weeds: First, be sure to lay the mulch down on soil that is already weeded, and second, lay down a thick enough layer to discourage new weeds from coming up through it. It can take a 4- to 6-inch layer of mulch to completely discourage weeds, although a 2- to 3-inch layer is usually enough in shady spots where weeds aren't as troublesome as they are in full sun.

Types of Weeds

Like flowers, there are annual, biennial, and perennial weeds. Each group poses its own control problems, so you need to know which group they fall into. Here's a rundown:

Annual Weeds: Annual weeds, like lamb's quarters, wild mustard, pigweed, purslane, and ragweed, live only one season. But they produce thousands of seeds, guaranteeing success through sheer strength of numbers. Control them by pulling them before they flower and set seed.

Biennial Weeds: Biennial weeds, like Queen-Anne's-lace, form a rosette of leaves their first season. The following year, they flower, set seed, and die. Control them by removing their rosettes the first season, or pull the weeds the second season, before they set their seed.

Perennial Weeds: Perennial weeds include dandelion, Canada thistle, bindweed, dock, wild onions, ground ivy, plantain, pokeweed, and wood sorrel. Some of the worst perennial weeds are grasses, including crabgrass and quackgrass. They live for years, set seed, have deep, persistent root systems, and often have creeping stems; so a single plant can send up offspring all over the garden. The same is true for woody weeds like poison ivy. To control these difficult weeds, dig carefully to remove as much of the root system as possible. Then pull up the plants that grow from the pieces you've missed.

The best organic mulch is compost, a mixture of decomposed organic materials. For directions on making compost, see Chapter 1.

You can purchase bags of decorative wood chips or shredded bark from the local garden center to mulch your flower garden and shrub borders. A less expensive source of wood chips might be your tree-care company or the utility company. They may be willing to sell you a truckload of chips at a nominal price. Many communities are also chipping yard debris or composting grass clippings and fall leaves, then offering the result back to the community for free or for a small charge.

If you have a lot of trees on your property, shredding the fallen leaves creates a nutrient-rich mulch for free. You can use a leaf-shredding machine, but you don't really need a special machine to shred leaves—a lawn mower with a bagger will collect leaves and cut them into the perfect size for mulching.

You can spread a wood chip or shredded leaf mulch anywhere on your property, but it looks especially attractive in flower beds and shrub borders. Of course, it's right at home in a woodland or shade garden. Wood chips aren't a great idea

for vegetable and annual flower beds, though, since you'll be digging these beds every year and the chips will get in the way.

Grass clippings are another readily available mulch, but they aren't particularly attractive. Some people pile the nitrogen-rich clippings under shrubs or on flower beds, but they are more appropriate on vegetable beds, where appearance is less critical. Your vegetables will thank you for the nitrogen boost!

Another great mulch for the vegetable garden is straw, salt hay, or weed-free hay. It looks good and has most of the benefits of mulches: retaining soil moisture, keeping down weeds, and adding organic matter to the soil when it breaks down. But be sure the hay you use is weed- and seed-free, or you'll just be making trouble for your garden. And don't pull hay or straw up to the stems of vegetables or the trunks of fruit trees, or you'll be inviting slug and rodent damage.

USING PLASTIC MULCH

Mulching a vegetable garden with sheets of black plastic film can do wonders. The plastic heats up in the sun, warming the soil and radiating heat during the night, effectively creating a microclimate about 3°F warmer than an unmulched garden. Because the plastic film remains warm and dry, it protects the fruits of vining crops such as strawberries, melons, and cucumbers from rotting and keeps them clean. And of course, the mulch prevents weed growth and retains soil moisture.

In raised bed gardens, lay down a sheet of plastic over the entire bed. Bury it at the edges or weigh the plastic down with rocks. Then punch holes in it for the plants. A bulb planter makes quick work of hole cutting. Sow seeds or plant transplants in the holes. You should be able to reuse the plastic for several years if you take it up and store it over winter.

Because water can't permeate the plastic, the mulch retains soil moisture but can also keep rainwater from soiling the planting bed. That means you'll have to water the garden yourself, with a drip irrigation system or soaker hoses placed beneath the plastic. The simplest method is to shove the end of the hose through a hole in the plastic and turn it on.

Don't use black plastic as a mulch under shrubs. Although it keeps out weeds and can be camouflaged with decorative mulch, black plastic destroys the shrubs' long-term health. Because water and air cannot penetrate the plastic, roots grow very close to the soil surface—sometimes right beneath the plastic-seeking moisture and oxygen. The shallow roots suffer from lack of oxygen and moisture and from extremes of heat and cold. Eventually the plants decline and die. Stick to organic mulches such as shredded leaves, bark, wood chips, or compost under your trees and shrubs.

Unlike black plastic, geotextiles—or landscape fabrics—let air and water through to the soil beneath while keeping weeds from coming up. But geotextiles have some of the same drawbacks as black plastic. If exposed to light, they degrade, so you have to cover them with a second mulch (they're ugly, so you'd want to, anyway). Some studies have found that shrub roots may grow up into the geotextile mulch, creating real problems if you want to remove it. And weeds that germinate in the mulch on top of the geotextile can send roots down into the fabric, tearing it when you pull them out.

Feeding Your Plants

Plants make their own food through the process of photosynthesis, but gardeners play an important supporting role by making sure that all the necessary raw materials are available. Organic gardeners do this primarily by enriching their soil with a wide variety of organic materials. Feeding your plants with organic fertilizers can also help to provide them with optimum nutrition.

Organic gardeners use fertilizers like seasonings: They add the finishing touch that brings out the very best in plants. Because an organically managed soil is biologically active and rich in nutrients, organic gardeners don't need to pour on fertilizers to get good plant performance.

CHEMICAL VERSUS ORGANIC

Many organic materials serve as both fertilizers and soil conditioners—they feed both soils and plants. This is one of the most important differences between a chemical approach and an organic approach toward soil care and fertilizing. Soluble chemical fertilizers contain mineral salts that are readily available for uptake by plant roots. However, these salts do not provide a food source for soil microorganisms and earthworms, and they will even repel earthworms because they acidify the soil. Over time, soils treated only with synthetic chemical fertilizers will have decreased organic matter and altered biological activity. And as soil structure declines and water-holding capacity diminishes, a greater proportion of the soluble chemical fertilizers applied will leach through the soil. This results in ever-increasing amounts of chemicals needed to feed the plants.

Most chemical fertilizers are synthesized from nonrenewable resources, such as coal and natural gas. Others are made by treating rock minerals with acids to make them more soluble. Fortunately, there are more and more truly organic fertilizers coming on the market. These products are made from natural plant and animal materials or from mined rock minerals. However, there are no national standards regulating the content of organic fertilizers. Read labels to be sure that commercial fertilizers labeled "organic" contain only safe, natural ingredients. Look for products labeled "natural organic," "slow release," and "low analysis." Be wary of products labeled organic that have an NPK (nitrogen-phosphorus-potassium) ratio that adds up to more than 15 (one labeled 10-10-10, for example).

Continued ➔

USING ORGANIC FERTILIZERS

If you're a gardener who's making the switch from chemical to organic fertilizers, you may be afraid that using organic materials will be more complicated and less convenient than using premixed chemical fertilizers. Not so! Commercially formulated organic fertilizer blends can be just as convenient and effective as blended synthetic fertilizers. You don't need to custom-feed your plants unless it's an activity you enjoy. So while some experts spread a little blood meal around their tomatoes at planting, then some bonemeal just when the blossoms are about to pop, most gardeners are satisfied to make one or two applications of general-purpose organic fertilizer throughout the garden.

If you want to try a plant-specific approach to fertilizing, you can use a variety of specialty organic fertilizers that are available from mail-order supply companies or at many well-stocked garden centers. For example, you can use blood meal, chicken-feather meal, or fish meal as a nitrogen source. Bonemeal is a good source of phosphorus, and kelp and greensand are organic sources of potassium.

Dry Organic Fertilizers Dry organic fertilizers can be made from a single material, such as rock phosphate or kelp, or can be a blend of many ingredients. Almost all organic fertilizers provide a broad array of nutrients, but blends are specially formulated to provide balanced amounts of nitrogen, potassium, and phosphorus, as well as micronutrients. There are several commercial blends, but you can make your own general-purpose fertilizer by mixing individual amendments.

The most common way to apply dry fertilizer is to broadcast it and then hoe or rake it into the top 4 to 6 inches of soil. You can add small amounts of fertilizer to planting holes or rows as you plant your seeds or transplants. Unlike dry synthetic fertilizers, most organic fertilizers are nonburning and will not harm the delicate roots of your seedlings.

During the growing season, boost plant growth by side-dressing dry fertilizers in crop rows or around the drip line of trees or shrubs. It's best to work side-dressings into the top inch of the soil.

Liquid Organic Fertilizers Use liquid fertilizers to give your plants a light nutrient boost or snack every month—or even every two weeks—during the growing season. Simply mix a tankful of foliar spray, and spray all your plants at the same time.

Plants can absorb liquid fertilizers both through their roots and through leaf pores. Foliar feeding can supply nutrients when they are lacking or unavailable in the soil, or when roots are stressed. It is especially effective for giving fast-growing plants like vegetables an extra boost during the growing season. Compost tea and seaweed extract are two common examples of organic foliar fertilizers.

Some foliar fertilizers such as kelp are rich in micronutrients and growth hormones. These foliar sprays also appear to act as catalysts, increasing nutrient uptake by plants. You can make your own liquid fertilizer by brewing up compost or manure in water.

With flowering and fruiting plants, foliar sprays are most useful during critical periods (such as after transplanting or during fruit set) or during periods of drought or extreme temperatures. For leaf crops, some suppliers recommend biweekly spraying.

When using liquid fertilizers, always follow label instructions for proper dilution and application methods. You can use a surfactant, such as coconut oil or a mild soap (¼ teaspoon per gallon of spray), to ensure better coverage of the leaves. Otherwise the spray may bead up on the foliage and you won't get maximum benefit. Measure the surfactant carefully: If you use too much, it may damage plants. A slightly acidic spray mixture is most effective, so check your spray's pH. Use small amounts of vinegar to lower pH or baking soda to raise it. Aim for a pH of 6.0 to 6.5.

Any sprayer or mister will work, from hand-trigger units to knapsack sprayers. Set your sprayer to emit as fine a spray as possible. Never use a sprayer that has been used to apply herbicides.

The best times to spray are early morning and early evening, when the liquids will be absorbed most quickly and won't burn foliage. Choose a cool, clear day.

Spray until the liquid drips off the leaves. Be sure to concentrate the spray on leaf undersides, where leaf pores are more likely to be open. You can also water in liquid fertilizers around the root zone. A drip irrigation system can carry liquid fertilizers to your plants. Kelp is a better product for this use; fish emulsion can clog the irrigation emitters.

Staking and Trellising

Staking plants in the flower and vegetable garden is a job that busy gardeners sometimes overlook. In most cases, however, the time you spend staking will be amply rewarded by the improved health and appearance of your garden.

Vining plants virtually require stakes or other support. Top-heavy, single-stemmed flowers like delphiniums, lilies, and dahlias benefit from support. Left unstaked, they are apt to bend unattractively and may snap off during heavy storms. Staking also improves the appearance of plants with thin, floppy stems that flatten easily.

Choose stakes and supports that match the needs of the plant and of you as a gardener. They must be tall enough and strong enough to support the entire mature plant when wet or windblown, and they must be firmly inserted in the soil. A stake that breaks or tips over can cause more damage than using none at all. Take care not to damage roots when inserting a stake,

Cover Crop Closeup

Legumes

Bean, broad, fava, or field (*Vicia faba*). A winter annual legume suitable for maritime Canada and along the U.S. Pacific Coast. Must have cool weather and ample water. Can withstand temperatures to 15°F. Prefers well-drained, heavy loams high in humus and lime. Turn under when growth is succulent for fastest breakdown. Fixes 71 pounds nitrogen per acre per year; inoculate with *Rhizobium* spp. bacteria to encourage nitrogen fixation, either by dusting the inoculant along the furrow or on the seeds. Sow on 8-inch centers, covering seed ⅛ to ¼ inch deep.

Clover, crimson (*Trifolium incarnatum*). An annual legume that will grow through the winter from New Jersey south. Must have adequate soil moisture for good germination and growth. Prefers loam soils that are high in humus, but will grow on any well-drained soil except muck or extremely acid soils. Will withstand shade and low fertility. Fixes 94 pounds of nitrogen per acre per year; inoculate with *Rhizobium* spp. bacteria to encourage nitrogen fixation. Sow ½ to ⅔ ounce per 100 square feet, covering seed ½ inch deep.

Clover, white (*Trifolium repens*). A hardy perennial legume that grows throughout Canada and the United States south to the Gulf of Mexico. Thrives in cool, moist climates. Prefers humus-rich, well-drained clay, clay loam, and loam soils. Grows well in shade. Needs high lime, phosphorus, and potash. Fixes 103 to 133 pounds of nitrogen per acre per year; inoculate with *Rhizobium* spp. bacteria to encourage nitrogen fixation. Sow ¼ ounce per 100 square feet, covering seed ½ inch deep.

Lupine, large white (*Lupinus albus*). An annual legume best grown in the Deep South, Northeast, and North Central states. The most winter-hardy lupine species. Prefers sandy loam soils and acid soils. Excellent soil-builder for barren, sandy, and worn-out soil. Good for opening up heavy clay. Inoculate with *Rhizobium* spp. bacteria to encourage nitrogen fixation. Sow 6½ ounces per 100 square feet, covering seed 1 inch deep.

Pea, Austrian winter (*Pisum arvense*). Also called Canadian field pea, this legume is a winter annual. It grows all over the United States and Canada; winter kills it in the North but it grows through the winter in the South. Requires cool, moist conditions and grows best in loamy soils high in lime. Fixes 48 pounds of nitrogen per acre per year; inoculate with *Rhizobium* spp. bacteria to encourage nitrogen fixation. Sow 4 ounces per 100 square feet, covering seed 1½ inches deep.

Vetch, hairy or winter (*Vicia villosa*). An annual legume that can be grown in all parts of the United States. The most winter-hardy of the cultivated vetches. Will grow on any well-drained soil, including acid soils, alkaline soils, and soils of low fertility. Will tolerate drought. Fixes 80 pounds of nitrogen per acre per year; inoculate with *Rhizobium* spp. bacteria to encourage nitrogen fixation. Sow 2½ ounces per 100 square feet, covering seed ¾ inch deep.

Grasses

Barley, winter (*Hordeum vulgare*). An annual grass that grows all over the United States and overwinters in mild climates. Well adapted to high altitudes and semiarid regions. Prefers well-drained loam soils. Tolerant of salinity and alkaline soils; does not grow well on sandy or acid soils. Sow 4 ounces per 100 square feet, covering seed ¾ inch deep.

Oats (*Avena sativa*). An annual grass that grows all over the United States and is especially good in the South where it overwinters. Prefers cool, moist climates. Will tolerate acid soil. Will grow on many soils, but does not do well on heavy clay. Provide a firm seedbed to prevent frost-heaving in winter. Sow 4 ounces per 100 square feet, covering seed 1 inch deep.

Rye, winter or cereal (*Secale cereale*). An annual grass that will grow all over the United States, but is especially well suited for the North because of its ability to tolerate extreme cold. Grows best on well-drained loams, but will grow on any soil. Will tolerate acid soil. Prefers ample moisture. Sow 4 ounces per 100 square feet, covering seed 1 inch deep.

Ryegrass, annual or Italian (*Lolium multiflorum*). A weak grass grown as an annual. Will grow all over the United States, but is best adapted to the areas from New Jersey south. Prefers loam or sandy loam soils, but will grow on any soil. Will tolerate acid soil. Makes rapid growth and holds soil well with heavy, fibrous roots. Sow 1½ ounces per 100 square feet, covering seed ¾ inch deep.

Wheat, winter (*Triticum aestivum*). An annual grass that will grow all over the United States. Does well at high elevations. Prefers loam soils. Grows best in fertile soil, but will tolerate moderately fertile soil. Sow 4 ounces per 100 square feet, covering seed ¾ inch deep.

Continued →

and avoid tying the shoots too tightly to the stake. Install the supports as early in the growing season as possible so that the plants can be trained to them as they grow, not forced to fit them later on. When growing plants from seed, install the support before planting.

In the flower garden, choose supports that are as inconspicuous as possible. Thin, slightly flexible stakes that bend with the plant are less conspicuous and may be better than heavier, rigid ones. In general, select stakes that stand about three-fourths of the height of the mature plant. Insert them close to or among the stems so that as the plant grows, the foliage will hide the supports. Choose colors and materials that blend with the plants. Bamboo stakes tinted green are available in a variety of sizes and are a good, inexpensive choice for many plants. You can also buy wood, metal, and plastic stakes and trellises, and a wide assortment of metal rings and support systems. Using green twine or plastic-covered wire is an inconspicuous way to fasten plants to their supports.

In the vegetable garden, sturdiness is more important than appearance. Staking vegetables like tomatoes, peppers, and beans makes them easier to cultivate and harvest. It increases yields by preventing contamination with soilborne diseases and allowing for more plants in a given area. Choose tall, sturdy stakes or cages that can support the plant even when it is heavy with fruit, and insert stakes firmly into the ground. Use narrow strips torn from rags or bands cut from stockings to gently fasten plants to supports.

Perennial vines such as roses and grapes are commonly grown on trellises or on wires between sturdy posts.

Trees and tall shrubs are commonly staked temporarily at planting to help hold them upright until their roots become established. Fruit trees on dwarfing rootstocks may need to be permanently staked.

Standard Staking Methods

Here are four ways to stake plants in the garden. Be sure to match the staking method to each plant's growth habit:

Individual stakes: Sink stake firmly near the stem when plant is 6 to 8 inches high. A loose figure-eight tie connects stem to stake securely yet maintains the plant's natural form and prevents damage to the stalk. As the plant grows, add ties every 8 to 10 inches. Two closely spaced plants can be tied to one stake if it is placed between them. Top-heavy flowers like the delphinium need stakes almost as tall as the mature plant.

Twiggy brush: For plants such as peas, coreopsis, and baby's-breath, try lengths of sturdy, twiggy brush or branches. Cut the brush to the final height of the plants, and push it 6 inches into the ground between the plants.

Wire ring supports: Bushy plants with heavy flowers, like peonies, can be grown in a wire ring. The foliage will hide the ring as the plants grow. The natural form of the plant is enhanced, not disrupted.

Stakes and strings: Insert four stakes into the corners of the bed when shoots are a few inches high. Tie string (or wire) from stake to stake to form a box about 6 to 8 inches off the ground. Add strings as needed. Run additional strings across the bed or weave them back and forth to keep plants from falling inside the bed.

Using Cover Crops

Barbara W. Ellis

"Use it or lose it" is a phrase that could be applied to garden soil. Soil left without a protective covering of plants slips away like sand through an hourglass. Wind blows it away; rain washes it down hills and leaches nutrients out of the root zone. Fortunately, there is an easy way to not only stop this process but also to actually improve your soil to benefit future crops: Grow cover crops.

What exactly are cover crops? They're crops grown exclusively to feed, improve, and protect the soil. Also called green manure, cover crops—generally legumes such as clover and grains such as rye—are sown, allowed to grow, and then tilled into the soil either with a rotary tiller or by hand before they flower and set seed. In addition to stopping erosion, cover crops also prevent nutrients from leaching out of the soil. Planted into a mature crop or immediately after the ground is cleared, they act as holding tanks, taking up nutrients and keeping them near the soil surface. In spring, after the cover crop has been tilled under, new plantings will draw on this reservoir as the cover crop breaks down. Cover crops do more for the garden, though. Those that make a fast, dense stand keep weeds from getting a foothold after the fall harvest. As they decompose, they enrich the soil with vital organic matter, which improves structure as well as nutrient- and water-holding ability. Legumes such as sweet clover also convert atmospheric nitrogen into a form that is taken up by the crop, and then released into the soil when the legumes are tilled under. Cover crops also help to retain moisture in the soil and help to moderate temperature fluctuations. Both of the effects protect earthworms and other soil microorganisms.

Planting Cover Crops

There are several different ways to use cover crops in the garden. You can sow a winter legume like sweet clover or winter

rye in fall after you've harvested your vegetables and turn it under in early spring. Another option is to rotate garden beds by planting vegetables in a bed one year and a cover crop the next. You can also sow a cover crop directly under a vegetable crop, but the trick is to sow the cover crop after the vegetable crop has become well established so that they don't compete. For example, clover can be broadcast under sweet corn or other big vegetables after the last cultivation (about five weeks after corn has been sown). The clover can then be left to protect the soil in winter and tilled under in spring.

To sow a cover crop, lightly work the soil with a tiller or a spade, or just rough up open spaces between plants with a hoe, to prepare a seedbed. Then scatter the seed evenly, and rake or hoe lightly to cover it. For clovers, tamp the soil after sowing to provide a firm seed bed. If you're sowing in late summer or fall, the seeds will sprout and grow until temperatures get too cold. Some cover crops are winter-killed, others resume growing in spring. Either way, they're tilled under a few weeks before planting.

TILLING IT UNDER

The first step in turning under a cover crop is to cut back the top growth with a sickle, scythe, or mower. This is generally done in very early spring. Make several passes with a rotary mower to chop up the plants. A layer of compost or manure spread over the top will also help speed decomposition. Then, use a rotary tiller to work the plants into the soil. You can also hand-dig the crop under, although if your garden is large this can be a daunting task. If the tops of the plants were very lush, stop after two passes with the tiller and let the soil dry out for a few days. Then till the soil again until you have a manageable seedbed.

You'll need to wait 7 to 10 days after tilling under a legume cover crop before you plant vegetables or other crops; 14 days or more after a grain crop. That's because the decomposing cover crop releases ethylene gas for the first few days, which inhibits seed germination. Also, the microorganisms breaking down the crop tie up nitrogen, and the temporary deficiency will hinder the growth of seeds or transplants.

WHAT TO GROW

Basically, there are two types of crops that can be grown for green manure: legumes and grains. Legumes such as white clover or hairy vetch have the special ability to fix atmospheric nitrogen and add it to the soil by virtue of the *Rhizobium* bacteria that live in their root systems. The nitrogen becomes available to plants after the legume is tilled under. Grains such as winter rye, winter wheat, barley, or oats are grown for green manure because they produce lots of succulent growth that provides organic material when the plants are turned under to help build soil and boost microbial activity. They also have extensive fibrous root systems that take up and hold potassium in the soil. Buckwheat is a good source of phosphorus. Another advantage

Support Your Vegetables

Vegetables such as tomatoes, peppers, and beans need sturdy support in the garden. Try these methods to keep plants growing strong:

Lifetime Cages

The same welded steel mesh that gives reinforced concrete its strength is just the thing for making vegetable cages that will last a lifetime. You can buy it at just about any building supply center. Figure on buying at least 16 feet—enough for two cages.

The only tools you need are a small pair of bolt cutters to cut the heavy wire and a good pair of pliers. Be sure to wear work gloves to avoid cuts and blisters.

Lay the mesh strip flat on the ground. Measure an 8-foot piece by counting off 16 sections of the mesh (each section of mesh is 5¼ inches x 6 inches). In the middle of the 16th section, cut each cross wire in the middle. You'll use those loose ends later to fasten the cage together.

Next, trim off the bottom horizontal wire to create a row of 5-inch tines along the base of the cage. Now gently bend the prepared mesh section into a circle. Pull the clipped ends together, and use your pliers to twist them around each other to form the cage.

Set the cage upright around the plant, and push the tines into the ground to anchor it. Even high winds and bumper crops have a hard time toppling these cages. At the end of the season, clear off old vines and store the cages for winter, or leave the cages standing and have them double as compost bins.

Drying-Rack Trellis

For a simple trellis, set up an old wooden clothes-drying rack, lay it on its side in the garden, and set your tomatoes between the rungs, which will stand about 3 feet high. As the plants grow larger, they will be supported by the rungs, and the fruit will ripen well above the ground.

Custom Stakes

Tying up tomatoes and other vegetable plants is easy with custom-made stakes. First, take a ¾-inch x 1½-inch stake and make saw cuts about ½ inch deep and about 1 foot apart, staggering them on either side. Next, cut strips of panty hose ⅜-inch x 10 inches, and tie knots at each end. Put the stake in the ground, then put one end of a strip in one of the slots, using the knot as an anchor. Loop the strip around the tomato stem in a figure-eight pattern and secure it in another slot on the other side of the stake.

Continued →

of grain crops—especially winter rye—is that they can grow quickly in the fall when temperatures are cool and rapidly absorb easily leached nutrients and hold them until spring. Rye seeds can germinate at temperatures above 33°F, and will grow in the fall until temperatures drop below 40°F. They then resume growing in the spring, providing lots of green manure for tilth- and nutrient-building. If you allow rye (especially winter rye) to grow too tall in spring, you'll need machinery to turn it under.

Combinations of grains and legumes, such as rye and hairy vetch, hairy vetch with winter barley or wheat, or clover and barley, offer the best of both worlds. They provide nitrogen fixation from the legume and organic matter from the grain. When seeded together, the fast-growing grain protects the legume until it becomes established.

Harvesting the Low-Maintenance Way

Barbara W. Ellis, Joan Benjamin, and Deborah L. Martin

A big part of hassle-free harvesting actually happens months ahead of time, when you plant your garden. For example, at planting time you could choose cultivars that are ready to pick at different times, so you don't have to harvest anything at once. But once it's time to pick, a little planning and organization go a long way toward speeding up the harvest.

The pages that follow include ideas for quick picking, as well as pointers on how and when to harvest for peak flavor. And just in case you have to harvest early, or a few crops slip past their prime before you can get to them, you'll find suggestions for fast, tasty ways to prepare non-prime produce.

Good Timing Helps You Make the Most of What You Pick

Harvesting right can be one of the most time-saving things you can do in your garden. Not only will you make the most of your gardening efforts by picking produce when it tastes the best, but letting your harvest get out of control always means extra work. And cleaning up rotten fruit, pulling bolted plants, and hauling waste to the compost pile is unpleasant work at best.

Harvesting when weather conditions favor good flavor is an easy way to make sure you get the most from what you pick. Because heat and strong sunlight make plants lose water, your produce will be the most succulent if you harvest when the weather is cool and not too bright—in the morning or evening, or on a cloudy day. As an added plus, produce that's harvested during the cooler parts of the day is cooler, so it will chill faster when refrigerated and stay fresh longer.

Try to harvest when the plants are dry so you don't inadvertently carry diseases through the garden. (Disease-causing fungi spread from plant to plant through the garden in water droplets.)

SOME DON'T LIKE IT HOT

Some crops can't take prolonged heat; it ruins their taste. Vegetables that are touchy about heat include broccoli, cauliflower, lettuce, peas, and radishes. Plan to pick them if a week or more of hot weather—temperatures higher than about 80°F—is about to set in.

Warm temperatures cause them to bolt, or send up a flower stalk. Generally it's best to send crops that have bolted directly to the compost pile. If you take the time to bring them into the kitchen, you'll find that radishes grown in too much hot weather are very hot, while bolted broccoli and cauliflower will no longer have the crunchy heads they're grown for. Bolted lettuce leaves are bitter.

SET YOUR PICKING PRIORITIES

Good flavor can be fleeting; some crops pass their prime nearly overnight, while others stay stable for a week or two. If you are in a time crunch, first check the fruits and vegetables that won't wait, then the ones that are more patient.

You'll find harvesting at the right time means less waste—and that's good news for your plants and for your wallet.

Stretch Out Your Harvest with Simple Season Extenders

It takes just a bit of added effort to coax an extra-long harvest from many plants. What's in it for you? Sometimes weeks of harvest from plants you'd otherwise have to replace.

To get more from lettuce and other greens, for example, just remove tender outer leaves as you need them, leaving the rest of the plant to continue growing. When you harvest broccoli and cabbage, leave a few inches of stalk and a few lower leaves to encourage the plant to produce sideshoots—they'll be smaller but just as edible.

OH-SO-SIMPLE FROST PROTECTION

Protecting plants from an early frost is another way to extend your season and it doesn't have to take much more than a few minutes of your time. Providing temporary frost protection is a good way to buy time if the crop isn't ready to pick or you just don't have time to harvest. Often, a killing frost is followed by several weeks of warmer weather, so you may only have to protect plants for a night or two to extend the season by several weeks.

The quickest method is to cover the plants with sheets, blankets, or plastic on nights when frost threatens. It's primitive, but it works. Of course, you'll want to keep lightweight covers from blowing away by anchoring loose corners with rocks or bricks, or by resting dead branches over the top. Just be sure not to smash the plants in your efforts to save them. Avoid crushing especially delicate plants by placing a tomato cage over them before throwing on the cloth or plastic. Use clothespins to clip the cover to the framework.

Another method is to make a tent over a grouping of plants, using the same tent-making technique you perfected

as a child: Tie a clothesline to supports on either end of the grouping—garden stakes or the backs of lawn chairs will do. Then throw a blanket, tarp, or other covering over the clothesline and anchor the corners with rocks.

For an easy but more permanent solution to frost and cold, cover cool-season vegetables like beets and greens with a 6-inch layer of loose straw or leaves. You'll have fresh produce into winter.

Become a Quicker Picker

Take a few moments during a post-planting lull to get organized. This way, once crops are ready, you can make the most out of every harvesting minute. Think about ways you can save steps and handle your produce fewer times. Here are some proven shortcuts to get you started; see how many more you can come up with.

Slip into your shoes. Keep an old pair of slip-on shoes near the door so you don't waste valuable picking time hunting for footwear. Kick them off on your way back in so you don't have to clean dirt off the floor.

Pack while you pick. Carry along plastic bags and containers and pack the produce while you're in the garden. When you get to the kitchen, put the goods directly into the refrigerator.

Chill in the garden. If you'll be in the garden for more than half an hour, take along an ice chest and chill peas, corn, broccoli, and delicate greens and fruits; otherwise, they'll fade fast.

Sort the good from the bad. Carry an extra bucket for damaged fruits and vegetables, and toss them into it as you pick them. By sorting the good from the bad right away, you don't have to touch each piece again in the kitchen.

Clean it outside. Wash greens or produce you plan to eat right away while outside to prevent a mess in the kitchen. Fill a bucket with cold water, or use the kids' wading pool. While you're at it, pick off and compost the inedible parts like stems and husks.

Use Basic Tools as Handy Harvest Helpers

When it comes to tools, the fewer the better. You don't want to feel like a one-man band clattering your way to the garden. For most picking jobs, your hands are sufficient—you may want to wear gloves when harvesting crops that are scratchy or smelly though.

Take along a knife for harvesting thick-stalked crops like broccoli and cabbage, as well as leafy crops like lettuce. Use scissors or pruning shears to cut the stems of peppers, okra, and other crops that don't pull off easily. If you'll be harvesting potatoes and other root crops, carry a spade or garden fork; if the soil is dry, you'll make the job easier by moistening it slightly before digging. If you have tree fruit to pick, consider investing in a long-handled fruit picker to save you from struggling with ladders.

Smart Tips for Handling Pre- or Post-Prime Produce

If you have to harvest a little early because frost threatens, or if wet weather keeps you out of the garden during a critical week, you can still make the best of your produce.

Try these not-so-tough tricks. Conquer toughness in cookable vegetables by dicing, grating, or shredding them. Then sauté, stir-fry, or add to soup, stew, or egg dishes.

Puree not-quite-prime produce. Some vegetables are well suited, either cooked or raw, to being pureed with tomato juice to make a vegetable cocktail. Which ones you use is a matter of preference; for starters, try sweet peppers, celery, carrots, and a bit of onion.

Turn them into soup. Make a soup base by boiling vegetables until they're very soft. Strain the broth and compost the vegetables. Don't use members of the crucifer family, such as broccoli and cauliflower—their flavor is too strong.

Put up jam or jelly. Make jam or jelly from berries that aren't quite ripe.

Puree post-prime fruit. Any fruit past its prime can be pureed, then served over ice cream or mixed with fruit juice and chilled for a cooling summer beverage.

Add it to the soup. Make soup from carrots, peas, potatoes—even cucumbers. Also add pureed vegetables to soup stock.

Bake it. Make breads or muffins from apples, blueberries, tomatoes, carrots, or zucchini.

Make compost. Add rotten produce to the compost pile. The rejects decompose to form great fertilizer, and you keep diseases and insects off the plant.

Quick Tricks in the Kitchen

Produce is most flavorful and tender when picked at its prime—and picking produce at its peak also saves you time and work in the kitchen.

You can serve many fresh vegetables raw or give them a light steaming. By picking produce at the right time, you'll have fewer tough stems or leaves to discard, so less goes to waste and you get more food on the table.

WASHING CAN WAIT

When faced with a bushel of muddy produce fresh from the garden, you may be tempted to scrub the lot of it—using up your evening and messing up the kitchen in the process. Fortunately, you don't need to—in fact, in most cases you shouldn't. Washing most vegetables and fruits before storing makes them vulnerable to rot. It's better to wash produce right before you use it.

There are a few exceptions. Take a few moments to briskly but briefly swish greens—such as lettuce, chard, spinach, endive, and kale—in cool water, then shake off the excess and roll them in a towel before putting them into a plastic bag

Continued →

and then into the refrigerator. Cucumbers can be washed beforehand; so can leeks, which hide dirt in their layers.

Stretch Your Storage Time

With a little attention to how you wrap and refrigerate your produce, you'll increase its storage life. Fortunately, proper storage isn't complicated since most produce needs the same treatment: a plastic container or wrap, and a temperature of about 35°F. The few exceptions are listed below. (Note that the best storage temperatures are cooler than the average refrigerator, which is generally somewhat warmer than 35°F.) Check this list to find out how to store your produce properly and how long you can expect it to last.

COLD AND MOIST

To get the maximum storage from the vegetables listed below, keep them near freezing in a refrigerator. Store in a plastic container or wrap.

Asparagus	2 weeks
Beets	1–3 months
Blueberries	2 weeks
Broccoli	3 weeks
Brussels sprouts	1 month
Cabbage (early maturing)	3-6 weeks
Cabbage (late maturing)	3-4 months
Carrots (tops removed)	4-6 months
Cauliflower	2-3 weeks
Collards	2-3 weeks
Corn	4-8 days
Kale	2-3 weeks
Lettuce	2 weeks
Onions (green)	2-3 weeks
Parsnips	2-6 months
Radishes	2-3 weeks
Turnip greens	2-3 weeks
Turnip roots	4-5 months

COOL AND MOIST

Keep the following vegetables cold but not freezing—a root cellar or basement that stays about 40°F is ideal. Keep most vegetables listed in a plastic container or wrap; potatoes store better loose so they don't get moldy—and be sure to keep them in the dark.

Beans, green	1 week
Cucumbers	10-14 days
Eggplants	1 week
Peppers, sweet	2-3 weeks
Potatoes, Irish	4-6 months
Squash, summer	7-10 days
Watermelons	2-3 weeks

COOL AND DRY

The following vegetables need cool—about 40°F—and dry conditions for best storage. Try keeping them in an attic or unheated room, and don't put them in plastic containers or wrap.

Onions	2 months
Pumpkins	2-5 months
Squash, winter	2-4 months
Tomatoes (ripe)	1 week
Tomatoes (unripe)	Up to 1 month

Season Extension

Fern Marshall Bradley

Gardeners are never satisfied with the weather. It's either too wet or too dry, too hot or too cool. Northern gardeners struggle to grow heat-loving crops like melons, tomatoes, and peppers; southern gardeners strive for sweet, succulent lettuce, crispy radishes, and tender peas. While you can't change your climate (unless you're prepared to move and face a new set of challenges!), there are things you can do to create more-favorable microclimates within your garden.

In cold-climate areas, cold frames and row covers are standard weapons in the battle against late-spring and early-fall frosts. You may also want to choose cold-tolerant or fast-maturing cultivars of your favorite crops. In hot-summer areas, gardeners use shade cloth and heat-tolerant cultivars to extend the growing season for choice cool-season crops. In this section, you'll find helpful tips from expert growers across the country on how they stretch their growing seasons.

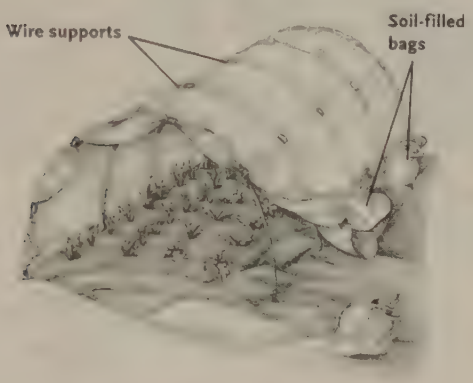
Simple Tricks for Extending the Season

Your efforts at season extension don't have to be fancy or complicated to work. Tools as simple as a piece of plastic or a few rocks can help you get an earlier start on the season.

WARM YOUR BEDS WITH PLASTIC SHEETS

Get a head start on planting your garden by prewarming the soil. Alton Eliason, who was named Farmer of the Year in 1991 by the Natural Organic Farming Association, plants two to three weeks earlier than his neighbors. Eliason says, "In mid-February, about six weeks before my first planting date, I cover the garden with a sheet of clear plastic, right on top of the snow.

Clear plastic raises the temperature by 10° to 15°F, whereas black plastic only raises it by 5° or so. The snow melts right off, and the soil's always ready a few weeks earlier than normal." Eliason gets his big plastic sheets from area greenhouse growers who replace their glazing every two or three years.



A tunnel of clear plastic protects fall crops from hard frost.

NEW WAVE PLANTING TECHNIQUES

The lay of the land in your garden beds can affect how and when soil warms. Bill McDorman, the founder of High Altitude Gardens, an Idaho mail-order seed company, finds that one of the most effective techniques for combatting cold soils is shaping the garden surface before planting.

"This is similar to making raised beds, except that you shape the beds like waves in the ocean. I make the beds 3 to 4 feet wide, and slope them to the south," explains McDorman. He plants warm-weather crop seeds, such as squash, on the south face of his waves, just below the ridge. The soil drains well there, just as it does in a raised bed. The southern exposure warms the soil, and cold air is directed by the soil configuration to fall into the "valley" beyond the wave. Other heat lovers like basil and corn also benefit from this planting technique.

GROW THEM FAST UP NORTH

Extending the growing season is an absolute necessity in places like Glover, Vermont, home of Lewis Hill, a nursery owner and the author of *Cold-Climate Gardening.* Hill's growing season is only 90 to 110 days, with occasional frosts in July. "This is the icebox of New England," says Hill.

How does Hill successfully produce corn, tomatoes, peppers, eggplant, pumpkins, and squash in such a harsh environment? "My favorite technique is to get intensive growth as fast as possible during the early part of summer when the days are long," explains Hill. To promote vigorous plant growth, he waters frequently and makes liberal use of liquid fertilizers, such as manure tea and fish emulsion. Standard season-extension tricks like covering seed beds and young plants with floating row covers or plastic jugs are a necessity for keeping the chilly spring and fall air from the plants. To stack the odds in favor of a good harvest, it's also smart to start with cold-tolerant and fast-maturing cultivars of normally slow-ripening crops like melons and winter squash.

TRANSPLANT TO HASTEN HARVESTS

Looking for a way to get your heat-loving crops off to a fast start? Take a tip from Jacob R. Mittleider, Ph.D., who teaches beginning farmers in Zaokski, Russia, a town about 100 miles south of Moscow (at about the same latitude as Edmonton, Alberta, in Canada). In the summer of 1991, he and his students produced more than 220 tons of food on 23 acres.

What is his secret? "I transplant everything: beans, corn, beets," says Dr. Mittleider. "I would do it with carrots, but if I do, they will never get larger than 4 inches. Transplanting gives an even harvest, not a mix of big plants and little plants."

Dr. Mittleider plants his transplants outdoors with special care so they won't lose ground during the transition. He plants in shallow trenches in raised beds and protects the young plants until they are well-established by covering them with heavy plastic supported by wire hoops.

PUTTING ROCKS INTO THE GARDEN?

Gardeners are always trying to get rid of rocks in their garden soil, but here's one tip that calls for using rocks. "I plant on the south side of rock or concrete walls wherever I can. This generally speeds plants up by as much as one month. But I don't have as much wall space as I'd like, so I import rocks into the garden," says Bill McDorman, the founder of High Altitude Gardens, an Idaho mail-order seed company.

To use McDorman's method, cover the soil around the base of each plant with a circle of whatever rocks you can find. Place the rocks close to but not touching the plants to avoid damaging the tender stems. The rocks gather and store heat during the day. At night, the rocks release the heat, helping to protect the young plants from frost. The rocks also help to moderate changes in soil temperature, encouraging better root growth. You can leave the rocks in place all season, and they'll serve as a mulch to keep moisture in the soil and prevent weed growth around your plants.

Cold Frames and Other Covers

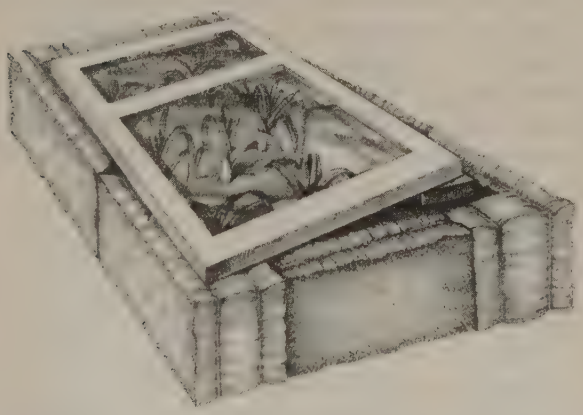
The greenhouse effect is a phenomenon that northern gardeners can take advantage of to help extend their growing season. No, not on a global scale, but by using enclosures like plastic or glass covers that trap the sun's heat and create tiny oases of warm air around growing plants.

SLITTED TUNNELS FOR SUPER TOMATOES

Plastic covers suspended over rows of plants are a great way to protect tender crops from spring chills. But they do require regular ventilation to prevent heat from building up inside on

Continued →

Soaker hoses and drip irrigation. For small beds, soaker hoses (left) are great, releasing water slowly and evenly to the whole bed. Cover the hoses with mulch to conserve moisture. For large beds, use a drip system (right), which delivers water through spaghetti tubes directly to the base of each plant.



Six bales of straw and an old window or a wooden frame covered with plastic serve well as a temporary coldframe. Use blocks of wood to vent the frame.

sunny days. If you don't have the time or inclination to keep raising and lowering the sides of a solid plastic cover, try a slitted row cover instead.

A slitted row cover is "a tunnel with 6-inch openings punched through at regular intervals to ventilate the tunnel. It has been a great season extender for us," says Ward Sinclair, an organic vegetable farmer from Pennsylvania.

One year, he and his partner, Cass Peterson, planted 'Siberia' tomatoes in the field in early April and covered them with slitted row covers. "The tomatoes were flowering like crazy on Memorial Day," recalls Sinclair. "They were bursting out of the tunnels, just lifting the plastic off of the ground."

But the plants are not the only thing that tries to lift row covers at their Flickerville Mountain Farm and Groundhog Ranch. "Our main problem is wind," adds Sinclair. "You have to cover the edges of the plastic with soil along the whole length of the tunnel. You can't just put a handful of soil here and there and expect it to hold." Long metal pipes or boards also make good anchors for row covers. They are easy to move and reposition when you need to temporarily uncover the plants for maintenance or harvesting.

PROTECT PLANTS WITH PORTABLE FRAMES

If you want to protect a lot of plants with plastic row covers, try framing the row covers to make them easier to set up and take down. Robert F. Becker, a retired associate professor at Cornell University's New York Agricultural Experiment Station in Geneva, has created a design for sturdy framed covers that are easy to move around the garden. Here's how to make them:

1. Using 2 X 4's and nails or screws, make a square wooden frame, 18 inches on each side.
2. Drill four holes halfway through the frame from the top, one in each corner.
3. Make two arches of rigid wire (9- or 10-gauge works well). Position each arch diagonally over the frame, inserting the ends of the wires into the holes. This creates a dome shape.

4. Cover the frame with a piece of clear plastic, stapling it to the wooden frame.

The wire domes sit about 1 foot above the soil surface, giving enclosed plants plenty of head room. Becker cuts a ventilation hole in the side facing south after positioning the frames. When plants need additional ventilation, Becker props up one side of the frame with a brick or rock. This extra ventilation helps harden off the plants before he removes the cap. "The only trouble with these frames is storage," admits Becker. "You need a place to keep them during the winter. I like them, though, because they're portable and inexpensive. The plastic needs to be replaced every two to three years, but the frames last for years."

KEEP PLANTS WARM WITH WATER

Wallo'Waters surround individual plants with water-filled plastic tubes, which store heat during the day and radiate it out at night to keep plants warm and toasty. Ward Sinclair, an organic vegetable farmer from Pennsylvania, thinks they are one of the best season extenders around.

"It's a fantastic device," Sinclair declares. "It keeps peppers perfectly." Sinclair has used Wallo'Waters to produce early tomatoes and muskmelons that blossom on Memorial Day. Once the danger of frost is past, he plants basil between the tomatoes. "I lift the Wallo'Waters off the tomatoes and set them over the basil," he says. The result? Basil a month early, to complement your early tomatoes!

One way to save some money when buying Wallo'Waters is to buy a full case of 36 and split it with your gardening neighbors, friends, and relatives. Or if you're extremely thrifty, you can follow the example of Miranda Smith, an agriculture writer and organic market gardener from Massachusetts, and build your own. Just fill 2-liter plastic soda bottles with water, set them around peppers or eggplants, and encircle the ring of bottles with a sheet of plastic.

THE WORLD'S LARGEST ROW COVER

Ever wonder what you could grow if you put your entire garden under cover? It's not as farfetched as it sounds, according to Otho Wells, Ph.D., a New Hampshire Cooperative Extension vegetable specialist. Dr. Wells calls garden-size covers "high tunnels" because they are about 6½ feet tall at the center.

"I would recommend a 14 x 36-foot tunnel for a garden," Dr. Wells suggests. "You can put an awful lot of stuff in a 14 x 36, especially when you consider companion planting." You can grow just about anything from sweet potatoes to cut flowers inside of a high tunnel. Only a few crops such as sweet corn or winter squash take up too much room.

High tunnels "give you two to four weeks head start in the spring, depending on the conditions, then take you into the fall, to Thanksgiving, and even to Christmas," says Dr. Wells. "They're like small greenhouses, but they're not greenhouses because they have roll-up sides. They give you tremendous protection against the environment: wind, rain, insects, and diseases."

Jeff Cox

At one time or another, most of us have run into a water shortage. We couldn't wash our cars, water our lawns and gardens, or let the children play in the sprinkler. It lasted maybe a few weeks; then it rained and life returned to normal. Or so it seemed. Running on empty is becoming a way of life in state after state in the United States and in a growing number of countries around the world.

Another problem is water quality. In coastal areas with shallow water tables, for example, heavy pumping of groundwater allows salt water to seep into wells. In heavily agricultural areas, pesticides and fertilizers are tainting both surface and groundwater supplies.

While we can't as individuals change patterns of water use in commercial agriculture, we can all take steps to reduce water usage in our homes and yards.

So how do you go about conserving water *and* watering your garden at the same time? One answer is drip irrigation. A drip irrigation system delivers water directly to the root zone of plants, without the waste of evaporation or runoff. Coupled with basic conservation techniques such as using mulch, selecting plants that require less water, and limiting lawn area, drip irrigation can help conserve water while ensuring a healthy garden.

Conserving Water in the Garden

With a little planning, it's possible to have good gardens, a beautiful lawn, and landscaping that need very little supplemental watering. The first step, of course, is to increase the water-holding capacity of your soil by adding organic matter. In deep, rich soil protected by mulch, plants find it much easier to develop the strong, deep root systems necessary to find water during dry periods. Cultivating the soil between row crops also helps water filter into the soil.

Continued ➔

There are many other things you can do to reduce watering needs without sacrificing the beauty or pleasure of your yard and gardens:

- Mulch trees, shrubs, and other plants with up to 3 inches of mulch.
- Water less frequently, but water deeply, making sure to soak the root zone rather than the whole yard.
- Select native plants that require less water.
- In arid climates, follow the principles of Xeriscaping in planning and maintaining your yard. A Xeriscape (from the Greek *xeros*, meaning dry) is a water-saving garden designed for a dry region. Many municipal and state water departments publish low-cost or free guides for the beginning Xeriscaper. Check your library, bookstore, or the government listings in your phone book to read more about planning a Xeriscape. Publications on this topic are available from the National Xeriscape Council, P.O. Box 163172, Austin, TX 78751-3172.
- Limit the size of your lawn. Replace lawn with groundcovers, mulches, and shade trees to help you and your yard keep cool.
- Add a walkway, deck, or patio to help reduce water consumption while adding more enjoyment to your yard.

Using Drip Irrigation

For those situations in which you have to water, always strive for the most efficient method. When you water with the hose or an overhead sprinkler, some water is immediately lost to evaporation from plant surfaces, through surface run-off, or by falling in areas that don't need water, such as a street or walkway.

A more efficient method is a custom-designed drip irrigation system that will water all or any part of your landscape. Also called "trickle" or "weep" irrigation, drip systems are as beneficial for dryland gardeners as for those in the northern, eastern, and southern parts of the country. The water savings and increased plant growth in your garden will more than make up for the cost and effort involved in the design and installation of a drip irrigation system.

A drip irrigation system delivers water directly to a plant's root zone, where it seeps slowly into the soil one drop at a time. Almost no water is lost through surface runoff or evaporation, and soil particles have plenty of opportunity to absorb and hold water for plants. It also means very few nutrients leach down beyond the reach of plant roots. Furthermore, since drip irrigation delivers water directly to the plants you want to grow, less is wasted on weeds. The soil surface between plants also remains drier, which discourages weed seeds from sprouting. All these benefits add up to the fact that drip irrigation systems can save a great deal of water—and money in terms of reduced water bills. Studies show that well-designed drip systems use at least 30 percent, and in some cases 50 percent, less water than other methods of watering such as sprinkling.

For busy gardeners, the main benefit of installing a drip irrigation system is the savings of both time and effort. Drip systems eliminate the need to drag hoses and sprinklers around. For systems that use a timer, gardeners need only spend a few seconds to turn the system on; the timer automatically turns it off.

Plants watered with drip systems grow more quickly and are more productive, because they have all the water they need and their growth isn't slowed by water stress. (This is especially true when drip irrigation is used in conjunction with mulch.) These systems also keep water off the foliage, which helps prevent some foliage diseases such as powdery mildew.

DESIGNING A SYSTEM

The first decision to make in designing a drip irrigation system is what you want to water. Do you want a system only for your vegetable garden or for your entire landscape? Topography is also a consideration: If your garden is hilly, you'll probably need to use emitters that compensate for pressure changes in the line.

You can design your own system, but most companies that sell drip irrigation equipment will design systems for you if provided with a scale drawing of your garden, information on what you're growing, your soil type, and garden topography. Their design will come complete with a list of parts and spacing for emitters. Whatever method you choose, start by making a fairly accurate drawing of your garden to determine how many feet of tubing you'll need.

Plants can become "addicted" to drip irrigation, because roots will concentrate in the area where the water is available. When designing a drip system to carry water along the rows of a vegetable garden or to the roots of a prized rhododendron, it's important that the water be spread uniformly throughout the irrigated area so root growth will be uniform. For example, if you are irrigating larger plants such as trees and shrubs, place emitters on two or more sides of each plant to encourage roots to grow out in all directions rather than clustering on one side. Using your system for frequent, short waterings, rather than long, slow ones, is a bad idea for the same reason; the water doesn't have a chance to spread far in the soil, and consequently the roots form a tight, ball-like mass around the emitters.

Soaker Hoses Soaker hoses are another type of drip irrigation system that provides many of the advantages of emitter drip systems at a fraction of their cost. Some ooze water over their entire length; others spurt water through tiny holes. When using soaker hoses with holes, be sure to face the holes downward so the water doesn't squirt up in the air like a sprinkler. Systems using these hoses need no assembly; it's easy to lay out the hoses between small plants and along narrow rows.

Don't Waste Time on Water Wasters

Overthirsty plants, soil that drains too fast or too slowly, poor watering techniques, and inefficient garden plans not only waste tremendous quantities of water; they also waste your time and money. Look at your yard and garden and see which of the water wasters below are drinking you dry. Then try one or more water-saving solutions for quick relief.

Water Wasters	Water-Saving Solutions
Bare, uncovered soil. Water evaporates quickly from uncovered ground. Since wind and rain can beat at it at will, bare soil is often hard-packed or has an impenetrable crust, so water runs off it without soaking in.	Cover the ground with 2 to 4 inches of organic mulch. Use attractive mulches like bark chips or flower beds, trees, and shrubs, or plant bare areas with groundcovers to help hold moisture in place. Use any handy mulch materials—compost, grass clippings, shredded leaves, straw—for vegetable gardens.
Poor soil. Hard-packed soil, or soil that's either high in clay or high in sand, creates watering problems. Hard-packed or clayey soils may drain so slowly that water puddles and drowns plants or runs off without soaking in. Sandy soils may drain so quickly you spend all your time trying to keep plants from wilting.	Adding organic matter in the form of compost, shredded leaves, or aged manure will improve any type of soil—it improves drainage on hard-packed and clayey soils and helps sandy soils hold water longer. Keeping your soil covered with organic mulches helps add organic matter, but for dramatic improvement, add an inch of organic matter each year, working it into the top few inches of soil. After two to four years, you'll have a yard and garden that need less water and less care of any kind.
Planting plans that mix moisture-loving and drought-tolerant plants. This arrangement not only wastes water but creates plant health problems, too. If you give moisture lovers enough water, you'll injure or drown their dry-soil companions.	Group plants with similar water needs together. Plant them in different beds if possible. If you can't, cluster them together within beds. You'll be able to water each group according to its needs without wasting water on neighbors that don't want it.
Thirsty flowers, shrubs, trees, and vegetables. Plants that droop and beg for water every time you walk by only mean more work for you.	Keep a 2- to 4-inch layer of organic mulch around plants to conserve moisture. For even more water savings, replace extra-thirsty plants with drought-tolerant ones. Native trees, shrubs, and vines are generally good choices, as are deep-rooted perennials like peonies, yarrows, daylilies, coreopsis, globe thistles, pinks, and sedums. Plant wide rows of closely spaced vegetables to protect soil moisture from evaporating.
Overhead sprinkling. Sprinklers are inefficient at delivering water to plant roots. Much of the water that's shot into the air evaporates as it falls to the ground; winds also send it in unwanted directions.	If water pressure fluctuates, sprinklers won't run efficiently or cover the areas you aim at. Switch to soaker hoses or drip irrigation so water stays on the ground. Or to reduce evaporation, choose sprinklers that create large water droplets that fall more quickly. Watering in early morning instead of during the heat of the day also reduces evaporation. Purchase a pressure regulator to ensure that sprinklers have enough water to operate effectively.
Misdirected sprinklers. Inground or overhead sprinklers that water buildings, pavement, or weeds mean big water bills; only the weeds benefit.	Adjust sprinkler heads to cover only planted areas or purchase ones with spray patterns that fit your plantings. Drip irrigation or soaker hoses spread through planting beds will deliver water exactly where you want it.
Sprinkling plants until the ground looks wet. Watering a thirsty plant just until the soil surface looks damp creates more problems than it solves.	Plants watered this way need more frequent watering and develop very shallow roots. Water less often, but water deeply each time you do it so you soak the entire root zone. This encourages plant roots to grow deep into the soil, making them more drought-resistant. After a watering session, jab your finger into the ground to see how deeply you've really watered. (Or use rain gauges to see how much water you've delivered.) You'll be amazed at how dry soil can be under a surface that "looks" soaking wet.
Lawns. Large expanses of lawn grasses are the greediest water hogs of all. They demand weekly watering to look their best in the heat of summer.	Replace the thirstiest stretches of lawn with drought-tolerant groundcovers that can fend for themselves. If you can't part with even a small bit of your lawn, replace water-demanding grasses like Kentucky bluegrass gradually by overseeding with cultivars that require less moisture. Check with your extension agent or garden center manager for good choices for your area. You can lower your water bill even more if you use drought-tolerant, low-growing grasses like turf-type tall fescue, fine fescue, or buffalograss.

Soakers save water, reduce loss through evaporation, and keep leaves dry. However, since water emerges evenly along the length of the hose, water delivery can't be directed as precisely as with an emitter system. Soaker hoses can be used for short runs (100 to 200 feet) over flat surfaces. They're useful for crops such as carrots that are closely spaced.

Also known as dew hoses, soaker hoses can be made of canvas, various types of plastic, or rubber. Hoses made of rigid plastics or rubber can be hard to lay flat and difficult to bend around corners. Plastic and rubber soakers are resistant to fungal attack and seldom develop leaks at couplings or seams, so they can be left in the beds for long periods of time without

Continued ➔

deterioration. In contrast, canvas hoses are susceptible to mold and mildew and should be drained and dried after each use.

Save Time, Save Water

Fern Marshall Bradley

In a water-conscious era, we need to be as efficient as we can about water use. But most gardens need some supplemental water. Try these tips for reducing the amount of water you apply and the time you spend doing it.

Design Around Your Downspouts

Save a few spins on your water meter by taking advantage of downspouts to irrigate plants naturally. "Pay attention to where your downspouts are," advises Jim Borland, a Colorado garden writer and consultant on dryland gardening. If your downspouts lead directly to the gutter, reroute them to give your garden a boost.

Plan your design to make the most of rainwater, says Borland. Shape the soil into shallow basins to catch the runoff, or construct rills of slightly hilled soil to direct water to your plants. Place water-hungry plants closest to the extra moisture. In areas with frequent rainfall, some gardeners create a miniature marsh garden near downspouts, using plants such as cardinal flower (*Lobelia cardinalis*), lesser celandine (*Ranunculus ficaria*), marsh marigold (*Caltha palustris*), yellow flag (*Iris pseudacorus*), and water-loving sedges and rushes.

Wait For Signs of Water Stress

Instead of watering your entire landscape with an inch of the precious wet stuff every week, water only when the plants need it. Generally speaking, plants in pots may need water every day, lawns every three days, and established trees every ten days, says Tom Bressan, a California irrigation specialist. But watering needs vary widely depending on the species of the plant. Stretch the time between waterings until you see signs of distress, advises Bressan.

"Eyeball it!" he urges. Look at your plants to see which ones show stress first. Stay alert to the not-so-obvious signals of plant distress, such as foliage that seems dull or less glossy or shows curling edges. Watch for leaf drop, a signal that the plant is trying to conserve water. Serious wilting needs attention right away to save the plant.

Water Wisely With a Timer

Using a timer is one way to make sure your plants are getting the water they need. "Be sure your timer has separate zones for flowers, shrubs, lawn, or other areas," advises Susan A. Roth, the author of *The Weekend Garden Guide*, "so you can water them on different days for different lengths of time, according to their individual needs." Deep-rooted perennials, for instance, generally need less water than your lawn, and shaded areas stay moister than full-sun locations. You might keep lawn grass in one zone; drought-tolerant perennials, trees, and shrubs in another; and water lovers in a third.

A good timer is well worth the investment, Roth says. "Water infrequently but deeply," she urges. "Many timers can only deliver a quarter-inch of water each time they run. This is murder on your plants—and wasteful." It's also a good idea, adds Roth, to run that timer on the manual setting so you can provide water only when Mother Nature doesn't. If you set a timer on automatic, you are all too likely to end up watering your lawn during a rainstorm.

Top 10 Ways to Conserve Water While Caring for Your Garden

Vicki Mattern

Water is vital to the life of your garden and yard, yet gardeners often waste this precious resource. Whether your area is suffering from a drought or not, follow these guidelines to cut down on water usage:

1. Water deeply, making sure to soak the root zone rather than the whole yard.
2. When landscaping, choose native plants that require little or no water beyond what nature provides.
3. Plant groundcovers and shade trees to help keep your yard cool.
4. Mulch your garden regularly to lock in soil moisture.
5. Use watering methods such as drip irrigation or soaker hoses to reduce evaporation by directing water to plant roots.
6. Closely space plants in your raised vegetable garden, so there is less area to water (make sure to provide enough room for root development).
7. Follow the principles of xeriscaping, a water-saving garden design method used by many gardeners in more arid climates.
8. Limit the size of your lawn by adding a deck, patio, or walkway, which also adds backyard enjoyment.
9. Connect a rain barrel to a gutter on your home to create a ready source of water for your plants.
10. Recycle household water from drinking glasses and steaming or cooking vegetables and pasta to water plants.

Depend on Drip

Drip irrigation is a tailor-made way of applying water just where you need it. Tom Bressan, a California irrigation specialist, recommends polyethylene tubing with emitters punched into it where you want them. Drip tapes with holes, he says, are too thin-walled for permanent plantings. It's easy to install drip irrigation in an existing bed. "Use the claw side of a hammer," Bressan advises. "Drag it along the ground to create a shallow trench for the tubing." Add extra emitters for plants that need more water. After your layout is complete, bury the tubing in mulch. (Avoid placing drip tubing on top of existing mulch, because the mulch will absorb the water intended for the soil.) Pull the mulch aside if the system needs maintenance.

In an annual bed or vegetable garden, Bressan uses the drip system without mulch. If the plantings are closely spaced, Bressan recommends using emitter lines with regularly spaced, pre-installed emitters. In an annual bed, the leaves screen the tubing, he says, and the impact of the flowers draws the eye away. And in a vegetable garden, no one objects to a visible irrigation system.

LET THIS HOSE LEAK

A leaky hose may be the best irrigation device for the vegetable garden. Arizona garden writer Lynn Tilton uses a lawn spray hose, which has holes punched all along its length, to irrigate his tomato and corn rows. The hose delivers a gentle spray of water every foot or so. Tilton mulches the beds with grass clippings and then lays out the hose. He turns on the water, and the hose sprays upward so the water falls on top of the mulch, binding it together. Then he flips the hose upside down so that the water is forced out directly through the mulch and into the soil. Tilton says, "Our sandy soil makes regular hose watering almost impossible. When I use the sprinkler hose, I get a better crop with one-third the water."

Watering the Low-Maintenance Way

Barbara W. Ellis, Joan Benjamin, and Deborah L. Martin

Tired of dragging hoses and paying ever-increasing water bills? There are ways to stop spinning your wheels and your water meter. End your watering woes by using mulch or exchanging thirsty plants for drought-tolerant ones. There are tools, techniques, and watering systems that can do the work for you—and reduce your water bills—no matter what you grow.

Chances are your yard needs a water-wise makeover. In this section, you'll find ways to make your landscape less thirsty. Once you've added mulch and improved your soil, you'll find most established ornamental plantings need extra water only during droughts. Water is more crucial for new plantings, fruits, and vegetables, but in the pages that follow, you'll find a variety of efficient tools and techniques you can use to safely cut back on the time you spend watering them, too.

Spend Your Watering Time Wisely

Mulch can reduce your plants' water needs drastically, but there may come a time when they need a drink. When they do, you'll save time and avoid rotting roots, fungus diseases, erosion, and high water bills by applying the right amount of water when and where it's needed. Here's how.

Water only when plants are thirsty. When plants need a drink, they start to wilt, top leaves first. They droop in the heat of the day, then recover in the evening as the temperature cools down. As days pass and their thirst gets worse, leaf edges curl and leaves may take on a dull look. Eventually they don't perk up when temperatures cool, leaf edges turn brown and crispy, and, finally, they collapse.

To keep plants healthy, give them a drink when they start wilting slightly. If you wait until they are stressed, they'll be more likely to have problems.

Put water where it's needed. You'll waste less water if you use soaker hoses and drip systems to apply it to the ground directly around plants. These systems keep water off pathways, where it encourages weeds to grow, and off sidewalks and driveways, where it's wasted. You'll also have fewer disease problems with these systems since they don't wet plant leaves (which encourages fungal diseases).

Know how much is enough. The best rule is to soak the soil 1 foot deep when your plants get thirsty. Deep watering encourages deep rooting, which helps plants survive drought.

How do you know when you've soaked 1 foot deep? It depends on your soil type. Sandy soils let water pass through quickly, so ½ inch of water is all it takes to reach 1 foot down. If you have a loamy soil, ¾ inch of water will give you the desired results. Clay soils soak up water slowly, so you'll need to apply 1¼ inches of water for clay soil, spread out over several hours to keep water from pooling on the soil surface.

To measure water output for soaker hose and drip irrigation systems, follow the instructions that came with your system—their flow depends on water pressure. Use rain gauges to measure rainfall and water applied from overhead sprinklers.

Water when the time is right. If you're using an overhead sprinkler, the best time to water plants is early morning when the wind is calm and the sun is low. Water evaporates quickly during the heat of day, so much of it never reaches your plants. Plants watered in evening with overhead sprinklers or by hand tend to stay wet all night, which encourages disease. Soaker hoses and drip irrigation systems make it easy and effective to water any time, since evaporation isn't a problem and these systems don't wet the foliage.

Save Time with a Water-Saving Landscape

Do you race around your yard in the summer pouring water on every plant in sight? If so, you'll save loads of time and aggravation if you start using plants and techniques, like the ones shown here, that conserve water throughout your yard, landscape, and gardens.

It's best to start new plantings off on the right foot by selecting drought-tolerant plants. For existing gardens, though, it's often easier to change your watering methods than your plants. One good place to start cutting down on watering chores is to pick out which plants in your yard really need water and which do just fine with what they get from Mother Nature.

When They Need Water Most

CROP	CRITICAL TIME	BEST METHODS
Beans and peas	Germination, flowering, and while pods are developing	Drip, soaker hoses, hand-watering provided foliage is kept dry
Cabbage, broccoli, cauliflower	For 2 weeks after transplanting, and while heads are developing	Drip, soaker hoses, hand-watering if aphids are present
Carrot, radish	Germination, and while roots are enlarging; excessive water at maturity can cause roots to crack	Hand-watering or sprinkler; allow time for foliage to dry before nightfall
Corn	Germination, and from tasseling to maturity	Soaker hoses, drip, sprinklers in dry climates to increase humidity during pollination period
Lettuce, other leafy greens	Shallow roots demand constant moisture throughout life cycle.	Hand-watering, sprinkler, light mulch
Melons	Germination, and during first 3 weeks following fruit set; moderate dryness enhances flavor of almost-ripe fruits	Soaker hoses, drip
Onions, garlic	While roots are enlarging and all leaves are still green; allow soil to become dry when leaves begin to brown	Soaker hoses, drip
Potatoes	Constant moderate moisture during last month of growth	Soaker hoses, drip, hand-watering if aphids are present
Squash, cucumbers	Germination and starting 1 week after the first flowers appear until fruit has set	Soaker hoses, drip
Tomatoes, peppers	For 2 weeks following transplanting, and continuously from first flowering to maturity	Soaker hoses, drip, hand-watering of containers

Water to Suit Soil Type

We all know that water moves downward through soil. But how fast and how far it moves depends on the composition of the soil.

Soil particles collect a film of water, holding it against the pull of gravity. A clayey soil has many very fine particles with lots of surface area to hold water. A sandy soil, made up of fewer, larger particles, has less water-holding capacity. In a clay soil, if you apply 1 inch of water over a given area and allow it to soak in, it will wet the top 4 to 5 inches of soil, but in a sandy soil it will wet the top 12 inches of soil. Most plant roots are found in the top 6 inches of the soil, so applying an inch or more of water at a time to a clay soil makes sense. However, 1 inch of water would be excessive for a sandy soil, because some of it would quickly drain past the zone of most root growth and be wasted.

In heavier soils—those with a good percentage of clay—applying water to one spot, as with a drip emitter, can wet a 12-inch-diameter circle of soil.

Follow these guidelines for watering different types of soil:

Loamy soil. Water evenly and moderately for loam soils.

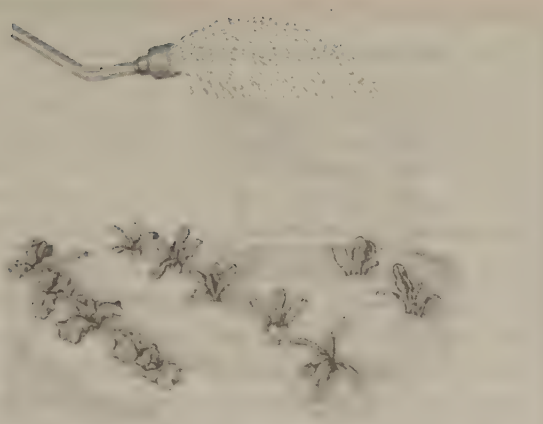
Sandy soil. Water less long but more often for sandy soils, which drain water quickly.

Clayey soil. Water longer for clay soils, allowing runoff to sink in before continuing.

For all soils, if the top 3 inches of soil are dry during the season of active growth, you probably need to water.

To decide what plants to water, determine which ones are essential to you. Do you depend on food from the vegetable garden? Do you have heirloom shrubs or flowers that you just can't live without? Do you have newly planted trees and shrubs that need regular watering until they become established? Will your neighbors harass you if your lawn goes dormant? Try to limit yourself to three areas that absolutely must have additional water and let the others fend for themselves.

1. **Select drought-tolerant shrubs and plant groundcovers.** Drought-tolerant shrubs like hypericum and Northern bayberry are just as attractive in foundation plantings and flower beds as thirstier shrubs like azaleas. And groundcovers need much less water than lawn to look their best. Replacing lawn with groundcovers around trees and shrubs will cut down on the water they need—and your mowing chores as well.



When you water young seedlings, mimic light rainfall by directing the spray in a gentle arc up and out over them.

2. **Use drip irrigation.** Install a soaker hose or drip irrigation system in your vegetable garden. Keep a thick layer of straw or other organic mulch on your garden on top of your soaker hoses so you won't lose water to evaporation or runoff.
3. **Collect free water.** Place a rain barrel under your downspout for a free water supply.
4. **Mulch, mulch, mulch.** Keep soil under flowers, trees, and shrubs mulched with wood chips, pine needles, or other organic mulches to hold moisture in the soil. Mulch discourages water-hogging weeds, too.
5. **Grow drought-tolerant flowers.** In flower gardens, plant drought-tolerant perennials such as coneflowers and other deep-rooted perennials like daylilies. Many ornamental grasses are drought-tolerant, too.

Make a Custom Watering System for Vegetables

Cut-to-fit irrigation systems are an easy way to make a custom system for watering vegetable gardens with parallel rows. Stretch the main supply line across the top or bottom of your garden, and attach sections of rubber ooze hose wherever you have a row of plants. You can cut the ooze hose to any length you need. To keep moisture in the soil and discourage weeds, install the system and cover it with organic mulch.

Make Your Hoses Behave with Handy Hose Tamers

Have you ever given your hose a tug and then looked on in horror as it leveled a row of cherished plants? The hose is not your enemy—it just needs a little guidance. Use the tools and techniques shown here to make it behave.

Flip tangled hoses free. A flick of the wrist is all it takes to turn a snarled hose into a model of good behavior. Detach your tangled hose from the faucet, grasp a free end, and keep flipping and rolling the hose until all the tangles are worked out.

Connect hoses with quick-release couplers. Stop struggling with hose ends that are difficult to screw onto faucets or other hoses. Brass quick-release couplers make connecting and disconnecting hoses easy: Just screw them onto hose ends, faucets, and all your attachments, and you'll be able to snap all your watering devices together or apart as needed. They're made to swivel so hoses won't kink. Plastic couplers are cheaper than brass ones, but some won't let water out of a faucet unless a hose is attached. Buyer beware!

Hang hoses high. Hoses last longer if you keep them off the ground. Inexpensive metal hangers, which you can attach to a shed, garage, or house, keep hoses organized and ready to use. Freestanding hose hangers are an option if you want to keep your hose near a garden. They're usually made of wrought iron and have prongs that let you anchor them into the ground. They're attractive but pricey.

Play It Again

Three Good Places to Coil a Hose

You can hang a hose from a rack or buy a reel to coil it, but if you're looking for more resourceful (and less expensive) options, here are three ways to give cast-off items a second life bringing order to your hoses.

- **Garbage can coil.** Cut down an old plastic trash can for a good hose-storage spot. Using a sharp, sturdy knife, carefully cut around the circumference of the can about 2 feet from the bottom. It may be easiest to do a rough cut first, and then go back and trim the edge. Turn the cut can over, and punch several drainage holes in the bottom with a hammer and large nail. Then coil your hose inside. In winter, you can drag the container and hose into your garage, basement, or shed for neat storage.
- **Wheel rim coil.** An old automobile or truck wheel rim makes a good place to coil a garden hose. Spiff it up for garden use by sanding off any rust and then applying two coats of white, green, or black metal primer. Then simply lay the wheel on the ground and coil the hose around it.
- **Big pot coil.** If you have a large terracotta pot that's lost its looks due to cracks and chips—or a half barrel planter that's become too fragile to hold plants—you have a great item for coiling your hose. Just turn the pot over, and coil your hose around the outside of the pot. Stow the male end, or nozzle, in the pot's drainage hole.

Continued →

Take weight off your back. Wheeled carts and reels can make dragging hoses easier. A cart lets you move several hoses around your yard at once with ease; add a reel and winding and unwinding hoses becomes a simple, nonsnarling task.

Direct hoses with homemade guides. To make a simple, inexpensive hose guide, stick a piece of rebar in the soil deep enough to it's sturdy; leave several inches above ground to keep your hose in place. Cover the rebar with a piece of bamboo (if looks are important) or PVC pipe. Place the guides in front of vulnerable plants or anywhere you don't want your hose to go. Or sink wooden stakes into the ground, leaving 6 to 8 inches exposed, and cover them with plastic soda bottles.

Handy Helpers: Tools to Make Hand Watering a Breeze

You could spend the summer with your thumb hooked over the end of your hose, but it's not only uncomfortable, it's also one of the least efficient ways to complete your watering chores. For the times when hand watering makes sense, the tools shown here will help make hand watering a breeze. They'll cut down on the time you spend hand watering and reduce the amount of water you use. All the items listed are available through garden-supply catalogs and at garden centers.

1. **Bubblers and water breakers.** These attachments can turn a hard stream of water into a gentle flow or spray, so they're great for watering fragile seedlings and areas that erode easily. Lay them beside a plant and they'll water while you do other work. Move them frequently to prevent flooding.
2. **Water wands.** If you have to water plants in the middle or back of a flower bed, extend your reach and gain control of your hose end with an inflexible, lightweight aluminum or plastic wand. You'll be able to direct water at the base of a plant or along the undersides of leaves to rinse pest insects away.
3. **Watering cans.** For indoor or outdoor container plants, or for a drought emergency in the garden, watering cans are time-saving choices. They let you haul small amounts of water around quickly without lugging out hoses. Consider the filled weight of a can before you buy. Water weighs slightly more than 8 pounds per gallon, so a 2½-gallon can will weigh over 20 pounds filled. Select a smaller can or plan on filling halfway. Attachments can make your life easier, too. The oval "rose" on the spout of some cans produces a gentle spray that's perfect for seedlings or new transplants.
4. **Fan sprayers, nozzles, and spray guns.** These attachments work great if you need to rinse off a dusty plant or wash off pests like aphids. They're not good for watering plants since they put out a high-pressure blast that sends mulch and soil flying.

Collecting Rain Makes Watering Easy

Rain barrels make it easy to collect and distribute rainwater: If you already have gutters and a downspout, all you need is the barrel. You can buy plastic ones with spouts, through mail-order garden catalogs. Or make your own barrel out of a plastic trash can if you'd prefer a do-it-yourself model.

Set the barrel under a downspout as close to your garden as possible. Keep it covered to keep mosquitoes out. Then run your downspout into the barrel, attach a garden hose to the spout, and you're in the water business. Run the hose to your garden or a landscape spot downhill for automatic watering. Otherwise, use your rain barrel for filling watering cans or dip water out as needed.

Build a Snow Fence Windbreak

When the purpose of a windbreak is to conserve soil moisture, using a material that casts low shade while filtering wind is ideal. This simple version uses wood snow fencing, which is inexpensive, easy to install and remove, and may be attractive enough to leave up year-round.

Snow fencing is designed to let wind pass through it, and the openings between the slats also allow filtered sunlight to reach nearby plants. You can install a Snow Fence Windbreak for just the peak growing season or for high-wind periods, and put it to use again in winter to encourage snow to accumulate in places where you want it to melt in spring. Wood snow fencing, which is held together with wire, is the most attractive kind to use in your garden, but you can opt for lightweight, inexpensive plastic snow fencing if you prefer.

You Will Need

Tools: Measuring tape, sledgehammer, wire cutters, pliers

Enough 6-foot-tall steel fence posts to place a post every 8 feet along the fence

One 50-foot roll of 4-foot-tall wooden snow fencing

Plastic cable ties

1. Determine the location for your fence, which should be on the south or west side of the plants to be shaded, about 3 feet from the center of the row. Use a sledgehammer to drive posts into the ground at each end, and at any intermediate corners or bends. Install additional posts at 8-foot intervals.
2. Unroll the fencing and use the wire cutters to cut it to the length of your desired fence, allowing a few extra inches if the fence rounds a corner.
3. With the base of the fence resting on the ground, attach one end to a post with three plastic cable ties. Pull the fence tight and secure it to each successive post with zip ties.
4. Once the fence is attached to the final post, trim the excess with wire cutters and bend back any exposed wires with pliers. When it's time to remove the fencing, just snip off the plastic zip ties and roll up the fence for storage.

Let Timers Watch Your Watering

If you don't want to spend time monitoring your soaker hoses or sprinklers—or have to ever again worry about remembering to turn them off—let a timer do it for you. Inexpensive ($10-$30) mechanical timers let you turn a dial to set the amount of water to apply. Set the dial and go about your business, and the timer will turn the water off automatically.

If you can't always be there when your garden needs you, look into the benefits of battery-operated electronic timers. They're more expensive than the mechanical models ($30-$70), but

Drip Irrigation: Watering Without the Worry

Roger Yepsen

Six Good Reasons to Drip Instead of Spray

Like any number of garden improvements, installing a drip irrigation system takes time initially but spares you considerable trouble in years to come. Here are a half-dozen reasons to switch from overhead sprinkling.

1. You'll use 30 to 70 percent less water.
2. You distribute water just where you want it, shutting out the weeds.
3. Foliar diseases are less apt to be a problem if leaves remain dry.
4. Any pesticide or fungicide you place on leaves will stay put longer, meaning you can use less of it.
5. Because the watering network is already in place, you don't have to lug sprinklers around or stand there with a hose.
6. There's just a subtle trickle, meaning you can work in the garden while watering!

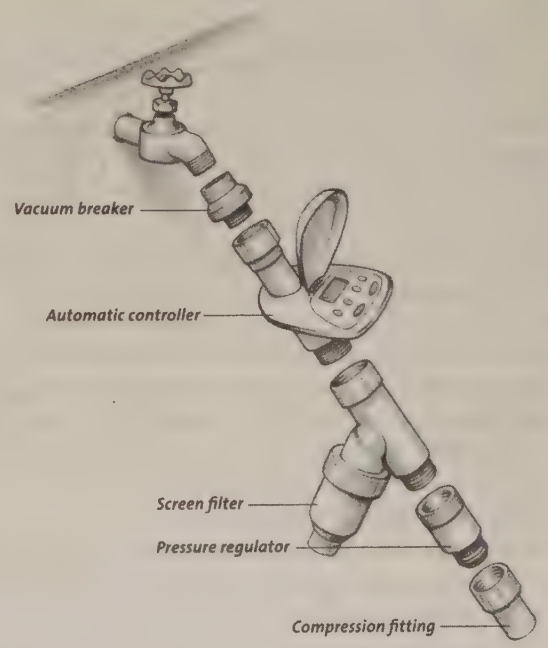
Watering the garden is a time-honored task. It's also time consuming. As a result, plants may go thirsty when your summer schedule heats up. With a timed drip-irrigation system, you don't have to attend to sprinklers or stand around with a hose. The plants are apt to be happier, too, because they're spared the growth-slowing effects of water stress.

The system begins at the hose bib, and this is the nerve center of the whole works.

- Plan on installing a Y-connector at the faucet so that you can have a separate line for a garden hose.
- A simple timer will water plants for the optimum duration. A more sophisticated model can be set to do the watering at the best time each day. That means you can go on vacation feeling confident that your garden is getting enough moisture—not necessarily the case if you were to rely on a neighbor's kind offer to stop by and water while you're away. There even are gizmos that detect the moisture in the soil and adjust the watering schedule accordingly.
- A pressure regulator will probably be needed to lower the household water pressure to the manufacturer's recommendation.
- You may want to install a filter at the faucet, so that bits of debris don't clog the system. The usual sort of filter in a hose washer doesn't have a sufficiently fine mesh.
- If you understand how siphoning works, you'll understand why a backflow preventer is important. It keeps water in the irrigation lines from being drawn back into the home water supply.

A typical irrigation kit involves a plastic hose that extends aboveground to the garden, where it can branch into several lines as needed. The water is delivered in any of a few ways: through a slowly seeping soaker hose; through emitters that deliver water underground to plant roots; or through microsprays that operate much like tiny sprinklers. The timer can be operated by AC current or a battery.

Set the timer, turn the tap—and here's one less routine gardening task to clutter your summer.



Continued ➔

once you set the watering schedule, they'll turn the water on and off for you at the times and days you specify. These devices are particularly helpful if you're working with water restrictions that limit the days and hours you can irrigate. The only time you're likely to encounter a problem is when it rains. Unless you're home and can turn the system off, it will merrily water or overwater your plants, even during a deluge. Some timers have optional moisture-sensing probes that will turn the water off when the soil is moist and back on again when it's dry.

Easy-Does-It Watering: Fast Fill-Up for a Slow Drip

Watering new plants properly takes time and patience, but it's all-important if they're going to get a healthy start in life. You have to drizzle the water on slowly so it soaks deep into the soil. And you don't just have to water once at planting time—you're looking at a summer of weekly watering sessions. While you could set up an elaborate watering system or spend hours standing over your new plants with a hose, there's an easier and cheaper alternative: Make your own low-tech drip system from containers. Drip containers will let you leave gallons of water around a plant in a flash, and then drip it out slowly into the soil without wasting a drop. Use them for new plants or to provide extra water for particularly water-sensitive ones.

Plastic milk jugs, soda bottles, and plastic buckets make fine containers for drip-watering plants. All you need to do is punch one or two very small nail holes in the bottom of the container. Since you want the water to drip out a drop at a time, put some water in the container and start with the smallest hole you can make. Gradually enlarge it until the water drips out at the rate you want.

To water, place one or more empty drip containers beside a thirsty plant. (The number of containers you use depends on how much water the plant will need; use several containers to give large trees and shrubs several gallons of water; one or two for smaller perennials.) Then fill the container with water from a bucket or garden hose and let the water slowly drip into the soil.

Store-bought drip containers work in a similar way. One, called the Treegator, looks like a heavy-duty plastic sack that opens up so you can place it around a tree. Zip it up and fill its pouch with up to 20 gallons of water; small holes near the bottom let the water drip out at a controlled rate. Treegators are available from Spectrum Products, P.O. Box 18187, Raleigh, NC 276199-8187; (800) 800-7391.

EASY CONTAINER WATERING

Potted plants can be tricky to water, especially when you're in a hurry. They flood their saucers, and water bounces off leaves and soaks your table or the floor.

You can avoid these problems by using one of the systems described above for watering large tubs and containers. Plastic soda bottles are especially handy for indoor use—their narrow shape fits even medium-size containers. Or try making your own wick-watering system and water from the bottom up. You'll avoid the fuss and muss of watering from above, and your plants can get a drink whenever they need it, even if you're away for a few days.

Let Drip Systems Water Your Ornamental Plantings

Mixed plantings of trees, shrubs, and flowers aren't made for watering with sprinklers—some plants get too much water; others, too little. You can avoid the aggravation of watering individual plants with your hose by installing a drip irrigation system. A well-planned system, is versatile enough to handle a variety of plant sizes and shapes.

Run the main hose line next to the plants you want watered. Emitters set in the line let water drip out at a steady pace and are perfect for wetting closely spaced plants. For shrubs or other plants off the main line, use spaghetti tubes to send water exactly where it's needed. Use one tube for small plants, two or more for large plants. Cover the entire system with mulch to stop evaporation.

Drip Irrigation: The Way to Water Wisely

Vicki Mattern

When Mother Nature fails to provide all the water that your plants need to perform at their peak, you've got to step in and provide that essential 1 inch per week yourself. But what's the best way to water? Drip irrigation, for several reasons:

- It uses water efficiently, delivering it directly to plants' roots (unlike overhead sprinklers, which waste a lot of water). Almost no water is lost to surface runoff or evaporation.
- It helps prevent fungal diseases that find a hospitable environment by the soil-splashing action of sprinklers and hoses.
- It provides precise control, allowing you to maintain a steady level of soil moisture and to water a larger area (at the same time and at the same rate) than with hit-or-miss sprinklers.
- It more than makes up for the cost and effort involved in design and installation in water savings and increased plant growth.
- It delivers water directly to the plants you want to grow and less is wasted on weeds. And the soil surface between plants remains drier, which discourages weed seeds from sprouting.

Consider Your Options

Depending on your garden size and watering needs, you could get away with a setup as simple as a soaker hose, or you could take the plunge by investing in a full-feature professional kit. Most gardeners opt for something in between. Let's take a closer look at the possibilities.

Soaker hoses. Also known as a weeper hose or oozer hose, this simply is a length of porous hose, often made of recycled tires combined with polyethylene. Water soaks through the entire surface of the hose.

Soaker hoses generally are very durable. They aren't prone to freezing or cracking, and many brands resist the degrading effects of the sun's ultraviolet rays. Still, soaker hoses can come apart or develop leaks if the water pressure is too high—generally, above 10 pounds per square inch. If you remember to never open your faucet more than one-quarter turn, you probably won't have a problem. Or assure yourself of staying within this limit by inserting a pressure regulator disc in the female end of the hose.

Drip tubing with punch-in emitters. These drip kits feature lengths of ½-inch-diameter polyethylene hose in which you insert small plastic emitters. The emitters come in different shapes and can release water at various rates—usually from a half-gallon to 4 gallons per hour.

The main advantage of this type of system versus a soaker hose is that you can target the water so that it is delivered to very specific areas. For instance, if you have shrubs or trees or crops spaced widely apart, you can insert your emitters so that they drip only where the plants are located.

With emitters or a soaker hose, the drip rate can vary from one end of the line to the other—especially if the length exceeds 100 feet and/or your garden slopes significantly. The solution is a drip kit with pressure-compensating emitters, which are designed to put out water at the same rate regardless of the length of the hose or the slope of your yard.

Drip tubing with in-line emitters. These tubes are just like the punch-in type, except that the *emitters* are preinstalled inside the solid polyethylene tube. Typically, the emitters are spaced 12 inches apart all along the length of the hose, but 18-, 24-, and 36-inch spacing is also available.

Drip-irrigation kits. These drip systems come with everything you need—typically a soaker hose, a solid polyvinyl hose, a pressure regulator disc, end caps to close off each length of hose, and various plastic connectors. More-sophisticated systems may even include special filters and backflow preventers.

Putting It All Together

Don't go overboard by buying more watering equipment than you need. In the moderately rainy East, a simple soaker hose can do the trick. For a 5 x 40-foot ornamental border, for instance, two 50-foot lengths of hose should be adequate. Attach them to a single faucet with a twin coupler. When rainfall is scarce, turn on the faucet and let the hoses run for about an hour at a time. You can even let most types stay in place all season long, tucked beneath a couple of inches of mulch.

In drier climates, such as the interior West, you'll probably want a more complete system that can supply water to your entire property. To make the job easier, use electronic timers to turn the water on and off routinely. As the season progresses—and watering needs change—you can program the timer to keep the water running for longer or shorter periods. But if you use a timer, be sure to keep an eye on the batteries. If they run down, you may not know there's a problem until your plants start to wither.

No matter where you live or what type of drip system you use, the key to success lies in the proper placement of the tubing. Aim to create a zone of continuous moisture below the surface of your growing beds by placing emitters 6 to 18 inches away from the stems of your plants. This will spread moisture broadly below the soil surface and promote a very wide, deep root system. And by placing the drip tubing so that it doesn't drench the very center of the plant's root system, you avoid problems such as root rot.

Another advantage of creating this zone of moisture is that you don't have to worry so much if one or two of the emitters

Drip Irrigation for Free

Roger Yepsen

An old hose, plastic cider jug, or bucket is all you need to try out the benefits of drip irrigation without spending a dime.

A New Use for an Old Hose

If you have a vintage garden hose that loves to kink and cause trouble, use an electric drill to make tiny holes in the last several feet of its length; install a screw-on cap at that end, and you have a drip irrigation system. For a low-tech timer, set your watch to beep when the watering period is up.

One-Drip-at-a-Time Irrigation

You can use plastic jugs and weary buckets as individual plant waterers. Poke or drill small holes in the bottom, no more than ⅛ inch in diameter, and place these dripping containers next to tomato plants or shrubs. Arrange a few of them in a circle around newly established trees, rather than applying a lot of water all at once and watching most of it run off. To keep the jugs and buckets from blowing away when empty (and to make them less conspicuous), you can set them in the ground. When you make daily rounds with a hose, stop by to give the containers a fill-up.

Continued →

clogs because the overall moisture present in that area of the garden will compensate for the loss of the emitters.

How far apart should you space emitters to create such a moisture zone? For loamy soils, space them 18 inches apart; for sandy soils, keep the emitters 12 inches apart; and for heavy clay soils (which hold water naturally), space emitters 24 inches apart.

Finally, there's the aesthetic question: to bury or not to bury the hoses? Packing your hoses beneath the soil line may look better, but it can cause some problems. Tunneling gophers may be attracted to the sound of the running water and leave you with a munched-through line that you won't notice until your plants begin to fail. Emitters also can clog with soil as a result of the reverse flow that occurs when the system is shut off.

The answer is to compromise. Simply cover the tubing with 1 or 2 inches of mulch. This hides the hoses and assures that your drip lines are easily retrievable at any time for repair or modification.

Ingenious Ways to Water

Barbara Pleasant

Thoughtful Watering

Water is elemental to plant life, and the presence of water in the garden can be as enjoyable as sharing company with beautiful flowers. Yet water is an increasingly precious commodity, so whether you are using it to nurture plants or treating yourself to the sound of a trickling fountain, water should be regarded as a natural treasure.

In most climates, a gardener's watering challenges change with the seasons. Sometimes there's too much water and other times there's not enough, so finding ways to even out your garden's water supply makes perfect sense.

WATERING YOUR GARDEN'S NEIGHBORHOODS

Smart gardeners understand that watering needs are rarely uniform from one end of their landscape to the other. Instead, most yards are comprised of ecological "neighborhoods"—some bright and sunny, some cool and shady. Some have rich, loamy soil that holds moisture well, while others are sandy and dry. Each district of a garden provides a suitable home for some plants, while others would feel out of place in the same spot. A good gardener is like a city planner who gets to know each neighborhood and delivers water services where they are needed most.

To promote harmony in your garden's neighborhoods, try to group plants with similar watering needs together—you'll save time and water this way, and the plants will appreciate it, too. The watering needs of vegetables should be addressed on a crop-by-crop basis in keeping with their growth cycles. With flowers, use a plant list to design a colorful landscape in which plants are matched to the naturally available water supply and the amount of water you are willing—and able—to provide.

Shaping Up a Water-Wise Garden

From the earliest days of agriculture, humankind has learned to shape the land into furrows, swales, and terraces to maximize the benefits of rainfall, minimize runoff, or channel away excess water when cloudbursts bring too much of a good thing. Shifting your garden's shape to help it handle water better requires a little forethought and spadework, but it doesn't have to cost a cent and is one of the simplest ways to satisfy plants' needs for moisture.

CONTOURS THAT CONSERVE WATER

If your garden tends to need more water than nature provides, there are several ways to add contours to help move water toward plant roots, and keep it there until plants have a chance to make use of it. Here are several approaches to consider.

- Plant vegetables in furrows or shallow trenches, and dam the ends with a mound of earth. This strategy turns planting rows into shallow moats. Should rain become abundant, simply make breaks in the sides of the furrows to allow excess water to drain away.
- In chronically dry climates, conserve scant water with sunken beds. To make a sunken bed, dig out the soil at least 12 inches deep, and set it aside. Mix half of the excavated soil with an equal amount of compost or other organic matter, and refill the pit with this mixture. Use the remaining soil to make wall-like mounds around the bed. In addition to channeling water toward thirsty plants, the walls above the bed will reduce water loss due to evaporation and wind.
- When setting out large plants, create a shallow basin over the root zone, enclosed by a raised ring of soil or mulch. Water will pool inside the basin and then seep down into the soil below. These basins can be 6 to 10 inches in diameter for tomatoes, roses, and small shrubs, or up to 3 feet across for larger shrubs and fruit trees.
- To slow the runoff down a slope, create natural barriers by hilling up berms across the slope. Plant them with densely rooted perennials such as daylilies or clump-forming ornamental grasses.
- Terrace hillside gardens to create a series of level tiers. Each terrace will retain water that would otherwise rush down the slope.

FLOOD-PROOFING WET AREAS

In high rainfall areas, too much water causes as many problems as does too little water in other areas. Using raised beds will go a long way toward reducing damage to plants caused by

waterlogged roots. You can also use large containers to grow plants that are sensitive to flooding. To carry away the torrents of water that flow from your gutters and then wash across your lawn, incorporate a Rock Swale into your landscape's design. Even when no water is present, a curving Rock Swale suggests the fluid presence of water.

Do make sure that the water that runs through the swale ends up near a storm drain, or in some other place where it will not cause damage to your property, your garden beds, or a neighbor's property. And, in some instances, it's wise to check with local zoning authorities before installing a swale that will channel water toward roadways, sidewalks, and utility areas.

Keeping the Water You Have

Conserving water makes more sense than pouring it on, week after week. You'll save time and slash water bills if you take simple steps to minimize water loss due to evaporation. You can't control the weather factors that increase evaporation—intense sun and dry air—but you can reduce water loss by taming persistent wind and by using mulches and highly efficient watering methods such as soaker hoses or drip irrigation.

MOISTURE AND MULCH

Mulch forms a physical barrier between sun and soil, and the same mulches you use to prevent weeds and add organic matter to your soil can be strong allies in your quest to conserve water. When water conservation is a priority, one of the smartest strategies is to layer coarse mulch materials over a base mulch of newspapers. By some estimates, a 3-inch layer of mulch reduces evaporation loss by 50 percent, and most mulches cool the soil, too. Mulch also traps and holds additional moisture from rain at the surface, which raises the humidity level around plants. In very dry weather, a slight increase in humidity can enhance pollination of corn, tomatoes, and several other vegetables.

If you are using a stationary watering system such as soaker hoses, wait until after the watering system is in place to pile on the mulch. That way, all of the water you provide will be insulated from surface evaporation, and the mulch will protect rubber or plastic drip lines from degrading due to exposure to strong sun.

Heavy mulching does sometimes have a drawback. Moist mulches create an ideal habitat for leaf-eating slugs and snails. If you don't have slug problems in your garden, have your mulches in place before your dry season begins.

WATER-SAVING WINDBREAKS

Wind pushes evaporation into high gear, so using windbreaks is a fundamental way to conserve water. Windbreaks can serve other purposes, too, such as reducing the physical torture plants endure as they struggle to stay upright. Windbreaks are designed to turn a wind-chilled garden into a warm oasis of calm, but when your goal is to conserve moisture, it helps if the windbreak also provides filtered shade to the root zones of plants. This is exactly what happens if you use a Snow Fence Windbreak, which has saved many a tomato patch from drying to a crisp in arid Southwest gardens.

Ways to Water

There is no such thing as a garden that never needs its keeper to provide supplemental water. How much water plants need depends on soil, weather, and the plant itself. For example, established plants growing in porous, sandy soil usually need 1 inch of water per week in warm weather, while plants situated in moisture-retentive clay soils demand only half as much water. On the other hand, germinating seeds need constant moisture; shallow-rooted crops grow best when the soil never becomes truly dry; and tomatoes and some other vegetables develop physiological problems such as cracked fruits or blossom end rot when soil moisture fluctuates between wet and dry. Depending on the size of your garden, you may use one or several of the following four methods to deliver water to thirsty plants.

Hand watering is the most practical way to make sure germinating seeds and newly transplanted seedlings have adequate moisture, or to provide water to plants growing in containers, small raised beds, or other tight spots. Use adjustable nozzles to change the force of water when watering directly from a hose; a strong spray dislodges aphids and some other insects, but a softer shower is gentler to plant leaves. If you keep numerous containers, a Watering Wand is a valuable accessory when watering by hand.

Drip irrigation, in which small drips of water slowly ooze out of a drip hose or perforated container, is extremely efficient and effective when the drips are targeted to reach plant roots. If you install a large system, turn it on before you plant so you will know exactly where the puddles of moisture are located. Smaller drip buckets and bottles are an easy way to water widely spaced plants or closely planted beds.

Soaker hoses weep moisture evenly along their length, and they can be curved if needed to match the contours of your beds. A soaker hose left on for several hours at very low pressure provides excellent deep penetration of water, yet the plants' leaves remain dry. Keep soaker hoses short, to less than 50 feet long, because long soaker hoses often release more water close to the water source, and noticeably less near the end of the hose. Soaker hoses work beautifully when used beneath mulch. You can buy soaker hoses made from recycled tires at most garden centers.

Sprinklers are much less efficient than other watering methods, yet they are a practical way to water large areas of lawn or expansive plantings of flowers or vegetables. It is best to use sprinklers in the morning, or early enough in the evening to allow time for foliage to dry before nightfall. Pulsing a sprinkler by running it for 15 to 20 minutes, interspersed with 10-minute breaks, helps water to penetrate deeply into the soil.

Continued →

WHEN TO WATER

How can you tell when your plants need water? Wiggling your finger into the soil is a good test. If the soil feels dry knuckle-deep in containers or between shallow-rooted plants, make plans to water. Checking the soil is often a more reliable method than simply watching your plants. Almost all vegetables and flowers wilt in the middle of a hot day, but midday wilting does not always tell a true story of what is going on below the ground. If the plants regain their perky posture by nightfall, they probably do not need supplemental water—unless they are at a life stage where any moisture shortage can lead to drought stress. The best ways to satisfy water needs are summarized below.

Working with Hoses

As time-consuming as watering with a hose can be, it's a mainstay of most gardens. When water is needed for a new planting—or to revive a plant that's unexpectedly run dry—turning on the faucet provides the fastest form of relief. The best-equipped gardeners own two types of hoses: high-quality, heavy-duty hoses that don't kink when moved around, and a comparatively inexpensive hose with thin walls that's easy to cut and splice.

As for your good hoses, they will last for many years and be well worth their initial cost if you give them good care. Coil a hose when it is not in use, either by arranging it in a figure eight on the ground, or by winding it around a hose reel. Start with the female end (the larger fitting that screws on over a smaller one) when you coil a hose; that way, the male end (which attaches to nozzles, sprinklers, or soaker hoses) will be at the top when you need to use it. Drain hoses before storing them for winter. When storing a hose, connect the male and female ends together to keep insects or debris from getting inside.

Because bad things often happen to good hoses, it's wise to buy a few basic hose repair items when you purchase a hose. On the hose aisle at any hardware or home supply store you will also find male and female couplers, as well as splicing kits for repairing hoses that accidentally get chopped by mowers or spades. As long as these fittings match the diameter of your hose, installing them is a simple matter of trimming the hose end with a utility knife, soaking it in hot water for a few minutes to make it more pliable, and then screwing on the fittings.

HANDY HOSE ACCESSORIES

You can make life easier for yourself and increase the versatility and efficiency of a hose by installing various accessories.

- Save wear and tear on your faucet—and your back—by adding a 3- to 4-foot-long extension hose to your outdoor faucet. Then attach other hoses to this extension. To make an extension, use a utility knife to cut through the hose 4 feet from its female end, and install a male coupler to the cut end. If your outdoor faucet is hidden behind dense or prickly shrubs, add a second faucet mounted on a wood board to your hose extension.
- A splitter, often called a Y connector, allows two hoses to be attached to one faucet. With a splitter, you can keep a hose attached to one outlet and use the other for filling watering cans, rinsing produce, or washing your hands. Look for a splitter that has shut-off valves for each outlet. You also can buy four-way splitters, sometimes called gang connectors, that allow up to four hoses to run off of a single faucet. When doubling or quadrupling your outlets, bear in mind that the water pressure will be reduced by each hose you run simultaneously.
- Snap connectors take the frustration out of screwing and unscrewing hose connectors, which have an uncanny talent for going on crooked, so you end up sprayed with water when you turn on the faucet. Snap connectors screw onto the end of a hose, and you put matching connectors on nozzles, sprinklers, or other water-handling hardware.
- A simple mechanical or battery-operated timer between the faucet and the hose allows you to precisely control how long the water stays on, and makes it safe to forget that you left a sprinkler running. If you don't have a timer, other tricks to help you remember to turn off the water include using a kitchen timer, clipping a clothespin to your shirt, or slipping a hair scrunchie or big rubber band over your wrist. When you notice these odd accessories, you'll remember to turn off the water.

Extend a Hard-to-Reach Spigot

Tired of dodging spiders as you shimmy into the shrubs to turn on your faucet? Install a temporary twin faucet on the open side of the shrubs, which can be connected to the primary faucet with a short piece of hose. When winter comes, simply unscrew the hose, pull up the mounting board, and store the second spigot in your garage.

Don't be intimidated by the strange-sounding plumbing parts used to make this project. Any hardware store can provide you with the materials for a few dollars, and they will fit together like pieces of a puzzle.

You Will Need

Tools: Handsaw, drill with ⅞-inch bit, two adjustable wrenches, screwdriver, hammer
One 2-foot-long 1 x 4 pine or cedar board
1 tube of latex/silicone caulk
1 roll of Teflon plumber's tape
One ¾-inch x 1½-inch pipe nipple
One ¾-inch brass sillcock with threaded inlet (spigot made for mounting)
One ¾-inch lock washer
One ¾-inch male-female pipe-thread to hose-thread adapter
One 1½-inch-long wood screw
Small piece of scrap lumber
2 female hose couplers
Piece of ¾-inch garden hose long enough to reach between the two spigots

1. Use the handsaw to make two 45-degree cuts at one end of the 1 x 4 to form a rough V-shaped point.
2. At the other end of the board, 3 inches from the end, drill a ⅞-inch hole in the center of the board. Spread caulk around the hole on both sides.
3. Wrap a single thickness of Teflon tape around the threads on the pipe nipple, which will help to tightly seat the threads when the other pieces are screwed into place. Stretch the tape slightly as you wrap it around the pipe nipple.
4. Insert the nipple through the hole in the board. Using both wrenches, tighten the faucet into position on one end, leaving at least ½ inch of the pipe nipple exposed on the other side of the board.
5. On the back side of the board, place the lock washer over the end of the pipe nipple, and then screw on the pipe-thread to hose-thread adapter. Use two wrenches to firmly tighten the faucet and the adapter.
6. When the faucet is oriented correctly, position a wood screw in its retaining slot and screw it into the board. Place the piece of scrap lumber over the top of the mounting board, and drive the pointed end of the plank into the ground with a hammer.
7. Install female couplers onto both ends of the piece of hose. Connect the new spigot to the old one with the piece of garden hose.

Make a Long-Handled Watering Wand

After 10 minutes using a Long-Handled Watering Wand, you will feel as though your arms have grown 3 feet longer—a miraculous change that makes it much easier to water containers using a hose rather than a watering can. A Watering Wand also lengthens your reach in the garden, making the root zones of plants in the middle of a bed much more accessible. In a pinch, you can even let your watering wand do double duty as a sprinkler by slipping the end of the wood handle into a PVC pipe sleeve.

You Will Need

Tools: Utility knife, measuring tape, handsaw, screwdriver
One 4-foot piece of garden hose
One male hose coupler
One female hose coupler
1 wood broom or mop handle, or a 30-inch-long ¾-inch wood dowel
Four #20 metal hose clamps
1 small roll of duct tape
1 adjustable spray nozzle with cut-off valve

1. If needed, trim the ends of the hose with the utility knife before installing the male hose coupler at one end, and the female coupler at the other.
2. Cut the broom handle or ¾-inch dowel to 30 inches long.
3. The male (small) end of the hose will be at the head of your wand, so line it up with the dowel until it is 1 inch beyond the end of the dowel. Install a hose clamp over the dowel and the hose, ½ inch from the end of the dowel. Tighten it firmly, but don't crimp the hose wall.
4. Space the other hose clamps at regular intervals, with the last clamp 1 to 2 inches from the end of the dowel.
5. In the spaces between the two lowest clamps, wrap the hose and dowel together with duct tape to create a hand grip.
6. Screw the nozzle onto the top of the wand.

Make a Working Rain Barrel

The basic idea behind rain barrels couldn't be simpler: Just put a barrel under a downspout, and every time it rains, you'll store up water. You can tap the full barrel by opening the spigot installed near the bottom, or by dipping water out with a pail or handled saucepan. If the barrel is higher than your garden, a hose can be attached to feed the water into a drip or soaker hose system.

Keep the following safety precautions in mind as you plan this project.

- Make sure the lid is completely childproof and mosquito-resistant. If mosquitoes do get into the water, keep them from breeding by adding a doughnut of *Bacillus thuringiensis israelensis*—a safe biological pesticide often used in water gardens.
- Find a barrel that was used to store food products or soap rather than chemicals. If you can't find a used barrel, buy a feed barrel at a farm supply store, or use a plastic garbage can.
- Never drink water from your rain barrel.

You Will Need

Tools: Level, screwdriver, hacksaw, saber saw or coping saw, drill with ⅝-inch bit, adjustable wrench
Gravel
2 concrete blocks
One 50-gallon or similar-size plastic barrel or sturdy plastic garbage can
2 downspout elbows
One piece of downspout long enough to connect the elbows to the existing downspout
Twelve ½-inch No. 8 self-tapping sheet-metal screws
1 square foot of window screen
One ½-inch boiler drain (downward-facing faucet)
1 tube of latex/silicone caulk
One 9/16-inch rubber O-ring
Two ½-inch plastic basin locknuts
6 feet of ½-inch-diameter vinyl tubing
One ½-inch-to-½-inch nylon barb adapter

1. Prepare the site by leveling the ground beneath the downspout, leaving a very gentle slope away from the foundation. Place 2 inches of gravel on the ground, and position the concrete blocks to support the barrel.

Continued →

2. Find the seam in the downspout closest to 6 foot height. Remove the screws and then the downspout. Store these pieces so you can reinstall them in winter.

3. Assemble the downspout elbows and hold them over the barrel so the lower end is 2 inches above the barrel's top and the upper end is under the downspout. Measure and cut a piece of downspout to link the elbow assembly with the existing downspout. Screw the pieces into place.

4. Use the saber saw or coping saw to create a hole 6 inches in diameter in the top of the barrel beneath the downspout elbow. Screw the scrap of window screen over the hole to keep debris and mosquitoes away from the standing water inside.

5. To install the spigot (boiler drain), drill a ⅝-inch diameter hole in the side of the barrel 2 inches above the bottom, or just above where the side straightens vertically. Drill a second ⅝-inch diameter hole 3 inches below the top rim of the barrel, about 8 inches to one side of the lower hole. This will be the outlet for the overflow pipe.

6. Coat outside of the lower hole with caulk. Slip the O-ring over the threads of the boiler drain, and then screw on one of the basin locknuts. Push the threaded pipe part of the boiler drain through the lower hole from the outside. On the inside of the barrel, coat the edges of the hole with caulk, and then screw the second basin locknut onto the back of the boiler drain. Use the adjustable wrench to tighten both of the locknuts.

7. Coat both sides of the upper hole with caulk. Push the vinyl tubing onto one end of the barb adapter, and push the other end into the hole. Allow the sealants to dry overnight.

8. Use a hose to run several gallons of water through the gutter and into the barrel. Check to make sure it is firmly seated, and also check for leaks around the spigot. Tuck the overflow pipe behind the barrel. When heavy rains fill the barrel, position the overflow pipe to direct water away from the foundation of your house.

Make a Bucket Drip System

This simple gravity drip irrigation system is comprised of a 5-gallon plastic bucket that is raised to chest height and then connected to two drip irrigation tapes. Similar systems are widely used in underdeveloped countries, and they have a proven track record of delivering enough water to grow excellent crops when no other water is available. In your garden, a bucket drip system can save hours of watering time over the course of a growing season. Hand-watering a 25-foot row with a watering can takes about 15 minutes, but you can refill the bucket reservoir in less than 5 minutes. In addition, none of the water is lost to evaporation, and the plants' leaves remain dry while their roots receive the moisture they need.

A Bucket Drip System also can solve the problem of maintaining moist soil conditions for newly planted seeds, and may mean the difference between success and failure when you are planting carrots or broccoli for fall harvest during the hot days of summer. And, during severe droughts when water use is restricted, you can fill the bucket reservoir with slightly used water saved from washing dishes.

Don't be discouraged by the length of the supplies list for this project. All are inexpensive to buy. If you can't find irrigation tape and fittings at a local farm supply store, you can order them by mail. A 100-foot roll of irrigation tape (enough to make two bucket drip systems), plus fittings, costs only about $15. You also may want to innovate with the stand; any stand that lifts the reservoir pail at least 3 feet off the ground will work. At the end of the season, simply detach the irrigation tubes and rinse them off. When they are dry, roll them up and store them inside the bucket. With good care, they will last from 3 to 5 years.

You Will Need

Tools: Hammer, spade or post-hole digger, drill, utility knife
Two 5-foot-long wood posts or 2 x 4 pine boards
Two 16-inch-long pieces of 2 x 4 pine
Eight 3-inch nails
One 5-gallon plastic pail, preferably with lid
One 5-foot-long piece of garden hose
One female hose coupler
One 2-inch square of polyester window screening
One rubber band
1 small tube of latex/silicone caulk
One male hose coupler
1 hose splitter (Y connector)
50 feet of 100-mil polyethylene irrigation tape
2 irrigation tape end caps
2 irrigation hose starter fittings

1. To assemble the stand for the reservoir bucket, place the two 5-foot posts or boards on a level surface, 16 inches apart. Six inches from the tops of the posts, nail a 16-inch piece of 2 x 4 on the side of the posts. Flip the stand over, and nail a second 2 x 4 to the other side.

2. Dig postholes and set the stand at the end of a 30-inch-wide, 25-foot-long garden row. Ideally, the row should slope very slightly away from the stand.

3. Drill a hole in the bottom of the 5-gallon plastic pail. It should be only large enough to allow the hose to pass through it.

4. Install a female coupler on one end of the hose. Place the piece of screening over the coupler opening, and secure it tightly with a rubber band.

5. Working inside the pail, pass the bare end of the hose through the hole in the bottom, and pull the hose through until the screen-covered end is just above the hole. Coat the inside and outside of the hole with silicone caulk, and seat the female coupler securely over the hole. Allow the caulk to dry.

6. Install the male coupler to the other end of the hose, and screw on the splitter. Place the bucket assembly on the stand.
7. Measure and cut two 25-foot-long pieces of irrigation tape. Place them in parallel lines down the length of the row, 10 inches apart. Install the two end caps at the far ends of the irrigation tape. Install the two hose starter fittings at the ends close to the reservoir, and attach them to the splitter.
8. Fill the reservoir pail with water, and cover it with a lid to keep out insects and debris. Observe where the water forms wet spots along the irrigation tapes. Plant seeds or plants in these wet spots. When the plants are established, weed the row and spread mulch over the irrigation tapes. Refill the reservoir pail whenever your plants need supplemental water.

Small-Scale Drippers

You can't beat the Bucket Drip System for watering closely spaced plants growing in a row, but there are other ways to drip water to widely spaced tomatoes and peppers, densely planted raised beds, or trees and shrubs scattered around your yard. Here are seven small-scale slow drippers that will save you watering time and make sure water reaches deep into the soil. When they're refilled with water from a hose or watering can, very little water will be lost to evaporation.

FLOWERPOT RESERVOIRS

Unglazed clay pots slowly lose moisture through their porous walls, and the least expensive clay pots are the most porous ones of all. To use clay pots as water reservoirs in raised beds, cover the drainage holes in several 4-inch pots with duct tape, and bury the pots almost to their rims among your plants. Fill the pots with water, and cover the tops with 4-inch-diameter disks of cardboard. The pots will empty slowly, over a period of 2 to 3 days, and are easily refilled with a hose or watering can.

LEAKY JUGS

Some of the most versatile water drippers can be made from plastic milk jugs or other large drink containers. Use a hammer and a thin finishing nail to tap two holes in one side of the jug or bottle, about 1 inch from the bottom. Fill the jug with water, cap it, and carry it upside down to a plant that needs water. Place it on the ground right side up, with the holes facing the plant. You may need to loosen the cap a bit before it will start dripping. When most of the water has dripped into the soil below, the inch left behind will keep the jug or bottle from blowing away. If you live in a very windy area, you can drop several small rocks into your Leaky Jugs to give them extra weight.

DRIPPER PAILS

If you can't reach the root zones of some plants with Leaky Jugs, or you need to water plants growing in containers, try a Dripper Pail made by inserting narrow tubing into a hole drilled into the side of a plastic pail, about one inch from the bottom. For the tubing, try the inexpensive tubing used to repair window screens, called spline. Insert the spline through the hole in the pail, caulk it into place on both sides of the pail, and place the end of the spline where you want the water to drip. As long as the pail is raised slightly higher than the outlet tube, it will slowly drip out water. If the water drips too fast, slow it down by placing a small piece of sponge over the end of the spline inside the pail.

SLOW SOAKER PIPES

Deep watering is sometimes a challenge, especially in clay soil. To make sure your plants receive water 12 inches below the surface, make Slow Soaker Pipes from 14-inch-long pieces of 2-inch-diameter PVC pipe. Drill several ¼-inch holes in one end of the pipe, and pound it into the soil around thirsty plants. Pull it back out, clear the plug of soil inside the pipe, and pound it back into the ground. Then simply fill the pipe with water as you water your plants.

BURIED BOTTLES

If you know you will be faced with water shortages, plan ahead by including Buried Bottles in your planting rows. Cut the bottoms from 2-liter soda bottles or half-gallon plastic milk jugs, leaving about ½ inch of plastic intact on the "cutting" line so the bottoms form hinged lids that can be bent back. Bury the bottles spout side down between plants, with the open bottoms 2 inches above the soil line. Open the bottoms to fill the bottles, and let the water seep into the ground.

WINE BAG WATERER

The double plastic bags and attached spigots that come in boxed wine make great little water reservoirs. Cut the corner from the bag opposite the spigot, fill the bag with water, and loosely bind

Continued →

the cut edges together with a rubber band. Use a second rubber band to bind the top of the bag to a stake. Open the spigot very slightly, so a drip comes out every few seconds. If the bag has a push-button spigot, wedge a toothpick into the button to keep it partially depressed.

SEEPING COOLER

Put an old cooler to work as a movable drip irrigator. Place the cooler near plants that need water, fill it with a hose, and partially open the drain so that water dribbles out slowly. Meanwhile, you can move on to other tasks with the hose.

Using Soaker Hoses

Unlike drip watering devices, which use gravity to move water from a reservoir into the soil, soaker hoses depend on low water pressure to push water through porous hose walls, or through small holes. Purchased soaker hoses can be snaked among plants and then covered with mulch, which makes them last longer by protecting them from sunlight. When buying a soaker hose, look for brands made from recycled materials. If you accidentally run over a soaker hose with your mower and need to repair it, the same couplers or other connecting hardware used for regular hoses can be used to fix a damaged soaker hose.

A slightly different type of soaker hose, called a sprinkler hose, has thousands of tiny holes or slits that emit a fine spray when turned hole-side-up, or work like soaker hoses when turned hole-side-down. A sprinkler hose is less efficient than a soaker hose, and may cause soil erosion around plants if the pressure is turned too high.

As long as you keep them short, homemade soaker hoses made by punching small holes into regular garden hoses will often do a good job. However, be prepared to see some holes emitting lots of water, while others weep very little. You can solve this problem by or by wrapping your homemade soaker hose with strips of cloth, tightly tied in place. The fabric will help slow down water that moves through oversize holes a little too fast.

SMART SOAKING

How many soaker hoses do you need, and where should you put them? Soil is a big variable, because soil type affects how water soaks into it.

- In sandy soil, water moves downward quickly, so soaker hoses should be placed closer together and run for only 1 to 2 hours. For example, if you have sandy soil, you need 2 soaker hoses to thoroughly water one 14-inch-wide row. If no rain comes, you will need to run your watering system again in a few days.
- Loamy soil takes up water more evenly, so soaker hoses can be 12 inches apart and still give excellent penetration when turned on for about 3 hours every 4 to 5 days.
- Clay soils absorb water very slowly, so it's important to give soaker hoses plenty of time, at very low pressure, in order to deliver water deep into clay soil. When left on overnight, a single soaker hose will often rehydrate a 16-inch-wide band of clay soil. Depending on weather conditions, clay soil may retain enough moisture to keep plants happy for more than a week.

Keep in mind that soaker hoses begin putting out water in the section of hose closest to the water source, so there is often a big difference in water output between the head and tail ends of very long hoses. This is seldom a problem when soaker hoses are kept to less than 50 feet long.

The Flower Garden

INTRODUCTION

Planting Flower Gardens

Jeff Cox

What can brighten a yard like flowers? They add color to any yard, whether you use them along the front of your foundation planting, to line a walk leading to a patio, to brighten a shady spot, or throughout your entire landscape. A cutting garden can bring the beauty of flowers into your home—watch a winter-bare bed erupt with purple crocuses and golden daffodils, or the late autumn sun set behind a planting of purple asters and yellow goldenrod, and you won't be able to resist growing more.

In this chapter, you'll learn how to plan and grow a garden full of flowers—annuals, perennials, biennials, bulbs, and roses. You'll also learn how to maintain your garden and keep away pests and diseases, create a meadow, and grow the best flowers for cutting and drying.

Before you get started, you'll find it's helpful to learn about the different types of flowers.

Landscaping

Although you can use all types of flowers throughout your yard, there are ways to use perennials, annuals, and bulbs to best advantage. Here are some suggestions that will help you plan ways to use them in your landscape.

LANDSCAPING WITH PERENNIALS

Perennials are all-purpose plants—you can grow them wherever you garden and in any part of your garden. There's a perennial to fit almost any spot in the landscape, and with a little planning, it's possible to have them in bloom throughout the frost-free months. In addition to an endless variety of sizes, shapes, colors, and plant habits, there are perennials for nearly any cultural condition your garden has to offer.

Continued ➔

Most perennials prefer loamy soil with even moisture and full sun. Gardeners who have these conditions to offer have the widest selection of plants from which to choose. However, there are dozens of perennials for shady sites, too.

Perennials add beauty, permanence, and seasonal rhythm to any landscape. Their yearly growth and flowering cycles are fun to follow—it's always exciting to see the first peonies pushing out of the ground in April or the asters braving another November day. Here are some ways to use perennials effectively in your yard.

Borders: If you have a fairly long area that could use some color, such as a fence, a rock wall, or the side of a building, consider a perennial border. Group plants with similar requirements for soil, moisture, and sunlight. Also plan for pleasing color combinations and arrange them by height, form, and texture to create garden pictures.

Beds: Another way to use perennials is in beds. A bed differs from a border in that it is freestanding, without an immediate background such as a fence or wall. Plant beds to add color and drama to the sides of a path, use them to define the edge of a patio or deck, or create an island bed in your lawn to relieve all that green with a bright splash of color. Plant the tallest plants in the center of the bed, using progressively shorter plants toward the edges.

Specimen plants: Larger perennials make striking specimen plants. You can use them in the landscape wherever you want an accent but don't want to feature something as large or heavy-looking as a shrub or tree. Try a large clump of peonies at the corner of the house or use a specimen plant to point visitors to a specific view of the yard or mark the beginning of a path. For example, use a bold accent like a very large-leaved hosta at a bend in a shady garden path to attract attention and pull visitors into the garden.

LANDSCAPING WITH ANNUALS

When most people think of annuals they think of color, and lots of it. Annuals are garden favorites because of their continuous season-long bloom. Colors run the spectrum from cool to hot, subtle to shocking. Plants are as varied in form, texture, and size as they are in color.

Annuals have as many uses as there are places to use them. They are excellent for providing garden color from early summer until frost. They fill in gaps between newly planted perennials. They are popular as cut flowers. Annuals can make even the shadiest areas of the late-summer garden brighter. And since you replace annuals every year, you can create new garden designs with different color schemes as often as you would like.

You can use annuals alone or in combination with perennials or other kinds of plants. Bedding out is the traditional way of using annuals. The Victorians created extensive, colorful displays, usually with intricate patterns against emerald lawns, called bedding schemes. That's why annuals are often called bedding plants.

You can take a tip from the Victorians and create formal or informal designs in island beds or in borders. Fences, hedges, and brick or stone walls all make attractive backdrops for annual gardens. Annuals are also a good choice for outlining or edging garden spaces. Petunias, marigolds, begonias, and zinnias are ideal for beds in the sunny garden.

Many perennials are slow-growing by nature, so the average perennial garden takes up to three years to look its best. Annuals are perfect for filling in the gaps between new perennials and carrying the garden through the first few seasons. Take care not to crowd or overwhelm the permanent plants—try mid-season pruning or staking of overly enthusiastic annuals.

LANDSCAPING WITH BULBS

In spring, most gardeners' fancies turn to thoughts of bulbs—especially crocuses, daffodils, and tulips. But bulbs light up the garden throughout the year. Dahlias, lilies, glads, and many other familiar flowers are classified as bulbs. Here are some effective ways to use bulbs in your landscape.

Bulbs with groundcovers: Bulbs grow beautifully in groundcovers. There's nothing like a dark green groundcover background to make daffodils sparkle. Try them with pachysandra, English ivy, prostrate junipers, or common periwinkle (*Vinca minor*). Lawn grass is one groundcover that does not combine well with tall spring bulbs like daffodils. The reason is simple: Bulb foliage needs 8 to 12 weeks to ripen after bloom so the bulb can store enough food for the following season. By the time the daffodil or tulip foliage is ripe, the grass would be knee-high! If you enjoy the sight of blooming bulbs in your lawn, plant low-growing species like crocuses because their foliage generally matures before grass needs cutting.

Bulbs with perennials: With the exception of tender bulbs like cannas (*Canna* spp.) and dahlias that must be dug every year or treated as annuals, bulbs are perennial and should be used like perennial flowers. In fact, they're ideal companions for perennials. In spring, bulbs add color to the perennial garden when little else is in bloom, and perennials hide unsightly bulb foliage while it ripens. Peonies, hostas, daylilies, irises, and asters are especially good with bulbs.

Bulbs with trees and shrubs: Don't forget the beautiful show spring-blooming bulbs make under deciduous trees and shrubs. For best results, avoid planting bulbs under trees such as beeches and some maples that have very aggressive surface roots, which will outcompete the bulbs.

Bulbs with annuals: Annuals are perfect plants for covering dying bulb foliage or gaps in the flower border left by dormant bulbs. Marigolds, snapdragons, wax begonias, impatiens, and zinnias are all good "filler" annuals.

Bulbs with other bulbs: Don't forget about planting bulbs with bulbs. Clumps of mixed daffodils or scatterings of other types

of spring-blooming bulbs, such as tulips or crocuses, are well-known signs of spring.

Designing a Garden

Designing a flower garden—especially one that features perennials—may seem overwhelming at first since there are so many to choose from. But chances are your growing conditions are right for only a fraction of what's available. Let your moisture, soil, and light conditions limit the plants you choose. If you have a garden bed that gets full sun and tends toward dry soil, don't plant shade- and moisture-loving perennials like hostas and ferns. Instead, put in plants that like full sun and don't like wet feet, like daylilies and ornamental grasses. And don't forget to choose plants that are hardy in your area.

The first step in planning a flower garden is to choose the site you'd like to plant. If you're determined to grow sun-loving plants, the site should receive six to eight hours of direct sun. It's also best to select a site with good air circulation and shelter from strong winds. Take some time to examine your chosen site and learn about its soil and other characteristics so you can select plants that will grow well there.

When you've picked a site, outline the shape and size of your proposed bed right on the spot with a garden hose or string. Next, draw a rough sketch showing the shape of the bed, then measure and record the dimensions. Indicate north on your sketch with an arrow. Next, draw the shape of your bed or border to scale on a piece of graph paper. A good scale to begin with is one that assumes 1 inch on paper equals 1 foot of garden area. If your garden is extremely large, use a formula such as 1 inch equals 2 feet or 1 inch equals 3 feet. To make a plant list and draw a design, you'll also need regular and colored pencils or crayons, a tablet of paper (for plant lists), tracing paper, and a soft eraser.

To get an idea of how many plants you'll need, consider the approximate size at maturity of the types of plants you want to include in your garden. Perennial plants generally need 2 to 4 square feet at maturity; that means you can fit between 30 and 60 of them in a 125-square-foot garden. Shrubs and small trees may need 9 to 25 square feet or more.

SELECTING PLANTS

While it's relatively easy to plan and plant an annual garden, selecting plants for a perennial garden is a challenge. There are literally thousands to choose from and a confusing array of flower colors, sizes, shapes, and textures. Start with a list of favorite plants, then add ones you've admired in other gardens, nurseries, photographs, books, magazines, and nursery catalogs. Leave plenty of space between plants for making notes. Jot down plant descriptions, growing tips, bloom time, height, color, hardiness, and culture.

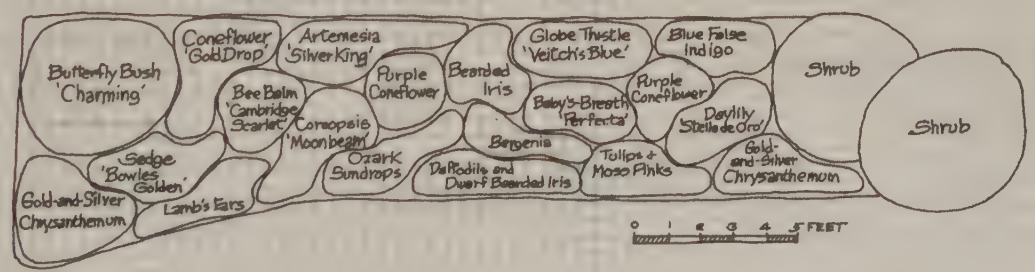
Keep an eye out for perennials with good foliage and a long season of bloom. Trees and shrubs with winter interest—like evergreens or ones with ornamental bark or branching habits—are also invaluable. Don't worry about making your list too long.

Periodically review your list and cross off plants that won't grow well in the site and don't fit your needs. If you have only shade to offer, cross off plants that need full sun. Do you want only easy-care plants? Eliminate those that need staking or deadheading to look their best. Do you want to save on water bills? Cross off any that may need supplemental watering.

CHARTING YOUR SELECTIONS

Next, make a chart to help identify plants that will add the most to your design. On a clean sheet of paper, make a column on the left labeled "Plant Name and Bloom Season." Draw lines across the page at intervals to indicate sections for each season of bloom. If you have a large garden, you can use a separate sheet for each bloom season. Write down the bloom seasons you want in the first column—early, mid-, and late summer, for example. Leave enough space under each season to list plant names.

Divide the right side of the paper into three or four columns to indicate plant heights and another three or four columns to



Drawing a base map. A simple base map of your property is valuable every time you want to make a design change. Try to draw the elements to scale, starting with an outline of the yard and proceeding to the house and other major features. Add your yard's dimensions, any low or high points, a north arrow, and any other relevant information (wet areas, rocks, and so on). Then sketch in potential perennial beds or borders with a dashed line.

Continued ➔

indicate flower colors. Add an extra column to indicate plants with attractive foliage or winter interest.

Starting with the first plant on your list, enter it under the appropriate bloom season on your chart. Then indicate height and color with an "X" in the appropriate columns. Repeat this process for each plant on your list. When you finish, look the chart over to make sure you have a fairly equal representation of "X's" under each column. Will some flowers of each color be blooming in each season? Are there a variety of heights? Add and subtract plants until you have a balance in all the categories and a manageable number of plants to grow. Last, number the plants on your list. Use these numbers to fill in the spaces as you draw your garden.

DRAWING YOUR DESIGN

To draw your design, use tracing paper over the scale drawing of your garden that you made on graph paper. That way, you can start over easily if you need to. Begin drawing shapes on the paper to indicate where each plant will grow. Try to draw them to scale, based on the sizes you charted as described above. Instead of drawing neat circles or blocks, use oval or oblong shapes that will flow into one another.

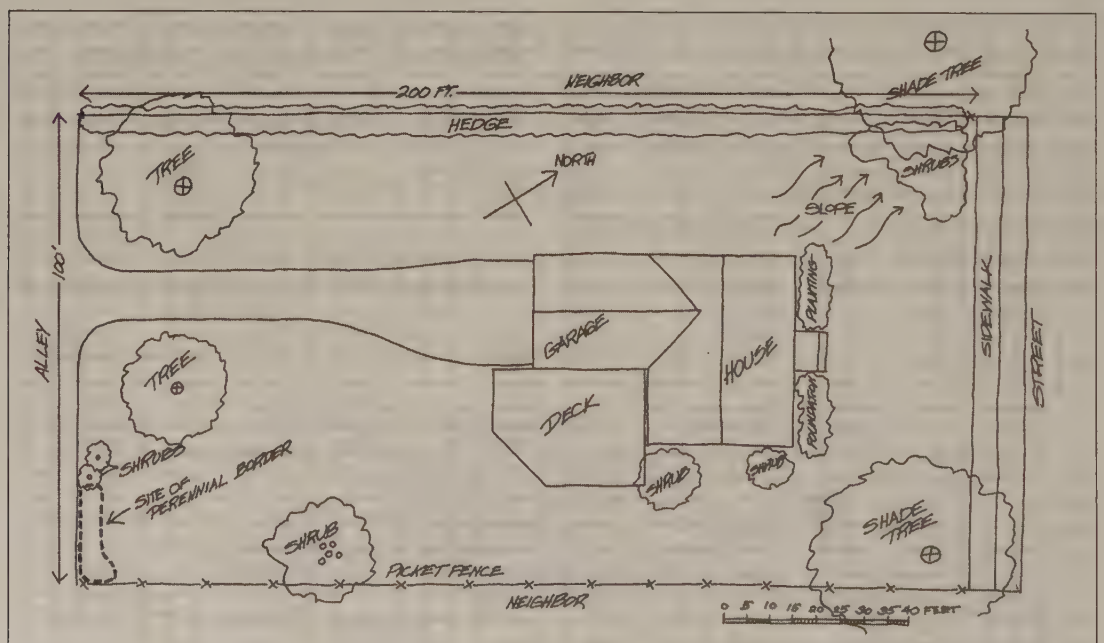
Arrange plants, especially perennials and small shrubs, in clumps of several plants. Because of the basic design principles of balance and repetition, you'll want to repeat clumps of at least some species. As a general rule, you'll probably want half as many species of plants on your list as the number of individual plants you can fit in your border.

Beginning with the first plant on your list, study its "profile" and decide where you want to plant it in the garden. Transfer its name or number to the corresponding shape—or shapes if you want to repeat it in more than one spot—on your diagram. Do this with all the plants that are on your list.

As you work, you'll have to decide how many of each plant you want to grow. You may wish to follow the "rule of three" for perennials that are relatively small at maturity. Three plants will make an attractive clump when mature. For large plants, such as peonies, you may want only one plant; for others, two. Also consider color combinations as you work, and avoid large masses of single colors.

As you grapple with these problems and refine your design, be sure to make changes on both the tracing paper and your master diagram. Expect to have to redo your design several times before you feel you have it right. Each sheet of crumpled paper brings you closer to your goal of creating a beautiful garden.

When you're ready to make your garden plan a reality, it's time to head out to the nursery or pick up the plant catalogs and buy your plants.



Making a bubble diagram. When you have an idea of the size and shape of your garden, draw its outline to scale on graph paper (1 inch on paper to 1 foot of ground is a good scale for most gardens). Use a pencil so you can "move" things around easily, and don't be afraid to make changes. Then draw in circles or "bubbles" to represent your perennials, making the scale of each bubble match the mature width of the plant. Write in the plant name, color, and bloom season in each bubble if you have room so you can see at a glance how good the combinations are likely to look.

Maintaining the Garden

Your flower garden will need basic routine care to keep it in top-notch form. If you've prepared the soil well before planting, planted carefully, and mulched your garden, you'll be well on your way to a healthy, vigorous garden. Here are some points for keeping your flowers looking their best.

START WITH THE BASICS

Weeding, watering, staking—these are just a few of the regular chores required to keep your flower garden blooming beautifully. The care you lavish upon your flower garden throughout the year will pay off with strong growth and flowering year after year. Here's a rundown on the basics of garden care.

Weeding: Weeds compete for water, nutrients, and light, so weeding is a necessary evil. Catch them while they're small and the task will seem easier. A light mulch of bark or shredded leaves allows water to infiltrate and keeps the weeds down.

Watering: Most plants need 1 inch per week for best growth. Bog and pond plants require a continual supply of water. Dry-soil plants are more tolerant of a low water supply, but during the hottest summer months, even they may need watering. Water with a soaker hose where possible and mulch to conserve soil moisture and cut down on watering.

Staking: Staking may be necessary for thin-stemmed plants such as coreopsis, yarrow, and garden phlox. Extremely tall plants such as delphiniums require sturdy stakes to keep flower spikes from snapping off. Heavy, mounding flowers like peonies may need hoop supports (circular wire supports set up on legs) to keep their faces out of the mud. You can also stake up a clump of plants by circling it with twine, then tying the twine to a sturdy stake.

Pinching: Pinching keeps plants bushy. Plants like chrysanthemums and asters have a tendency to grow tall and flop. Pinch them once or twice in the spring to encourage production of side shoots. Early pinching promotes compact growth without sacrificing bloom.

Thinning: Plants like delphiniums and phlox produce so many stems that the growth becomes crowded and vigor is reduced. Cut out excess stems to increase air circulation and promote larger flowers on the remaining stems.

Disbudding: Disbudding is another technique used to increase flower size. Peonies and chrysanthemums produce many buds around each main bud. Simply pinch off all but the largest bud to improve your floral display.

Deadheading: Removing spent flowers will help promote production of new buds in many plants. Just pinch or cut off faded flowers, or shear bushy plants just below the flower heads if the plant blooms all at once. Some perennials like baptisias and 'Autumn Joy' sedum will not rebloom, and their seed heads are decorative. Leave these for winter interest in the garden.

Winterizing: In autumn, begin preparing the perennial garden for winter. Remove dead foliage and old flowers. After the first frost, cut down dead stems and remove to the ground other growth that will die. (Leave ornamental grasses and other plants that add winter interest.) After the ground freezes, protect plants from root damage as a result of frost heaving with a thick mulch of oak leaves or marsh hay. Evergreen boughs are also good for this purpose. Snow is the best insulator of all, but most of us can't count on continuous snow cover. Mulching helps keep the ground frozen during periods of warm weather.

Dividing: Sooner or later, even the slow-growing perennials become crowded and need dividing. Divide plants in spring or fall in the North and in the fall in the South. (Some plants, such as peonies, should only be dug in the fall.) Some fast growers like bee balms, chrysanthemums, and asters should be lifted every 2 to 3 years. Other perennials such as peonies, daylilies, and hostas only need dividing when they've become overgrown. You'll know a clump is overgrown because it looks crowded, doesn't have as large or as many blooms as it used to, and may have died out in the center.

Controlling Pests and Diseases: The best way to avoid problems is with good cultural practices, good maintenance, and early detection. Healthy plants develop fewer problems. Here are a few simple tips:

- Water early in the day to enable plants to dry before evening. This helps prevent leaf spots and other fungal and bacterial problems.
- Don't overwater. Waterlogged soil is an invitation to root rot organisms.
- Remove old flowers and yellowing foliage to destroy hiding places for pests.
- Remove plants that develop viral infections and dispose of them.
- Never put diseased plants in the compost.
- Early detection of insects means easy control. Many insects can be controlled by treating the plants with a spray of water from a hose. Treat severe infestations with appropriate organic control such as a soap-spray solution. Follow label recommendations.

Growing Roses

The rose is the best-loved flower of all time, a symbol of beauty and love. Roses have it all—color, fragrance, and great shape. Many roses produce flowers from early summer until frost, often beginning the first year of planting.

The members of the genus *Rosa* are prickly stemmed shrubs with a wide range of heights and growth habits. There are as many as 200 species and thousands of cultivars, from miniatures less than 6 inches tall to rampant climbers growing

Continued →

to 20 feet or more. And you can find roses in gardens in just about every climate around the world.

Over the years, roses have gained a reputation for being difficult to grow. But many of the "old roses," plus a great number of the newer cultivars, are disease-resistant, widely adaptable plants able to withstand cold winters and hot summers.

SELECTING ROSES

With so many roses available, deciding on the ones you want may be the hardest part of growing them. To begin making choices, it helps to understand the differences among roses. This large, diverse genus can be divided into three major types: bush, climbing, and shrub roses.

Bush roses: Bush roses form the largest category, which has been divided into six subgroups: hybrid tea polyantha, floribunda, grandiflora, miniature, heritage (old), and tree (standard) roses. Here's a rundown:

- Hybrid tea roses usually have narrow buds, each borne singly on a long stem, with large, many-petaled flowers on plants 3 to 5 feet tall. Hybrid teas bloom repeatedly over the entire growing season.
- Polyantha roses are short, compact plants with small flowers produced abundantly in large clusters throughout the growing season. Plants are very hardy and easy to grow.
- Floribunda roses were derived from crosses between hybrid teas and polyanthas. They are hardy, compact plants with medium-sized flowers borne profusely in short-stemmed clusters. They bloom all summer long and are easily grown.
- Grandiflora roses are tall (5 to 6 feet), narrow plants bearing large flowers in long-stemmed clusters from summer through fall.
- Miniature roses are diminutive, with both flowers and foliage proportionately smaller. Most are quite hardy and bloom freely and repeatedly.
- Heritage (old) roses are a widely diverse group available prior to 1867, the date of the introduction of the first hybrid tea rose. Plant and flower forms, hardiness, and ease of growth vary considerably; some bloom only once, while others flower repeatedly. Among the most popular of the old roses are the albas, bourbons, centifolias, damasks, gallicas, mosses, and portlands; also some species roses.
- Tree (standard) roses are created when any rose is bud-grafted onto a specially grown trunk 1 to 6 feet tall.

Climbing roses: Roses don't truly climb, but the long, flexible canes of certain roses make it possible to attach them to supports such as fences, arbors, and trellises. The two main types are large-flowered climbers, with thick, sturdy canes growing to 10 feet long and blooms produced throughout the summer; and ramblers, with thin canes growing 20 feet or more and flowers borne in early summer.

Shrub roses: Shrub roses grow broadly upright with numerous arching canes reaching 4 to 12 feet tall. Most are very hardy and easily grown. Some only bloom once in early summer, while others bloom repeatedly during the summer. Many produce showy red or scarlet fruits called hips. Some species roses are considered shrub roses.

Groundcover roses: Groundcover roses are sometimes included with shrub roses. These have prostrate, creeping canes producing low mounds; there are once-blooming and repeat-blooming cultivars.

USING ROSES IN THE LANDSCAPE

To grow well, roses need a site that gets full sun at least 6 hours a day, with humus-rich soil and good drainage. If these conditions are met, you can use roses just about anywhere in the landscape. Try roses in foundation plantings, shrub borders, along walks and driveways, surrounding patios, decks, and terraces, or in flower beds and borders. Combine roses with other plants, especially other shrubs or perennials. You'll get the greatest visual impact by massing roses of a single color or cultivar.

Use climbing roses to cover walls, screen or frame views, or decorate fences, arbors, trellises, and gazebos. Grow groundcover roses on banks or trailing over walls. Plant hedges of shrub, grandiflora, and floribunda roses. For a single-row hedge, space plants 2 feet apart; for a wider hedge, stagger rows with 1½ feet between rows and 2½ feet between plants.

You can also grow roses in containers. For all roses except miniatures, choose a container at least 14 inches deep and 1½ feet wide. You can grow miniatures in pots as small as 6 inches in diameter. Use a soilless potting mix; fertilize and water regularly. In all but frost-free climates, overwinter pots in an unheated garage or basement.

GROWING GOOD ROSES

The key to growing roses successfully is to remember that they need plenty of water, humus, and nutrients.

Soil: Prepare a new site in fall for planting the following spring, or in summer for fall planting. If you plan to grow roses with existing plants, then no special preparation is needed. For a new site, dig or till the soil to a depth of at least 1 foot. Evenly distribute a 4-inch layer of organic material such as peat moss, compost, leaf mold, or dehydrated cow manure over the soil surface. Also spread on fertilizer. A general recommendation is to add 5 pounds of bonemeal and 10 pounds of greensand or granite dust per 100 square feet. Dig or till the fertilizer and soil amendments into the soil.

Planting: For much of the West Coast, South, and Southwest, or wherever winter temperatures reach no colder than 10°F,

the best time to plant bareroot roses is January and February. In slightly colder areas, fall planting gives roses a chance to establish a sturdy root system before growth starts. In areas with very cold winters, plant bareroot roses in spring, several weeks before the last frost. For all but miniature and shrub roses, space roses 2 to 3 feet apart in colder areas; 3 to 4 feet apart in warmer regions where they'll grow larger. Space miniatures 1 to 2 feet apart; shrub roses 4 to 6 feet apart.

To plant bareroot roses, dig each hole 15 to 18 inches wide and deep, or large enough for roots to spread out. Form a soil cone in the planting hole. Removing any broken or damaged roots or canes, position the rose on the cone, spreading out its roots. Place the bud union (the point where the cultivar is grafted onto its rootstock) even with the soil surface in mild climates and 1 to 2 inches below the soil surface in areas where temperatures fall below the freezing point.

Add soil around the roots, making sure there are no air pockets, until the hole is three-fourths full. Fill the hole with water, allow it to soak in, and refill. Make sure the bud union is at the correct level. Finish filling the hole with soil and lightly tamp. Trim canes back to 8 inches, making cuts ¼ inch above an outward-facing bud and at a 45-degree angle. To prevent the canes from drying out, mound lightly moist soil over the rose bush. Gently remove it when growth starts in one to two weeks.

Plant container grown roses as you would any container plant.

Water: Ample water, combined with good drainage, is fundamental to rose growth. The key is to water slowly and deeply, soaking the ground at least 16 inches deep with each watering. Water in the early morning, so if foliage gets wet, it can dry quickly. Use a soaker hose, drip irrigation system, or a hose with a bubbler attachment on the end. Roses grown in containers must be watered much more frequently. Check containers daily during the summer.

Mulch: An organic mulch conserves moisture, improves the garden's appearance, inhibits weed growth, keeps the soil cool, and slowly adds nutrients to the soil. Spread 2 to 4 inches of mulch evenly around the plants, leaving several inches unmulched around the stem of each rose.

Fertilizing: Feed newly planted roses 4 to 6 weeks after planting. From then on, for roses that bloom once a year, fertilize in early spring. Feed established, repeat-blooming roses three times during the growing season: in early spring just as the growth starts, in early summer when flower buds have formed, and about six weeks before the first fall frost. The last feeding should have no nitrogen.

Use a commercial balanced organic plant food containing nitrogen, phosphorus, and potassium, or mix your own, combining 2 parts blood meal, 1 part rock phosphate, and 4 parts wood ashes for a 4-5-4 fertilizer. Use about ½ cup for each plant, scratching it into the soil around the plant and watering well. As an alternative, apply dehydrated cow manure and bonemeal in the spring and use fish emulsion or manure tea for the other feedings.

Pruning: Prune in early spring to keep hybrid tea, grandiflora, and floribunda roses vigorous and blooming. Many of the newer shrub-type roses need very little pruning. Heritage, species, and climbing roses that bloom once a year bear flowers on the previous year's growth. Prune these as soon as blooming is over, cutting the main shoots back by one-third and removing any small, twig growth. Remove suckers coming up from the rootstock of any rose whenever you see them.

In the first pruning of the season, just as growth starts, remove any dead or damaged wood back to healthy, white-centered wood. Make each pruning cut at an angle ¼ inch above an outward-facing bud eye, which is a dormant growing point at the base of a leaf stalk. This stimulates outward-facing new growth. Also remove any weak or crossing canes. Later in the season, remove any diseased growth and faded flowers on repeat-blooming roses, cutting the stem just above the first five-leaflet leaf below the flower.

Winter protection: In areas with winter temperatures no lower than 20°F, no winter protection is necessary. Elsewhere, apply winter protection after the first frost and just before the first hard freeze. Many shrub roses as well as some of the polyanthas, floribundas, and miniatures need only minimal winter protection. Hybrid teas, grandifloras, and some floribundas and heritage roses usually require more.

Remove all leaves from the plants and from the ground around them and destroy them. Apply a fungicidal soap spray containing sulfur. Apply ¼ cup of greensand around each plant and water well. Prune plants to one-half their height and tie canes together with twine.

Where winter temperatures drop to 0°F, make an 8-inch mound of coarse compost, shredded bark, leaves, or soil around the base of each plant. In colder areas, make the mound 1 foot deep. Provide extra protection with another layer of pine needles or branches, straw, or leaves. Where temperatures reach -5°F or colder, remove the canes of large-flowered, repeat-blooming climbers from supports, lay them on the ground, and cover both the base and the canes.

Flowers the Low-Maintenance Way

Barbara W. Ellis, Joan Benjamin, and Deborah L. Martin

Flowers can be great care consumers, but few of us would want to be without them. The instant or anticipated charm of beautiful blossoms is a big incentive for clearing space in the schedule for flower gardening. For example, who objects to taking time

Continued ➔

to plant a six-pack of colorful zinnias or petunias? Designing flower gardens may seem like an intimidating task, but in this section you'll find simple guidelines to follow that can take most of the fuss out of garden design. With forethought and smart plant choices, you can create gorgeous plantings that don't demand lots of maintenance. In some cases, planting well-designed flower beds can even reduce the amount of time you usually spend on other routine yard chores, such as mowing the lawn or trimming around trees.

A Credo for Low-Work Gardening: Don't Fight Your Site

A near-holy commandment for the low-maintenance gardener is: Match the plant to the site. Instead of trying to change difficult conditions with soil amendments or raised beds, select plants that will thrive as is. Most common garden annuals—and many herbs—are suited only for average to good soil and good drainage. But among the huge selection of flowering perennials, bulbs, vines, and grasses available, you're sure to find plants suited to any garden situation. It makes sense to use those that will thrive instead of those that will struggle for survival.

For example, broaden your garden horizons with wildflowers that are naturally suited to difficult conditions. Do a little homework before buying, and search out nearby nurseries or specialty-seed sources. Buy seeds in single-species packets, not prepackaged mixes, for better impact and to avoid later thinning.

Whether Controlled or Care-Free, Flowers Can Be Nearly Maintenance-Free

Flower gardens can have a neat, controlled look, with every plant assigned its own particular place. Or, they can run with a looser rein, creating an informal "country garden" look, with perennials spreading at will and self-sowers filling in the gaps with charming serendipity. Whether you prefer neat or nonchalant is a matter of personal choice. Either type is effective in the low-care landscape. Home landscapes often have opportunities for both types of flower garden—perhaps a disciplined, refined planting as the main display bed, and a wilder bunch out by the mailbox.

The most important thing to remember is to choose plants that suit your style. For a semiformal garden, you'll want plants like irises and hostas that know their place; if you plant self-sowers or fast spreaders, you'll spend hours on hands and knees trying to keep things under control. For the freewheeling flower bed, focus on plants tht fill in fast, like yarrows, and that drop their seeds with abandon, like cosmos, so that the design of the garden is always an unexpected pleasure.

1. Keep formal beds manicured with mulch. Formal and semiformal gardens are unforgiving of imperfection. Weeds stand out accusatorily in a formal bed. But a controlled planting of well-behaved flowers is still within reach of low-maintenance gardeners, thanks to the miracle of mulch. Mulch smothers weeds and cuts down on watering, two big time-eaters. Plants in semiformal and formal gardens typically have a bit of open space around them, which can be an invitation to weed invasions. Make mulch your best friend, reapplying it whenever new populations of weeds crop up. Once you have a good layer of mulch down, you'll find that weeds yield easily to hand-pulling or a scuffle hoe.
2. Cultivate the country look. The informal jumble of a country garden is a good look for low-care gardeners. Combine reliable perennials, such as bee balms (*Monarda* spp.) and monkshoods (*Aconitum* spp.), with self-sowing annuals and biennials. A low-care garden should include plenty of annuals for color that lasts for weeks, often until frost. Choose annuals that resow themselves year after year. The serendipity of self-sown flowers is a part of the country garden's charm.

Invest in Plants for a Quick-Start Garden

Starting a flower garden by buying plants is more expensive than starting from seed, especially when perennials cost $3 a pot and more. But if you can afford it, it's a great time saver and a good start to a successful garden. You can install plants exactly where you want them, avoiding transplanting and thinning chores.

One-gallon pots—or even three-gallon pots—filled with healthy, vigorous perennials are mighty tempting, but your budget will be better off if you can resist the instant gratification. Four-inch starter pots of perennials may not give you as good a display their first year, but they're a great buy for gardeners on a budget. By the end of the season, the small plants will have caught up to their high-priced brothers, and by next year you probably won't be able to tell the difference.

Keep Mowing in Mind When You Design

Before you fill your yard with flowers, think about the physical layout of your beds and borders. Carefully planned flower plantings will eliminate some of that weekend drudge work behind the mower, but randomly placed beds can mean extra mowing woes.

Plan for flowering slopes. If you've been spending your Saturday mornings dragging a lawn mower up and down that bank behind the mailbox, replace that high-maintenance lawn grass with thick groundcovering perennials like daylilies (*Hemerocallis* spp.), creeping phlox (*Phlox stolonifera*), or pinks (*Dianthus* spp.). Be sure to mulch heavily until the plants are established to prevent weeds from contaminating the plot.

Size pathways to fit your mower. Keep the width of your mower in mind when designing the layout of your flower beds and borders. Allow enough space around and between beds for convenient access, according to the width of your mower deck. Few things are as frustrating—or as time-consuming—as having to add one last pass with the lawn mower to remove a final 6-inch strip of grass. If your mower cuts a 3-foot-wide swath,

a 5- or 5½-foot-wide path will be just the right size, allowing some overlap between passes. A smaller 2-foot-wide cutting deck requires a path sized accordingly.

Don't make yourself cut corners. Formal, geometric beds and borders with straight edges and sharp corners are a higher maintenance design than flowing, free-form, informal shapes. Maneuvering your mower around angled turns takes more time and thought than whizzing along the edge of a curved border.

Merge beds to minimize mowing. Combining several small flower beds into one large planting is another way to finish mowing faster. Integrate isolated landscape shrubs into the planting, too, to eliminate the need for mowing around each one. If you have several rose bushes dotted along the front walk, for instance, an underplanting of lavender, alyssum, and creeping thyme will make the roses look less naked and create a small, romantic garden.

Smothering Sod Lets You Spread Your Beds

By applying a super-thick or very dense layer of mulch to the intended flower bed, you are blocking light and air from the grass plants beneath, which eventually give up and die. Eight- to twelve-page sections of newspaper are an effective smothering device. Wet the newspaper with a garden hose to keep it from blowing away as you work. Apply the sections with plenty of overlap so that desperate grass can't force its way through to the air. Then blanket the newspapers with several inches of organic mulch such as aged straw or grass clippings. Top with a thin layer of fine decorative mulch if desired, such as shredded bark or buckwheat hulls. Wet it well. Wait at least three weeks, then plant the bed with perennials or annuals from containers, pulling the mulch aside to dig a planting hole. Remove any grass roots from the backfill. Water thoroughly, and apply 2 inches of mulch around the new plants. By the time the deep mulch rots down at the end of the season, the grass should be dead. Earthworms attracted by the mulch will make the soil below loose and friable.

Like the old Roman Empire, flower gardens have a way of expanding year by year, swallowing lawn as they grow. Turning turf into flowers is one of the more daunting tasks that a low-maintenance gardener faces, but there is an easy way: Simply smother your grass.

Simple Shortcuts for Combining Colors

For most gardeners, planning isn't as much fun as doing. Figuring out color schemes and plant combinations can be frustrating and time-consuming. Dispense with complicated plans and simplify your beds and borders by planting in large blocks of color. You'll get a bigger effect by planting a dozen or more of the same plant to fill a large stretch than you will by mixing plants or colors.

Limit your beds and borders to three main colors to make selecting and placing plants easier and more satisfying. Yellow, white, pink, blue, purple, and gray or silver are effective in any threesome combination. Red and orange are often difficult to weave into the garden. Here are some other simple solutions for using color in your garden.

Settle color clashes with white. There's an easy, no-dig way to soften clashing colors in the garden—separate the clashing combatants with neutral white-flowered annuals. Here's how it works: If your brilliant pink astilbes and bright orange lilies have surprised you by blooming at the same time, fill in between them with white-flowered annuals like impatiens or sweet alyssum to soften and separate the colors. You can move one of the offending colors in the spring or fall, when it's not in bloom. Or separate them permanently with white-flowered perennials that will be in bloom at the same time. Silver-foliaged plants like dusty miller also have the same effect.

Make your yard bigger with blue. It's true, cool colors like blue make things seem farther away than they really are. A garden of blue, soft pink, and white will make your yard seem larger than one planted in red, orange, and yellow. All without having to take care of another square inch.

Start color combinations on your doorstep. Can't decide what color would be right for your garden? How about selecting a color that matches or complements your house's trim? Plant mounds of lavender-blue bellflowers (*Campanula* spp.), spiky clumps of deep violet salvia 'East Friesland', and tall purple Canterbury bells (*C. medium*) beside the stoop to accent a teal-colored door. Remember to keep things in balance—a garden the same color as the house adds nothing to the overall effect. Mustard siding? Yellow flowers would be too much; go with blues instead.

A Word to the Wise: Think Twice before Planting Invasives

Many of the most-expert experts scorn invasive perennials (plants that spread vigorously), but it's all a matter of perspective. If you want a balanced planting in a mixed border, or if you have a small garden, invasives can quickly become major headaches. But if you want to fill a new bed in a hurry or plant an easy-care area, they're a great choice.

When you want hurry-up-and-grow plants, look for perennials that are *stoloniferous*, which means they spread by creeping underground stems. These plants often grow so thickly that they crowd out competing weeds.

Invasive perennials vary in their rate of aggressiveness. Lamb's-ears (*Stachys byzantina*), for instance, is a fairly well-mannered spreader that expands slowly and can be easily kept in line. But a single plant of one of the fastest-spreading perennials, the native sunflower known as Jerusalem artichoke (*Helianthus tuberosus*), can colonize a 4-foot-wide area in just a single year, and its brittle tubers are nearly impossible to remove completely once it gets going.

Some invasives are easy to control by hand-pulling, but others are insistent growers that spring back no matter how

Continued →

often you pull. You're not doing yourself any favors by planting these eager beavers where they'll need to be brought back into bounds a few years down the line. Save them for areas that are isolated from your less-aggressive plants, or use them to create a no-care flower bed along a sidewalk fence. To preserve good neighbor relations, don't plant aggressive invasives near property boundaries.

Is Deadheading Worth Your While?

Peach-leaved bellflower (*Campanula persicifolia*) bears stalks of lovely, soft, lavender-blue flowers, but when blooms fade, blossoms brown quickly and hang on the plant like old laundry. Balloon flower (*Platycodon* spp.) is another perennial that doesn't "self clean." Many gardeners accept faded flowers in the garden, but if you prefer a neat look, you may be better off replacing these plants with those of neater habit. For example, some annuals, such as begonias and Madagascar periwinkle (*Catharanthus roseus*), drop faded flowers and bloom continuously.

On the other hand, many gardeners find deadheading—removing tired and dying flowers—an agreeable chore that doesn't take much time. Even the most dedicated low-maintenance gardener probably won't eliminate daffodils or daylilies from the garden because of their tendency to hang onto faded flowers.

When you do deadhead, suit your technique to the plant. Pinch or clip off old blooms on plants like pansies that have thin stems. Brittle stems, like those on salvia, are easy to break off with the flick of a wrist. Or deflower salvias, petunias, marigolds, and other flowers that bloom all at once in a hurry with hedge clippers.

Twiggy Support for Top-Heavy Flowers

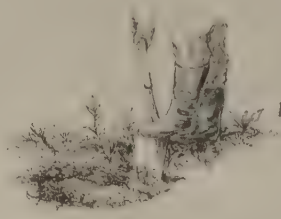
In the formal or semiformal garden, a flower that leans with the wind or its own weight may need a little help to straighten its backbone. A twiggy clipping makes an ideal plant support for flopsy annuals such as spider flower (*Cleome hasslerana*). Such clippings are easy to handle and blend right in among the plants. Strip any leaves off the clippings and leave them to dry in the sun for a day or two. (Otherwise, they may put out roots and begin to grow when you stick them in the garden.) Poke the dry branches into the soil so that they are well anchored. Put brush in place earlier in the season for prone-to-leaning perennials, such as delphiniums, so that flower stems grow up through it.

Planting a Flowerbed: The Traditional Way

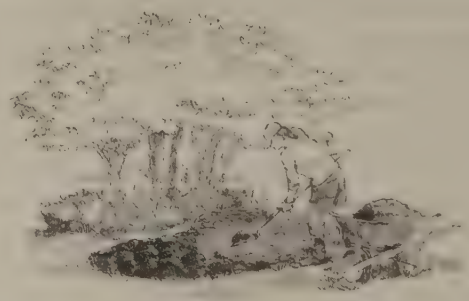
Larry Hodgson

You can start a garden the traditional way—by digging up what's already there—if there are no or few tree roots present. If so, thoroughly soak the designated area 24 hours before you begin digging, as slightly moist soil is the easiest to work with.

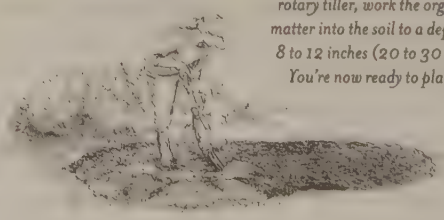
Start by removing whatever was growing there before. That may be lawn, an abandoned garden, brush, or weeds. If it's sod, cut into the soil about 2 inches deep with a sharp shovel, then slide the shovel under the sod and carefully lift it off. Use good-quality sod elsewhere in your yard, such as fixing a weakened section of lawn. Otherwise, simply compost it. If there is no sod, only weeds or other undesirable plants, dig them out individually. Make sure you get the weeds' entire root systems, or they will just sprout again.



Step 1. Remove brush, weeds, or lawn, making sure to get all roots.



Step 2. Add a layer of 3 to 4 inches (8 to 10 cm) of compost, peat moss, well-decomposed manure, chopped leaves, or other organic matter. Double that amount if the soil is heavy clay.



Step 3. With a garden fork or rotary tiller, work the organic matter into the soil to a depth of 8 to 12 inches (20 to 30 cm). You're now ready to plant!

Add a good layer of compost, peat moss, well-decomposed manure, chopped leaves, or other organic matter, and mix it into the top layer of soil. About 3 to 4 inches (8 to 10 cm) is probably enough in most soils, but if your soil is mostly clay, you might want to double that. Work it in thoroughly to a depth of 8 to 12 inches (20 to 30 cm). If you can use a rotary tiller in the chosen spot, you'll find it worthwhile renting one for this task, as turning over the soil and mixing it with the new amendments can be backbreaking work when done with a shovel or garden fork.

Personally, I gave up using the traditional method of starting a flowerbed years ago. I find it too much work, too slow (it takes about a full weekend just to prepare a medium-size

bed), and too traumatic for the soil's microorganisms. Worse yet, turning the soil over that way inevitably leads to great masses of weeds sprouting during the following months. This is a result of moving dormant weed seeds from under the soil and exposing them to the light, stimulating them to sprout—and of accidentally chopping up rhizomes of invasive species, thus spreading them throughout the garden. Make sure, if you do use the traditional method, you at least put down a thick layer of mulch as soon as you finish; this will bury the weed seeds again and let you get off to a reasonable start. Pull out any weeds sprouting from bits of rhizome as you see them before they begin to take over. The mulch won't stop them, but at least it will keep the soil friable and make pulling them easier.

Also keep in mind that any aggressive tree roots that are present will react to the pruning that was done as you turned over the soil by regrowing massively within a few short weeks. They'll quickly take over the bed again, much to the detriment of the plants you just put in. So if you use the traditional planting method in an area with heavy root competition, try to put in mature plants, as they are better able to cope with competition. Small or young plants are often unable to develop well under such circumstances and die out or grow only very weakly. Even years later, they'll be only a shadow of the plants that were grown using the traditional way with full-size plants or using the fast-and-easy method.

Planting a Flowerbed: The Fast-and-Easy Method

Larry Hodgson

If you have a lot of tree roots in the area where you want to plant your garden, then this is the method to use so you don't disturb tree roots any more than necessary. This is the method I prefer. It's easy to do, as there is no digging involved and no heavy rotary tiller to lug around. It takes only an hour or so to prepare and plant a medium-size garden (the traditional method takes a full weekend). And I like the fact that it resembles Mother Nature's own way of working: You never see her struggling with a rotary tiller. Instead, she simply deposits a new layer of organic material directly on the old layer. Of course, the fact that the resulting bed is weed-free and tree root-free are two more reasons why I prefer this method.

The whole point of this method is to leave the original soil intact. Be it rich or poor, rocky or organic, clay or sand—don't disturb it and don't try to improve it, just leave it as it is. Instead, you'll build a new bed on top of the old one. The old soil will simply become subsoil, and the quality of subsoil is of little importance. Instead, your new plants will be growing in a fresh layer of top-quality, weed-free soil. The microorganisms in what is now the subsoil will slowly move upward into the new layer of soil, as they would in nature when a new layer of fall leaves covers the ground. The natural microflora remain intact instead of being largely destroyed as they are in the traditional method.

Before you begin the fast-and-easy method, you'll need to save up newspaper (you'll see why in a minute). You'll need quite a bit of it for an average-size bed, so start putting it aside a good 2 to 3 weeks before you plan to start.

You'll also need to shop for soil. You don't want just any soil, but the very best. The soil you buy should be rich in organic matter, have a good structure, be perfectly friable, and be completely lacking in weeds. It should not come out of a plastic bag (living soil has to breathe), but from an open pile that has had organic matter added and been turned again and again until all weed roots and weed seeds have burned off (been decomposed). Ask your county extension agent where you can find top-quality soil locally. Have it delivered—or, if you have a pick-up or a trailer, go pick it up yourself (it's considerably cheaper that way).

Preparing a Flowerbed by the Fast-and-Easy Method

Step 1. Cut back vegetation, then cover the area with a thick layer of newspaper.

Step 2. Cover the newspaper with 8 inches (20 cm) of top-quality weed-free soil . . . and start planting!

The day before you begin your bed, mow the area (if it is in lawn) or use a brush cutter to chop back the vegetation if the area is covered with taller plants. You don't need to remove the resulting residue: Just leave it where it lies. It will decompose and further enrich your soil. When the soil has been delivered or you've trucked it in, you're ready to begin.

Continued →

On the big day, go pick out your plants from a favorite local nursery (unless you're growing them from seeds or cuttings). Make sure you've worked on your garden plan so you know exactly what you need. Bring them home, place them in a shady spot, and water them thoroughly. Of course, if you're having them delivered from a mail-order nursery, order them several weeks in advance with instructions as to the date you want them. Unwrap them upon arrival and water them well.

That same day, create a temporary barrier that will keep any weeds or other undesirable plants from pushing through the new layer of soil you are about to apply. Remember that in the fast-and-easy method you don't remove the original sod, weeds, or other growth. Instead, cover the entire bed with 5 to 10 sheets of newspaper, thus creating a barrier that efficiently controls the weeds and grasses that used to live there. Blocked under the newspaper barrier, without any access to light, the weeds will die and decompose. I've always felt that turning your enemies (in this case, weeds and invasive grasses) into compost was the best revenge of all! And this method smothers even truly nasty spreading weeds, like goutweed (*Aegopodium podagraria*), quackgrass (*Agropyron repens*), and horse-tail (Equisetum arvense). I can't say that I feel the slightest guilt at smothering goutweed! (In case you're worried about the possibility of colored newspaper ink containing lead and contaminating the soil, newspaper ink hasn't contained lead since 1986. Unless you're given to recycling truly old newspaper, there'll be no problem with lead contamination.)

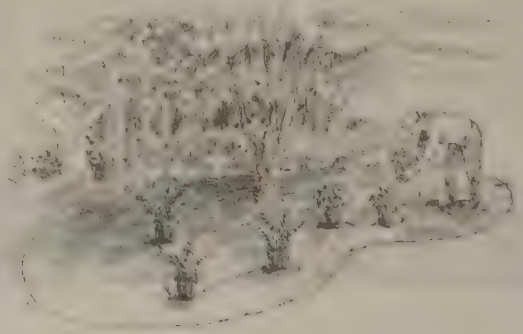
Make sure your layer of newspaper is perfectly intact, with each section thoroughly overlapping the other at the edges; otherwise, the plants below will find a way through. And if you accidentally pierce a hole in your newspaper barrier, cover it up with a few more sheets of newspaper. On windy days, soak the newspaper in water before you apply it so it won't blow away. Then cover the entire newspaper barrier with 8 inches (20 cm) of soil (or 12 inches/ 30 cm of soil if there are no tree roots to protect) to bring it up to the proper planting depth—and you're ready to plant!

The newspaper barrier will last 6 months to a year, then begin to decompose. That's long enough to kill the undesirable plants, which can't live without light, but not enough to kill the microorganisms from the soil below—nor will it kill underlying tree roots. They'll simply bide their time until the newspaper rots away, then happily move back up into the fresh new soil. The barrier does, however, offer your plants a bit of leeway in establishing themselves. They have about a good 6 months to a year before the tree roots start to move in, and about 18 months before they are back in mass quantities. That gives your plants a deadline to meet: They must be well established, with a healthy root system, within 18 months. If so, they'll be able to compete with the tree roots as equals. If they are poorly established, the tree roots will take over and they'll likely weaken and possibly even die. So give your plants the best of care for the first 18 months, and they'll be able to grow happily for the next 18 years!

After the newspaper is in place, add the new soil on top of it. You'll want to add only a relatively thin layer of fresh soil—adding too thick a layer could smother tree roots, as they need to breathe. Eight inches (20 cm) seems to be just about the right amount. It gives you enough soil to plant in (well, at least you can plant medium-size plants), yet it isn't deep enough to smother tree roots. If there are no roots to protect, go for a full foot (30 cm) of soil: Many of the world's best soils are made up of a mere 1 foot (30 cm) of good topsoil, so why not give your shade garden plants the very best?

Planting Time

Most likely you'll want to plant your flower bed immediately after you've finished preparing the bed—and there's no reason you can't! If for whatever reason you will not be planting within the next few days, though, cover the bed with mulch. The mulch will create a barrier from above to keep weed seeds from floating in and taking over the fresh soil, and it will keep the soil light and friable. You can always push the mulch to one side when it does come time to plant.



Before planting or even unpotting, always set the potted plants out at their proper spacing to test the effect.

OUT OF THE POT, INTO THE GARDEN

Most of the time the plants you'll be using will be growing in pots, with the main exception of bulbs. They may be plants you purchased or ones you grew from seeds or cuttings. Separate the plants according to whether they are to be permanent plants (this will likely include mostly perennials, ferns, shrubs, and any hardy grasses), spring or fall bulbs, or annuals.

The first plants to put in the ground are the permanent ones. In the long run, they'll be taking up most of the space in the garden and will need the best care. Set them on the soil, but don't remove the pots yet. Instead, place them carefully according to their recommended spacing, using a ruler to measure if needed, according to your garden plan. Remember that in most cases, plants (especially smaller ones) will look best when placed together in groups of three or more. Also, stagger your plantings rather than planting in straight lines. Once you have placed all your pots on the soil, move them around and adjust them until the effect is what you want. Then you can begin planting.

For most perennials, ferns, and grasses, a simple hand trowel will be the planting tool of choice, but for larger ones you'll need a shovel. Dig a hole for each plant, about the same depth as the pot is high, and twice as wide. Place the plant, pot and all, into the hole, making sure it is deep enough, then take it out again, adding or removing soil as needed to adjust the height. Add a dusting of mycorrhizal fungi to the bottom and sides of the potting hole. Don't yank the plant out of its pot; you could damage its root system. Instead, turn the plant upside down and, slipping your fingers around the base of the plant so your palm is supporting the rootball, give a sharp rap with the heel of your hand to loosen the pot, then pull it off. If the pot doesn't want to give, you may have to cut it off.

If the rootball of the plant is lightly covered with roots or shows a lot of brown soil, plant it intact. If there are a few circling roots at the base, spread them out before planting. If the entire rootball is covered with many circling roots, that means the plant is rootbound (it's been left in its pot for too long a time). If planted as is, its own roots may remain in a circle and come to strangle it over time! To prevent this, score the rootball with a sharp knife, running it from top to bottom, about ¼ inch (6 mm) deep on all four sides. This will cut the circling roots and force the plant to form new healthy roots that will radiate outward into the fresh soil.

If the plant is rootbound (surrounded by circling roots), score the rootball on four sides to encourage new root growth with a more outward habit.

You may also have plants growing in peat pots. They don't need to be removed: Plant them pot and all. Do cut off any part of the pot that sticks up above the ground; otherwise, it may act as a wick, absorbing water from the soil and causing the plant's root system to dry out.

Place the plant in its hole so it touches the mycorrhizal inoculum, and half-fill the space around the roots with soil. Water well, filling the hole and waiting until the water drains away (which it should do immediately if the soil is of good quality), then finish filling the hole with soil. Firm it down with your hand, and water well a second time. The "double watering" makes sure that both the lower and upper roots get their share of water.

Finally, don't forget to insert a plant label beside the plant—either one supplied by the nursery or one you've prepared yourself—so you can remember just what you planted and where. There is nothing more frustrating for a gardener than having a great plant you'd like to talk about, but not having the slightest idea what it is!

When planting, it's best to water twice: first when the planting hole is only halfway full, then when it has been filled in. That way, even the lower roots get their fair share of the water.

PLANTING BAREROOT PLANTS

Not all plants come in pots. You may have received bareroot plants through the mail or have dug up or divided plants from elsewhere. (For example, if you're overhauling an old and not-too successful flowerbed, you will probably have dug out a few survivors that you want to save and put back in the new bed.) These should be kept moist and in a shady spot until planting time. Cover their roots with burlap or landscape fiber, and spray them with water every day (more often if necessary) to prevent the roots from drying out. Don't leave bareroot plants out of the soil for too long, though. If you don't expect to be able to plant them for more than a week, pot them up temporarily in garden soil until you can get to them.

Planting bareroot plants is a bit more complicated than planting potted ones, as it's harder to judge just how deep to plant them. The idea is that, when you finish planting, the crown should be at the same depth as it was originally. You can easily see this, as the parts that were originally underground will be paler in color than those that were exposed to light. However, without a solid rootball beneath them, bareroot plants tend to sink down into the soil after watering. So I suggest digging a

Continued ➔

larger hole than for potted plants, about twice the depth and width of the roots. In the middle of the planting hole, form a cone of soil and firm it well, then place the base of the plant on this, spreading the roots all around. This cone will hold the plant at the required depth. If the cone is too short or too tall, add or remove soil from the cone and try again. Once the cone is the right height, set the plant on it, again spreading its roots out all around the cone, then sprinkle mycorrhizal inoculum directly on the roots. Add enough soil to half-fill the planting hole, water thoroughly, then fill the hole completely with soil, tamp down, and water thoroughly a second time.

When planting a bareroot plant, create a cone of well-firmed soil and place the base of the plant on this, spreading the roots all around. This will help keep it from sinking into the soil after it is watered.

PLANTING BULBS

If you're planting in fall, before you finish your shade garden with a layer of mulch, consider planting hardy bulbs. You can plant them more easily in a bed of freshly planted perennials, grasses, and ferns than you can in a bed that is established and full of plants. Simply dig a wide but shallow hole in open spaces between plants. It should be about 3 times the height of the bulb and large enough for about 7 to 10 large bulbs (or 20 or more smaller ones), spaced about 3 times their diameter. Add mycorrhizal fungi, place the bulbs in the hole with the pointed side up, half-fill the hole with soil, water thoroughly, then fill the hole, firm the soil, and water a second time.

ANNUALS AS A "JUST BEFORE FINISHING" TOUCH

A first-year bed composed only of hardy, permanent plants like perennials, grasses, ferns, shrubs, and bulbs often looks disappointingly barren. After all, you've probably put in relatively small plants and left room for their future growth, but they probably won't reach their full size for 2 or 3 years—maybe more (plants fill out more slowly in shady spots than when they are grown in the sun). But that's easily fixed: Simply plant shade annuals in the empty spaces! They'll fill in the bed and provide abundant color the first year.

MULCH: THE TRUE FINISHING TOUCH

Of course, the true finishing touch to any shade planting will be a nice, fairly thick layer of mulch: No shade garden should be without one.

Wildflowers

Barbara W. Ellis

Anyone who has enjoyed the beauty of a spring woodland carpeted with Virginia bluebells (*Mertensia virginica*) and bloodroot (*Sanguinaria canadensis*), or a colorful autumn meadow bursting with butterfly weed (*Asclepias tuberosa*) and goldenrod (*Solidago* spp.), has felt the magic of wildflowers. These plants also hold a special fascination because they thrive in all sorts of conditions—from dry, desert soils to boggy sites, and from full sun to deep shade—all without a gardener's helping hand. Not only are there wildflowers for nearly every part of the garden, they also require little maintenance, provided they're happy with the conditions in which they've been planted.

The key to growing wildflowers successfully is understanding the conditions they require in their native habitats. Wildflowers will grow best in locations that duplicate their native environments. Soil type, monthly rainfall, annual temperature range, and sunlight or exposure are all important. To pick the best wildflowers for your garden, try to find plants that naturally thrive in the conditions your garden has to offer. If you have a tree-shaded lot with loamy soil, for example, perhaps some of the Eastern woodland wildflowers such as wild columbine (*Aquilegia canadensis*) or Jacob's ladder (*Polemonium* spp.) would be suitable. Or, if you have a dry, sun-baked spot, consider planting California poppies (*Eschscholzia californica*), a reseeding annual, or one of the hardy prickly-pear cacti (*Opuntia* spp.), which bear brilliant flowers followed by interesting fruit.

Tips for Success

One good way to start developing a list of wildflowers to try in your garden is to look around you. Look at the plants that spring up in vacant lots, along roadsides, or in natural areas of nearby parks or gardens. Although often thought of as mere weeds, if they are growing in conditions similar to what your garden has to offer, they might be perfect prospects. Use a field guide to identify them, if necessary, and then look for them at your local nursery or in a mail-order catalog. You'll be surprised at how many common weeds are offered for sale.

Beware of weeds that live up to that name, however. Many native plants are quite aggressive and can spread very quickly—either by abundant reseeding or by wandering rhizomes—if not kept in check. If you have an out-of-the-way corner, this might be just what you want, but keep these plants away from areas where their thuglike tendencies might pose a

problem. Members of the daisy family, Compositae, such as goldenrod (*Solidago* spp.), are notorious.

Don't try to improve upon a wildflower's natural environment. Too much moisture may be stressful for a plant adapted to withstanding summer droughts, and rich soil may lead to lush foliage but little bloom if a plant is native to areas with sandy, poor soil.

Like other plants, wildflowers are sold as seeds, bare-root, or potted. Handle new plants just as you would any annual, perennial, or bulb.

Don't forget the many wildflowers that make superb additions even to formal beds and borders. In fact, many of these plants are grown in gardens so often, we forget they are actually wildflowers.

ACQUIRING WILDFLOWERS

There are several ways to obtain wildflowers to add to your garden. They're offered for sale everywhere. One sad fact to consider when purchasing wildflowers, however, is that many plants offered for sale were collected in the wild at the expense of native populations. Virtually all of the pink lady's-slipper orchid (*Cypripedium acaule*) plants offered for sale have been wild-collected. And these beautiful native orchids have exacting requirements that nearly always doom them to death once they're dug and moved to a garden. Other plants to avoid are other native orchids; native lilies (*Lilium* species, not the popular hybrid forms); *Trillium* spp.; and carnivorous plants, such as pitcher plants (*Sarracenia* spp. and *Darlingtonia californica*).

Don't buy collected wildflowers. Ask nursery owners about the source of the native plants they sell. Do not dig plants in the wild yourself unless you are participating in an organized conservation program.

So where should you buy? Reputable nurseries are now beginning to refuse to deal in wild-collected plants and are labeling their plants as horticulturally propagated. You can also buy wildflowers from plant sales organized by botanical gardens or local native plant societies. Or propagate your own—many are easy to grow from seed, and fellow gardeners are often happy to share plants via division.

Growing a Wildflower Meadow

For most people, the word meadow brings to mind scenes of large fields filled with grasses, daisies, and other flowering plants. Or perhaps it suggests a vast expanse of prairie with head-high grass as far as the eye can see. More recently, however, the word has been linked to gardening, and gardeners across the country are experimenting with creating their own meadows, both small and large.

MEADOW OPTIONS

There are many ways a meadow or meadow-style garden can be incorporated into the home ground. You can create a stylized meadow border with ornamental grasses and cultivated forms of native plants such as *Rudbeckia* 'Goldsturm', purple coneflowers (*Echinacea purpurea*), and sneezeweeds (*Helenium* spp.). If you have an uncultivated area, orchard, or old field that you simply mow to keep neat, consider letting it grow up, and sow seed or plant small potted wildflowers to add color.

If you're starting from scratch, you can use a seed mix or start with potted plants. Seed is less expensive and easier to distribute than plants, so it's the choice of most meadow gardeners. The best mixes to select are ones designed especially for your region or garden.

SOWING A MEADOW

Today many seed companies, as well as the seed rack at your local nursery, offer a wide range of wildflowers, which you can buy either as single species or in meadow mixes. Mixes are available for specific geographic (regional) hardiness ranges or for specific cultural conditions—sun or shade, dry or moist. There are also mixes selected for height and ones designed to attract birds or butterflies. Most meadow mixes will include an annual "nurse grass," which will germinate quickly and help to keep out weeds until the meadow plants have the opportunity to become established.

The key to success is in knowing what plants will do well in your specific gardening environment, and avoiding those that will not do well or that might prove invasive. Contact your local cooperative extension service or wildflower society for plant lists and other recommendations for developing a meadow in your area. Nearby botanical gardens in your area may also have demonstration meadows that you can learn from.

Compare the meadow mixes and wildflower seed offerings from several catalogs. Look at species included, the seed origin, and the price tag. Species that are native to your area will have the best chance of survival and should be tops on your list; avoid potentially invasive species. Since much of the seed offered is wild-collected, look for a statement that indicates the seed has been collected conservatively, so that collection hasn't harmed wild populations. If you collect seed yourself, be sure to do so responsibly: Always harvest much less than you leave behind.

Sowing Season. The next item on your agenda is to select the best time for seeding your meadow. Both fall and spring seeding are recommended, since cool daytime temperatures and not-too-cool nights are best for germinating seedlings. As a general rule, fall sowing is best if you live in the southern states (Zone 7 south); spring sowing in the North.

Site Preparation. You'll need to remove existing vegetation to prepare the seedbed. For a small area, try spreading black plastic over the entire site, secure it in place with dirt and rocks around the edges, and leave it for several months. This will kill existing weeds and cause weed seeds in the soil to germinate and die. You can also dig up existing weeds and cut out turfgrass to get ready

Continued →

for sowing. For a large area, you'll probably need to till the area, although deep tilling will often bring dormant weed seeds to the surface. If you do decide to till, plan on tilling several times at two- to three-week intervals to kill weeds that germinate.

Prepare the Seedbed. The next step is to lightly rough the soil's surface, so that the seeds can make good contact with the soil. If you have matched your seed mixture to the site, you shouldn't need to improve the soil unless you really want to.

Spreading Seed. Next, mix the seed with light sand (the white sand used for sandboxes is ideal), using 1 part seed to 4 or 5 parts sand. This will help you keep track of where the seed has been spread and also helps ensure that it's evenly distributed. For small meadows, you can spread by hand; use a crank seed spreader (available in most seed catalogs) for larger meadows. Look at the seed packet for the recommended application. Usually, 6 pounds of seed per acre or 4 ounces per 1,000 square feet are about average. Don't sow more thickly than recommended, because seedlings will become crowded and quick-to-germinate species will crowd out ones that get off to a slower start. After sowing, lightly sweep the seedbed with a broom or nearby tree branch to settle seed just below the soil surface.

Aftercare. For best results, a newly seeded meadow will require adequate moisture—either by rain or watering—to ensure that germination takes place and young seedlings have a chance to become established. A good soaking from the lawn sprinkler every several days is often the difference between success and failure in starting the meadow. Seeds will begin to germinate within seven to ten days after sowing.

ANNUAL MAINTENANCE

Once established, a meadow should require little in the way of annual maintenance. Healthy, established meadow plants don't need watering and fertilizing.

Change Is Natural

Change is a fact of life in a meadow, and in a meadow garden. New plants arrive, add new color, perhaps outcompeting other inhabitants. Some plants spread quickly via their abundantly produced seeds; others disappear because of competition from neighboring plants. Shrub and tree seedlings can move in and begin the transformation from a sunny meadow to a woodland. The changing appearance—both from season to season and year to year—is one of the fascinations of a meadow. It's also one of the reasons for annual maintenance.

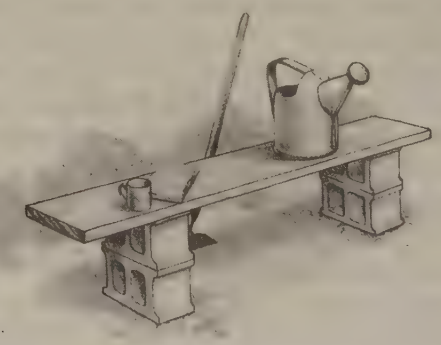
You'll need to weed as the need arises. If one species takes over, reestablish a balance by weeding or even removing it altogether. You may need to resow some annuals each year to keep populations healthy. Plan on a bit of hand weeding on a regular basis to remove undesirable plants.

Your meadow also will require an annual mowing to control trees and shrubs that find their way into the meadow, before they can become established. Mow in late fall or late winter when the plants are dormant. Many gardeners prefer mowing in late winter, because they enjoy the texture and color of the winter meadow and the birds and other creatures it attracts.

The best tool for the job will vary with the size of the meadow. A weed wacker or lawn mower will prove adequate for a small meadow; you'll need a tractor and mower for large meadows. Double-cutting a tractor-mowed meadow (once at a height of 18 inches and once at a height of 6 inches) will produce an excellent seedbed mulch for all of the seed that has dropped to the meadow floor.

Stop Tiptoeing Through the Tulips

Once you've prepared garden beds to a nicely light and fluffy state, it feels just plain wrong to go galumphing over them. Instead of tiptoeing apologetically, or threatening your lower back by reaching over the beds to plant, cultivate, and harvest, keep a gangplank on hand—a 2-by-12-inch board of convenient length that you can lay down between rows. The board will distribute your weight, much like a pair of snowshoes. It also can be used to help plant seeds in arrow-straight lines; lightly press its narrow edge into the soil to make an indentation. To give sprouting seeds a break from the sun, support the board on a few bricks as a shade. When the board isn't in use, you can rest it across two or three stacks of cinderblocks as a garden bench.



A sturdy board or two can serve both as a handy bench and as a plank for distributing your weight when it's necessary to stand in a garden row.

Flower Glossary

Annual: An annual is a plant that completes its life cycle in one year; it germinates, grows, flowers, sets seed, and dies in one growing season. Many plants we grow as annuals, such as zonal geraniums, are actually tender perennials.

Hardy annual: An annual that tolerates frost and self-sows. Seeds overwinter outside and germinates the following year. Examples: annual candytuft, cleome.

Half-hardy annual: An annual that can withstand light frost. Seeds can be planted early. Plants can be set out in fall and will bloom the following year. Often called winter annual. Examples: pansies, snapdragons, sweet peas.

Tender annual: An annual that is easily killed by light frost. Most annuals are in this category. Examples: marigolds, petunias.

Biennial: A plant that completes its life cycle in two years, producing a rosette of foliage the first and flowers the second. Biennials can reseed and come back year after year like perennials. Examples: foxglove, sweet William.

Bulb: A diverse group of perennial plants, including true bulbs, corms, rhizomes, and tuberous roots—all structures that store nutrients to support growth and bloom.

True bulb: True bulbs have layers of food-storing scales around a flower stalk and leaves in the center. They're often covered with a papery skin, called the *tunic*. Examples: onions, daffodils, tulips, lilies, hyacinths.

Corm: A corm is a rounded, swollen stem covered with a papery tunic. Corms are solid, with a bud on top that produces leaves and flowers. Examples: crocuses, gladioli.

Tuber: Tubers are fleshy underground stems that have eyes or buds from which leaves and flowers grow. Some tubers, such as caladiums and tuberous begonias, are cormlike. Unlike corms, tubers sprout roots from the sides and top. Examples: potatoes, anemones.

Tuberous root: Tuberous roots are swollen, fleshy roots. They have a pointed bud on top; roots sprout from the bottom. Example: dahlias.

Rhizome: Rhizomes masquerade as roots, but are actually thick, horizontal stems with roots on the bottom and leaves and flowers on the top. Examples: callas, cannas, bearded irises.

Little bulbs: A general term used to refer collectively to the many species of small, hardy bulbs, especially spring-blooming ones. Examples: crocuses, snowdrops, squills, grape hyacinths.

Perennial: A plant that flowers and sets seed for two or more seasons. Short-lived perennials like coreopsis and columbines may live 3 to 5 years. Long-lived perennials like peonies may live 100 years or more.

Tender perennial: A perennial plant from tropical or subtropical regions that can't be overwintered outside, except in subtropical regions such as Florida and Southern California. Often grown as annuals. Examples: zonal geraniums, wax begonias, coleus.

Hardy perennial: A perennial plant that tolerates frost. Cold tolerance of hardy perennials is ranked by zone.

Herbaceous perennial: A perennial plant that dies back to the ground each season. Most garden perennials fall into this category.

Semiwoody perennial: A perennial plant that forms woody stems but is much less substantial than a shrub. Examples: lavender, some varieties of thyme.

Woody perennial: A perennial plant such as a shrub or tree that does not die down to the ground each year.

BULBS

Bulbs the Low-Maintenance Way

Barbara W. Ellis, Joan Benjamin, and Deborah L. Martin

Flowering bulbs are so easy and undemanding that every low-maintenance garden should include them. Hardy bulbs, such as daffodils and crocuses, are true workhorses in a low-maintenance garden. So-called tender bulbs, such as caladiums, cannas, and tuberous begonias, are pretty tough customers, too.

In this section, you'll find techniques for succeeding with a variety of bulbs and bulblike plants. After all, what could be easier than a ready-to-grow flower that comes prepackaged with its own food source and blooms over a period of years?

Let Nature Take Its Course in No-Care Bulb Plantings

In an informal landscape, an utterly easy way to use bulbs is to naturalize them. Naturalizing involves planting bulbs into your existing landscape so that they look as if they grew there on their own. For best effect, group them in drifts rather than straight rows. Best of all, once the bulbs are planted and established, your efforts are over.

Good locations for naturalizing bulbs include grassy banks, meadows, property edges, around shrubs, and open woodlands. For naturalizing in your lawn, try small, low-growing bulbs such as crocuses, glory-of-the-snow (*Chionodoxa luciliae*), grape hyacinths (*Muscari* spp.), Grecian windflowers (*Anemone blanda*), striped squills (*Puschkinia scilloides*), miniature narcissus cultivars, netted irises (*Iris reticulata*), Siberian squills (*Scilla siberica*), snowdrops (*Galanthus* spp.), and spring starflowers (*Ipheion uniflorum*).

KEYS TO SUCCESS WITH NATURALIZED PLANTINGS

- Use large quantities of small bulbs for visual impact.
- Plant in loosely defined drifts, leaving space between the bulbs; they'll fill in by naturally dividing and seeding.

Continued →

One way to arrange them quickly is to lightly toss the bulbs and plant them where they land.

- One kind, one color is always effective. At most, limit yourself to two or three species or flower colors in one area.
- Let the bulbs' foliage ripen. When bulbs are planted into lawn, leave the lawn uncut until the bulbs' foliage matures, or subsequent years' flowers will be diminished or even eliminated.
- Keep species' site preferences in mind when you plant. Try crocuses in sunny areas, Siberian squills and daffodils in partial shade, and woodland natives such as winter aconites (*Eranthis* spp.) and trout lilies (*Erythronium* spp.) in shadier locations.
- Match form to function. Formal-looking bulbs can seem out of place in informal plantings. Try grape hyacinths (*Muscari* spp.) instead of stiffly upright Dutch hyacinths (*Hyacinthus orientalis* cultivars); tuck species tulips into your landscape rather than their hybridized offspring.
- Top-dress naturalized bulb plantings with compost or dried manure. Apply in spring, just as the leaves start to emerge, and again in early fall to nourish future flowers.

8 Hints to Help You Buy the Best Bulbs

Starting out with healthy bulbs gets your garden off to a good start and helps keep maintenance at a minimum. Vigorous plants look better and are better able to resist pests and diseases, all with little effort on your part. Use these tips to get the best bulb buys.

1. **Consider the source.** Buying bulbs locally lets you handpick each one, ensuring that you'll get the best they have to offer. However, mail-order companies that specialize in bulbs will have a greater selection. They may offer reduced prices for large quantities of bulbs.
2. **Consider the service.** Look for local suppliers that sell bulbs at planting time, not months before. Reputable mail-order firms will ship bulbs to you at the proper planting time for your area and guarantee bulb quality.
3. **Shop early in the season.** Placing mail orders early ensures the bulbs you want will be available and that they'll arrive at the proper time for planting. Local retailers will have the best selection early in the planting season.
4. **Select bulbs that like your locale.** Check with garden retailers and your county's extension office to learn which bulbs are right for your region. Remember that winter survival is only half the battle—some bulbs suffer when temperatures soar. Look for bulbs that will endure your local conditions.
5. **Buy the biggest bulbs.** With bulbs, you get what you pay for. Larger bulbs—often called "top size," "jumbo," or "double-nosed"—deliver the best flowers and are more likely to produce new bulbs to increase your flower planting. And they don't take any longer to plant than small bulbs.
6. **Weigh your decisions.** Buy solid bulbs that seem heavy for their size. Soft, lightweight bulbs will grow poorly, if at all.
7. **Inspect and reject.** Don't worry about small tears in the outer covering of bulbs as long as the protective skin is still there. Reject any bulbs that are moldy or showing signs of rot.
8. **Watch out for wild ones.** Collecting bulbs from their native wild habitats has endangered many species. If you buy species bulbs rather than cultivars, ask if they were nursery propagated. If you can't get a satisfactory answer, shop someplace else.

Buying Time for Your Tulips

Among the hardy bulbs, tulips tend to be short-lived perennials, sometimes producing only a couple years of bloom. Given the cost of bulbs and the effort of installing them, this gradual petering out can be a big disappointment. But not all tulips are fickle—some will return tirelessly for several years, and there are ways to encourage them.

Plant species tulips (or botanical tulips). These early-bloomers outlive their hybrid counterparts. Or select cultivars with a reputation for being long-lasting; they're sometimes sold as "perennial tulips." (Three years is perennial in hot climates; they'll last longer in cooler areas.) Plant cultivar tulip bulbs deeply, 8 to 10 inches below the soil.

Plant Combinations Bring Out the Best in Your Bulbs

In addition to keeping your bulbs healthy so they look their best, there are other ways to make the most of blooming bulbs in your landscape. By assembling some easy plant combinations, you can use bulbs to add color and sparkle to your gardens—without a lot of hassle.

Complement and contrast. In a spring garden, between the bulbs, set out low-growing flowers that bloom at the same time as your bulbs. Good bulb companions include pansies, Johnny-jump-ups, wallflowers (*Cheiranthus cheiri*), and forget-me-nots (*Myosotis* spp.). You can also combine taller bulbs like tulips with smaller bulbs like grape hyacinths.

Use flowering trees or shrubs with your bulbs to supply contrasting colors. Try blue squills (*Hyacinthoides non-scriptus*) or glory-of-the-snow (*Chionodoxa luciliae*) near yellow forsythias, or yellow daffodils near white-flowered crabapples.

Combine and cover. Plant your bulbs among spring-flowering perennials such as basketgold (*Aurinia saxatilis*), purple rock cress (*Aubrieta deltoidea*), or perennial candytuft (*Iberis sempervirens*). Since spring bulbs virtually disappear from view when their tops die back, perennials planted adjacent to the bulbs can serve as markers to remind you not to dig there later in the season.

Later-blooming perennials that emerge as your bulbs are flowering won't detract from the bulb flowers, yet they'll fill the aboveground spaces left by the bulbs and help to conceal the dying bulb foliage. Many perennials can fill this role, including daylilies, baby's-breath, hostas, and ferns.

Dig In and Double Your Bulbs

An added bulb bonus is their ability to multiply. Without your spending another penny, bulbs such as daffodils and crocuses will increase in number over the years.

If the number of flowers a bulb planting produces begins to decline over the years but there's lots of foliage evident, the bulbs have multiplied, creating a cluster of small, closely spaced bulbs.

After the foliage has faded, dig and separate the bulbs. Replant them right away, at the proper spacing. Given more space, they'll soon grow to flowering size again.

Get Maximum Impact with Minimum Effort

It's as easy to plant a garden of bulbs that blooms for months on end as it is one that blooms for only a few fleeting weeks. Why? Although most hardy bulbs flower in the spring, they don't all flower at the same time. So to make the most of your planting time, it pays to plant an assortment of different bulbs.

For example, some small bulbs like snowdrops and crocuses begin blooming in late winter, while some tulips may not finish flowering until early summer.

One good place to start is to look for the season of bloom in the descriptions of bulbs when you shop, whether you're looking in a local garden center or a catalog. You'll find ratings like "very early spring," "early spring," "mid-spring," and "late spring," for example. To get the longest bloom possible, select some from each season.

Don't just consider different species of bulbs like crocuses and tulips, either. Many bulbs, including daffodils, tulips, and lilies, have a wide variety of species and cultivars that bloom at different seasons, too. You can buy tulips, for example, that will bloom in late winter to very early spring, mid-spring, and late spring to early summer.

Also try using microclimates on your property to vary the bloom time of your bulbs—even if they're all the same cultivars. Microclimates are variations in the prevailing conditions that are caused by factors such as topography, shade, or proximity to buildings. For example, bulbs planted in a site with southern exposure will bloom earlier than the same species planted in a north-facing spot.

Tools to Make Bulb Planting a Breeze

Planting is easiest when you use the tool that works best for you and for the planting design you've chosen. For naturalizing small bulbs in a lawn or other groundcover, a narrow-blade trowel works well, as does a naturalizing tool. An auger attachment for your power drill eases the process of making individual holes for larger bulbs, while a spade is useful for digging a large hole to hold several bulbs.

Naturalizing tool. This crowbarlike tool gives you lots of leverage when planting small bulbs in your lawn. Use it much as you would a trowel, but without the bending—just use your foot to push the soil back after planting each bulb.

Trowel. Stab your trowel, daggerlike, into the soil and pull it toward you to open up a planting hole for a small bulb. Then remove it and tuck the bulb in by pressing the soil back into place.

Bulb planters. Both long- and short-handled bulb planters are useful tools for making individual holes for larger bulbs.

Auger. Turn your power drill into a bulb planter with an auger, which is also useful for digging holes for larger bulbs.

Spade. For excellent effect and a well-prepared planting site, use a classic garden spade to excavate a large hole that will hold many bulbs.

Increase Daffodils' "Face Value" with Good Site Selection

You wouldn't hang your favorite painting facing the wall. Likewise, when you plant daffodils, you want to see their faces—the open, cup-shaped sides of the flowers—not their backs.

When selecting a planting site for daffodils, it's helpful to know that their open blooms will turn toward the direction from which the strongest sunlight comes—usually south to west. Think about where you'll be when you're looking at your daffodils—at your window, perhaps, or coming up your front walk, and position plantings accordingly.

Terrific Techniques for Planting Bulbs

Whatever tool you use to prepare your site, don't skimp on the size of the hole and don't overcrowd. Bulbs planted at the proper depth and spacing live longer and are less subject to injuries from animals or cultivating tools. Try some of the tips that follow to create effective bulb displays throughout your yard.

Tuck in bulbs with single holes. To tuck bulbs between existing plants, such as in a perennial garden, use a spade, auger, or bulb planter to make individual holes.

Plant 'em together if you have the room. If you're planting lots of bulbs in an area that's free of other plants, simply dig a hole to the proper depth and space a group of them out over the bottom of the hole. This planting method maximizes the impact of their blooms and saves you from digging several individual holes.

Plant colorful beds of bulbs in planting areas. You can combine different bulbs and flower colors to create colorful designs anywhere in your yard. For best results, excavate and prepare the entire planting area all at once. Then work out your color and spacing by arranging the bulbs in the bottom of the hole before you cover them.

After planting, water thoroughly to firm the soil and to stimulate root growth. Top-dress the planting with organic fertilizer or compost. If the weeks following planting are dry, water periodically until the ground freezes. Apply mulch in late autumn to keep soil temperatures from fluctuating. Although nothing is visible above ground, vital root growth is occurring below the soil.

Try layering a planting of different-size bulbs. For a lot of pizzazz in a limited space, you can use bulbs with coinciding bloom times for a spectacular one-shot show, or with consecutive bloom for a longer-lasting display. Plant large bulbs deeply, medium-size bulbs above them, and small bulbs an inch or two below the soil surface. Choose bulbs that do not need frequent division; otherwise you may have to dig up the whole planting or put up with diminished flowering from bulbs that have multiplied.

The layered planting of crocuses, Spanish bluebells, and lilies will add color to the garden from early spring into midsummer. The lilies will hide the fading leaves of the earlier-blooming bulbs. Be sure to offset bulbs slightly from one layer to the next and leave enough soil in between the layers for normal root growth.

Let Soil Temperatures Tell You When to Plant Hardy Bulbs

Fall-planted bulbs need time to put down roots in a new site before the ground freezes for winter. In order to bloom properly, they also need a period of cold, but not freezing, temperatures, called a chilling requirement. Here's an easy guideline you can use to make sure you satisfy both these requirements when you plant: Wait until the soil temperature 6 inches beneath the surface is below 60°F.

This means planting in September in Zones 2–3; in September to early October in Zones 4–5; in October to early November in Zones 6–7; in November to early December in Zone 8; and in December in Zone 9. In regions with mild winters, bulbs like tulips are often given a cold treatment by refrigeration before they are sold for planting in early winter.

Bulbs Bloom Best in Sites Where the Sun Shines Bright

Your bulbs will give you the greatest effect for your effort if you plant them in a sunny site. Most bulbs need strong light to grow and flower well. But if your summer yard looks shady, don't despair. Go for early-flowering spring bulbs that do most of their growing before deciduous trees and shrubs extend their leaves. These bulbs won't grow in sites with heavy, permanent shade, however, such as under evergreens.

Crocuses, daffodils, glory-of-the-snow (*Chionodoxa luciliae*), snowdrops (*Galanthus* spp.), and squills (*Scilla* spp.), as well as early tulip cultivars, are all early bloomers that are quite happy in woodland gardens and other sites with summer shade. And don't miss the chance to deck a woodland garden with these bulbs that will grow in light to partial shade: Checkered lily (*Fritillaria meleagris*), hardy cyclamen (*Cyclamen hederifolium*), trout lilies (*Erythronium* spp.), snowdrops (*Galanthus* spp.), Spanish bluebells (*Hyacinthoides hispanicus*, formerly called *Endymion hispanicus* or *Scilla campanulata*), and winter aconite (*Eranthis hyemalis*).

Help Your Bulbs Live Long and Prosper

Once hardy bulbs are in the ground, they don't need much care. However, there are a few techniques that will pay off by adding years of healthy, vigorous growth to your bulbs' lives.

- Select sound, healthy bulbs and plant them properly.
- Spread about ¼ inch of dried manure over the top of your bulb plantings in spring, just as foliage is beginning to emerge, and again in early fall.
- Mulch plantings to protect the soil, preserve moisture, and prevent weed seeds from germinating. Mulch also keeps mud from splashing on flowers.
- Remove spent flowers from bulbs before seed heads form. This enables each bulb to store food for next year's flowers instead of forming seeds.
- Plant large bulbs like tulips and daffodils at the deep end of the recommended range to slow their rate of multiplication, since the smaller bulbs that result may take several years to reach flowering size.
- Plant lilies with their roots in the shade by mulching the root zone, planting groundcovers around them, or selecting sites where other plants or structures shade the roots without blocking sun from the foliage.
- In warm-winter zones, plant bulbs at the deepest end of the recommended range to avoid soil temperature shifts and too-early warming of the soil in spring.
- Select planting sites carefully. While most spring bulbs grow well in full sun in cooler climates, they often do better in light shade in hot climates.

Simple Ways to Hide Bulb Bare Spots

Like your spring bulb garden, but dread a bare plot later in the season? Try one of these simple techniques to keep your soil covered and your garden looking its best.

Grow bulbs with annuals. Sow or set shallow-rooted annuals such as marigolds, snapdragons, or wax begonias above bulbs as they are going dormant. This gives summer cover and color to your bulb site.

Cover your bulbs with groundcovers. Before making this choice, think about how the groundcover will look when the bulbs are blooming. Will it flower at the same time? Will the flower colors complement each other? Good groundcovers to use with bulbs include bugleweed (*Ajuga reptans*), creeping Jenny (*Lysimachia nummularia*), spotted lamium (*Lamium maculatum*), thyme, vinca (*Vinca minor*), and wintercreeper (*Euonymus fortunei*). Or try

barren strawberry (*Waldsteinia* spp.), English ivy (*Hedera helix*), pachysandra, and prostrate junipers over large, deeply planted bulbs.

Tips to Protect Your Bulbs from Beasts

Cute but pesky animals may decide that your bulb plantings are buffet tables located for their convenience. If chipmunks or voles eat up your bulbs, squirrels dig them up, or rabbits, woodchucks, deer, or birds munch on their flowers or foliage, try these techniques to end the tasting.

Plant bulbs that animals don't like. Even hungry animals leave poisonous daffodil bulbs alone; squills (*Scilla* spp.) and snowdrops (*Galanthus* spp.) are reported to be similarly unbothered. And the skunky scent of fritillaries (*Fritillaria* spp.) repels mice, squirrels, and voles from bulb plantings.

Put up a good defense. Take measures to prevent animal problems before they start. Put your bulbs in the ground inside a wire basket or cage—they'll still be able to send out roots and shoots into the soil, but animals won't be able to get to the bulbs. Or place sharp gravel around the bulbs at planting to discourage underground diners. Lay wire mesh on the soil surface above your bulb planting to keep squirrels from digging them up.

Take Time to Try Tender Bulbs

In comparison to their hardy counterparts, tender bulbs can hardly be considered low maintenance. However, many gardeners don't mind the extra effort it takes to grow tender bulbs. Among them are excellent plants for shady sites, such as tuberous begonias, caladiums, and calla lilies (*Calla* spp.). Gladiolus are tender bulbs that make great cut flowers; dahlias add valuable late-season color.

North of Zone 9, you can handle tender bulbs a couple of ways. For minimal effort, treat tender bulbs as annuals—purchase fresh stock each year and grow them for one season only. Plant them at the proper depth after the soil warms up in spring.

If purchasing them each year is too costly, save money by overwintering them—moving them to a warmer location. Bring potted bulbs indoors and allow them to rest; dig bulbs planted in the garden, then store them using one of the methods shown here. Overwintering tender bulbs takes time but saves the expense of using them as annuals in cold-winter areas.

Hang glads for good air circulation. To store gladiolus corms, shake off the soil and remove the foliage just above the corm. Break off the shriveled old corm under the new one and hang the new corms in plastic mesh bags in a dry, cool (around 45°F) spot.

Store tuberous begonias in vermiculite. After digging tuberous begonias, let the plants dry for a week or so, then cut the stems to just above the tuber. Let stem stubs dry completely, shake the soil off the tubers, and store them in vermiculite, dry peat, or sharp sand at 45° to 55°F.

Store clumps of dahlias. After frost, cut dahlias back to just above the ground, dig the clumps, and store them on their sides until the soil on the tubers dries. Store entire clumps with the soil still on them, or remove the soil and store them in barely moist peat or vermiculite in a plastic bag. Poke holes in the bag for ventilation, and store in a cool (45° to 50°F) spot. Sprinkle a little water on the peat or vermiculite during the winter if the roots wither. In spring cut the clumps up, making sure each piece has a pinkish "eye."

Storing Bulbs the Lazy Way

If you love tender bulbs but hate the bother of digging, packing, and storing them indoors through winter, try this simple technique from Ray Rothenberger, Ph.D., a professor of ornamental horticulture at the University of Missouri at Columbia. Dr. Rothenberger digs his big hybrid glads, Aztec lily (*Sprekelia formosissima*), Peruvian daffodil (*Hymenocallis narcissiflora*), and dahlias in the fall before freezing weather arrives. After digging the bulbs, he spreads them on the ground to dry in the shade or, if it's going to rain, indoors in the garage. "I leave soil on the ones that dry out easily, such as some of the dahlias—that way I don't have to fuss with storing them in vermiculite. The only dahlias I pack in vermiculite are those with very thin roots," Dr. Rothenberger says.

When the bulbs dry, he places them in plastic garbage bags, leaving the bags open. As he places the bulbs inside, Dr. Rothenberger makes absolutely sure that any soil clinging to the bulbs is dry, and he looks carefully for sow bugs. Later (when time allows), he checks them again. He flops the tops of the bags over loosely, never tying them shut, and inspects the bulbs periodically throughout the winter, throwing away any that begin to rot.

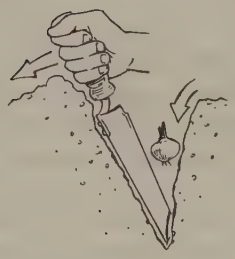
A Quick Way to Plant Bulbs

You can make quick work of planting bulbs without lifting the first spadeful of soil. "This technique will only work in deeply worked, well-amended, loose soil," says Ray Rothenberger, Ph.D., a professor of ornamental horticulture at the University of Missouri at Columbia, who likes the following technique for planting big bulbs such as Aztec lily (Sprekelia formosissima), Peruvian daffodil (*Hymenocallis narcissiflora*), dahlias, and hybrid gladiolus:

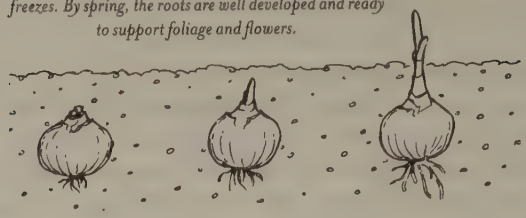
"The easiest way to do this is to throw down a 2 x 6 in the bed to make it easy to walk on," says Dr. Rothenberger. "Go along the edge of the board, push your spade straight down into the soil, and push it away from you to part the soil. Then you drop the bulb in behind the spade. When you pull the spade straight back out, the hole fills itself." The method works for smaller bulbs planted with a trowel, too. Dr. Rothenberger adds that you should never do this when the soil is wet, especially in clay soil, or you'll end up with a wad of concrete.

Continued ➔

When you dig bulbs to store for winter, point your shovel straight down in the soil. This guarantees you'll miss the bulb (unless you're standing right over it, of course). Loosen the soil and scoop up the bulb as you dig. If you push the shovel or fork into the soil at an angle toward the bulb you may gash it or cut it through.



Hardy spring bulbs are planted in fall and begin to grow roots from the time they are planted until the ground freezes. By spring, the roots are well developed and ready to support foliage and flowers.



Caring for Bulbs, Corms, and Tubers

Unlike some of the prima donnas of the garden, most bulbs are not very fussy. Plant them at the right depth in the right place and you can leave them alone for the rest of the growing season, and in the case of hardy bulbs, for years. That's why you can find Madonna lilies (*Lilium candidum*) planted 50 years ago still blooming among the crumbled foundations of an old homestead.

But like all garden plants, bulbs will do even better with a little attention to their needs.

CARE BASICS

The bulb is a storage system, a fat underground root or stem full of stored food. These underground pantries were a defense against the harsh climates where bulbs originated. An internal "clock" within the bulb evolved, to teach it to sleep during the baking heat of an African summer or the icy cold of winter in the Chinese mountains. When rain and warmth come again, the clock signals the bulb to start growing, using the stored food. After flowering is done, the leaves make food to replenish the bulb for next year. Then the bulb goes into its dormant period, waiting out the extremes. Successfully growing bulbs is a matter of understanding this cycle of growth and dormancy.

Watering

If you have planted your bulbs at the recommended depth and given them a good drink to get them started, you will have to water only when the plants look thirsty or during a long dry spell. (Foliage that wilts and stays wilted the next day is a clue that the bulb needs water.) It's also a good idea to give your bulbs a long, thorough soaking when the flower buds show.

Don't bother with sprinklers or hand-held spray nozzles. You need to get that water to the roots of the bulb. Either lay the hose among the bulbs to soak into the ground, or use a soaker hose so the water isn't wasted in evaporation. Water long enough to be sure it soaks deep into the ground where the roots of the bulb can drink.

Fertilizing

Fertilizing is especially useful soon after planting, when the roots are beginning to form. That's why it's a good idea to add some aged, well-rotted manure and bonemeal while planting new bulbs or to give old bulbs a boost. Slow-release fertilizers such as bonemeal or special bulb food can be scratched in in the fall.

For summer bloomers, an all-around fertilizer can be used in the spring when the first shoots appear above ground. Gladioli and dahlias are heavy feeders and need regular fortification with compost and aged manure to do their best. Flowers will be bigger if fed regularly after the buds form.

Mulching

A deep mulch over winter is a good idea for hardy bulbs if your soil is susceptible to frost heaving. Unmulched bulbs may be forced out of the ground by repeated cycles of freezing and thawing. If your soil is dry, a mulch during the growing season will help retain water.

Chopped leaves make a perfect mulch and can be left in place to decompose into humus. Straw, grass clippings, or evergreen branches are other possibilities.

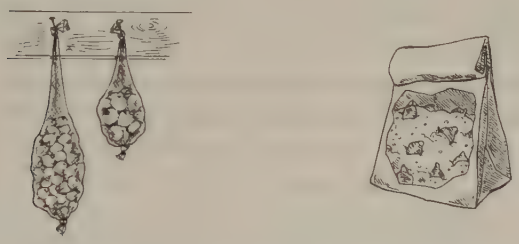
Don't worry about new shoots that poke up before freezing weather is over. They are unlikely to be damaged by cold or snow. Sometimes newly planted small bulbs such as grape hyacinths throw out a lot of leaves soon after planting. These leaves will not be harmed by winter weather and do not need to be protected by mulch.

Deadheading

Snip the faded flowers from your large spring bulbs as they finish blooming. If you allow the seedpods to remain, tulips, daffodils, and hyacinth bulbs may exhaust themselves with the effort of making seeds. Deadheading directs the plant's energy into producing food for next year's flowers.

Most summer-flowering bulbs also benefit from deadheading, since more of the plant's energy can go into producing food.

Removing dead flowers from the small spring bulbs like scilla and snowdrops isn't necessary, unless you don't want them to self-sow. But who doesn't want more of these first flowers of spring?



The plants flower in early spring and the flowers fade, but the foliage continues to grow and produce food for the following year. Many bulbs also produce natural divisions called offsets.

Ripening Foliage

Bulb foliage must be allowed to ripen without being cut, tied, or braided. The leaves make food to replenish the bulb for next year. Remove the leaves before they shrivel and die back, and you sap the vigor of the bulb. After the foliage has turned yellow or brown, you can cut it down and add it to the compost heap.

There are plenty of ways to draw attention from the ripening foliage, which can look unkempt and unattractive as it lengthens and then turns yellow. You can plant bulbs among ground covers such as bugleweed (*Ajuga* spp.) or wild ginger (*Asarum canadense*). Late peony-flowered tulips ('Angelique' is an ethereal pink) are lovely overplanted with ferns. Or you can interplant perennials or annuals to mask the maturing foliage. Hostas and daylilies work well to camouflage daffodil leaves.

Lifting Tender Bulbs

Bulbs that are not hardy in cold winters, such as cannas, gladioli, dahlias, and tuberous begonias, must be dug up in fall for storage. After the first light frost, when the foliage has begun to blacken, track down all of your tender summer bloomers and carefully lift them from the beds. A garden fork will do the job nicely. Be sure to dig deep enough to get beneath the bulbs, to avoid that sickening crunch of a fat tuber being sliced in half.

Replanting Stored Bulbs

The new shoots of summer-blooming bulbs such as dahlias and glads are vulnerable to frost, so wait until the weather has warmed and night temperatures stay around 50°F before you put your winter-stored bulbs back into the ground in midspring. You can plant your summer bulbs in pots or shallow boxes of damp peat to give them a head start. They can be set in a sheltered spot outdoors during the day, but be sure to protect them from frost on chilly nights.

Multiplying Bulbs

Fern Marshall Bradley

Bulbs are a lovely addition to your perennial landscape, and many of them gradually propagate themselves naturally over the years. Here are some ways to give nature a hand.

Scaling a lily bulb is a simple technique that lets you start new plants from pieces of the bulb. After your lilies flower, you can dig up the bulbs and pull off the outer scales. Given the proper conditions, the scales will produce new tiny bulbs that you can pot up.
Step 1. Gently break the scales off the bulb.
Step 2. Put the scales into a plastic bag with a few handfuls of moist vermiculite. Label and seal the bag with a pillow of air inside. Put the bag in a warm (70°F), dark place. After two months, check the scales for tiny bulbs every two weeks.

True Bulbs

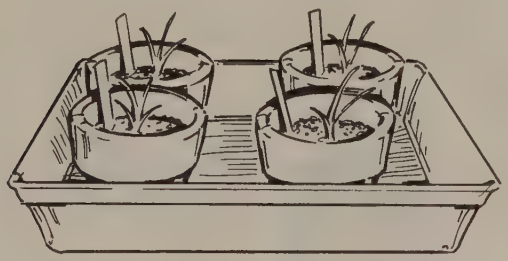
Bulbs that look like onions are "true" bulbs. Daffodils, grape hyacinths (*Muscari* spp.), and snowdrops (*Galanthus* spp.) are common examples of true bulbs that multiply rapidly. The easiest way to help them spread is to divide the clumps every few years. Wait until the foliage starts to turn yellow, then dig them carefully and separate the clump. Replant them immediately at the same depth or a little bit deeper. If it's more convenient, you can store the extra bulbs in a cool, dry, rodentproof area until fall and plant them then.

Continued →

Lilies

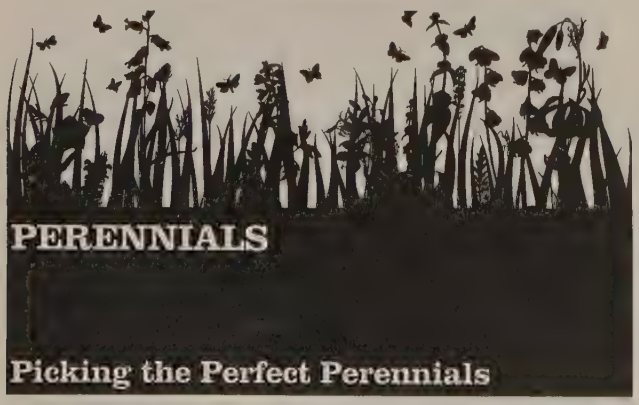
Lilies are the crowning glory of the summer garden, but the bulbs aren't cheap. They do multiply themselves slowly, but if you want to increase your lily display more quickly, there are two easy ways to go about it.

Lily bulbs aren't true bulbs: They look like a globe artichoke, with layers of scales. You can harvest scales from new bulbs before you plant them, as shown. A healthy bulb can donate up to six scales without any setback to its growth. If you find any small bulbs near the existing bulbs, harvest those, too. It will take about three years for each scale to grow into a blooming-size bulb. Let the potted scales grow for one year in a cold frame, transplant them into a nursery bed for a year or two, and then move them to their final home in your landscape.



Plant sprouted lily bulb scales in 4" pots. Leave the scales attached to the sprouted bulbs unless they are shriveled or rotting. Put the flats of pots in a warm, well-lit spot indoors. Move the young plants out to the cold frame in late spring.

Some lilies, including tiger lilies (*Lilium lancifolium*), make bulblets (tiny bulblike structures) cradled above each leaf along the stem. You can pot these up or poke them about an inch deep in your nursery bed in late summer. Within a few years, each bulblet will produce a blooming-size bulb to plant in your garden.



Larry Hodgson

The secret to easy perennial gardening is simple enough: Prepare the growing area thoroughly, then pick plants that are naturally tough and well adapted to your conditions . . . and plant lots of them! In fact, if you choose the right perennials, you'll scarcely have any work to do at all. Good basic care is all your plants will need.

10 Things to Look For in a Perennial

What exactly are you looking for in a perennial? The right color is probably the first thing that comes to mind, but it's not the most important, since most perennials are available in a wide range of shades. What you really should be looking for, if you want ease of care and a garden that is always attractive, are perennials that meet my ten criteria for a perfect perennial:

1. The plant should be adapted to a wide range of general conditions (sun and shade, rain and drought, heat and cold, etc.).
2. It should be well adapted to local conditions that can be limiting factors in your choice of perennials (extremely cold winters or hot summers, particularly dry or humid air, etc.).
3. It should be long-lived.
4. It should be quick to establish. (Who wants to wait five years for results?)
5. It should be naturally resistant to insects and diseases.
6. It should grow more strongly than most weeds, yet not strongly enough to become a weed.
7. It should need little in the way of pruning, staking, division, and other fussy maintenance tasks.
8. It should remain attractive over a long period.
9. It should be easy to propagate.
10. It should be widely available.

Sounds great, doesn't it? If there were such a plant, it would truly be the perfect perennial. But it doesn't exist. In fact, some of our criteria contradict each other. For example, criterion number 3, long-lived, and number 4, quick to establish, are almost never found in the same plant. Generally speaking, perennials that are long-lived are very slow to establish, while those that reach perfection in the first season are almost always short-lived perennials that scarcely survive longer than a biennial.

Generally, the best you can do is find perennials that share seven out of ten of the desirable traits. With plants that have seven out of ten good qualities, you'll be in for an easy, beautiful ride. Plants with at least five good traits can also be quite useful. Less than that, though, and you'll probably be in for a lot of work . . . and more than a bit of disappointment.

HOW TO KNOW WHAT YOU'RE LOOKING FOR

The worst error any gardener can make is to buy plants without thinking, as when you go to a nursery and pick a plant because "it was the perfect shade of pink and just looked so adorable in

its little pot that I couldn't resist." Trust me—looking good in a nursery pot is not a major criterion in picking a perennial. Instead, research your choices before you buy.

This doesn't mean you can never buy perennials on a whim, but if there's a plant you don't know and just can't resist buying, try to find out more about it at the nursery. (Ask around: If it's a good nursery, at least one of the salespeople will be an expert on perennials.) And when you do bring it home, read all about it before you plant it, not after it's comfortably installed in a totally inappropriate spot.

"Think Twice" Perennials

I call perennials with really major flaws—flaws that can override their best qualities and even make you wonder why you ever planted them in the first place—"think twice" perennials. But some of the plants that fall into this category are very popular with gardeners and are featured in many nurseries and catalogs, so they're impossible to ignore.

Often, "think twice" plants are particularly subject to disease or insects or are highly invasive. For example, garden phlox (*Phlox paniculata*) and bee balm (*Monarda didyma*) are both gorgeous garden plants with an unfortunate susceptibility to mildew. But the news isn't all bad—both have cultivars that are disease-resistant; you just have to know to look for them. And highly invasive plants can often be perfectly controlled just by planting them inside a root barrier . . . but you should know that before you plant them in your garden! In other words, think twice before you buy because you do have a choice between easy plants and difficult ones.

Regional Differences

Criterion number 2 in our list of "10 Things to Look For in a Perennial" is: "It should be well adapted to local conditions that can be limiting factors in your choice of perennials." This is a critical part of choosing a perennial because each area is different, and you need to know your local climate before you can garden with success.

For example, I live in frigid USDA Plant Hardiness Zone 3, where winters are long and cold and there are days on end when no one even expects the car to start. I often have success with plants rated hardy to Zones 6 and (occasionally) 7. Why? Because I have tremendous snow cover. Since snow stays at about the freezing point at all times, I have a thick, relatively warm blanket over my plants that keeps off the worst of winter cold and can help plants survive beyond their usual range. Plus, the snow cover lasts until well into April; by the time the snow has gone and my perennials have started to sprout, there is simply no danger of frost anymore. You can't say that for a lot of places much farther south!

Figuring Out Plant Names

It wasn't too long ago that if you so much as muttered a botanical name, your friends might label you a "plant nut." But times have changed, and botanical names are being used more widely. Just check mail-order catalogs: You'll find Latin names galore. If you're not up to speed yet on understanding and using botanical names for plants, read on. I'll do my best to guide you through the hows and whys of botanical nomenclature. In this section, I list plants by both common and botanical name. You can choose to use only the common name if you wish, but I recommend that you try to learn the botanical name as well.

Why bother with botanical names? One good reason is that common names for plants vary so much. One person's creeping Charlie is another's ground ivy. Other gardeners know the same plant as gill-over-the-ground, alehoof, cat's-foot, runaway robin, and field balm. But there's only one botanical name for this plant: *Glechoma hederacea*. Of course, if you did mention creeping Charlie to someone, they might well think you were talking about a very different plant: *Lysimachia nummularia* (a.k.a. creeping Jenny, creeping loosestrife, wandering Sally, and moneywort). There's even a houseplant, *Pilea nummularifolia*, that's called creeping Charlie.

BOTANICAL LATIN

Botanical names are composed of two parts. The first word in the name is the genus name. Many plants can share one genus name, just as many people can share the same family name. Genus names are always capitalized, and they're usually written in italics or underlined. *Hemerocallis* (daylily) is one example of a genus name.

The second word in a botanical name is the species name. It serves to identify individual plants. For example, *Hemerocallis citrina* and *Hemerocallis fulva* are both daylilies, but *H. citrina* (citron daylily) has lemony yellow flowers and *H. fulva* (tawny daylily) has tawny orange blooms. Species names are also underlined or written in italic, but they're not capitalized.

You'll notice that botanical names are always in Latin or latinized Greek: When Carolus Linnaeus developed this system of two-part names in the late eighteenth century, both languages were still in use by students of biology and botany. After Linnaeus developed his system, scientists soon found the need to separate some species into varieties or subspecies. For example, some specimens of *H. fulva* found in Japan had a more tubular flower than usual. Botanists didn't consider this difference significant enough to create a new species, so they added a third name instead—the variety name. The new plant became known as *H. fulva* var. *longituba* ("var." stands for "variety," of course) to distinguish it from *H. fulva*.

HOW ABOUT HYBRIDS?

You'll also notice the occasional use of a multiplication sign (x) in botanical names. These indicate a hybrid that has achieved species status. *Astilbe* x *arendsii*, for example, is a hybrid species that resulted from crosses between *A. chinensis* var. *davidii* and other astilbes. 'Amethyst', 'Cattleya', 'Erica', and 'Fanal' astilbes are some popular cultivars of this hybrid species.

Continued ➔

You'll also occasionally see an x in front of a genus name, as in *x Solidaster luteus*. This indicates a hybrid genus, resulting when two different genera (the plural of genus) are crossed together. In this case, an aster (*Aster ptarmicoides*) was crossed with a goldenrod (*Solidago canadensis*), resulting in a plant intermediate between the two. (By the way, you don't need to worry about pronouncing the x. It's silent.)

BEYOND LATIN

When Linnaeus created his naming system, he couldn't have imagined how the modern plant breeding industry would develop. Plant breeders deliberately look for mutations or plants with special characteristics that stand out from the natural form of a plant. They also crossbreed different kinds of perennials to try to create new plants, called hybrids. These days, they're even using genetic engineering to cook up new plants. These manmade plants are called cultivated varieties or cultivars. Cultivar names are written in single quotes, as in *Hemerocallis fulva* 'Kwanso'.

Many great cultivars that we grow were developed in Europe. This can create some name confusion because German horticulturists, for example, give their cultivars German names. But some of our nurseries prefer to translate those names into English. So, you may see one nursery offering *Oenothera fruticosa* 'Fyrverkeri', while another offers *Oenothera fruticosa* 'Fireworks'. Would you guess that they're the same plant? They are! I've listed alternate cultivar names in parentheses.

Buying Perennials

In most areas, especially near urban centers, there is no lack of nurseries selling perennials. During the spring season, department stores, hardware stores, supermarkets, public markets, and even "mom and pop" shops get into the act. And there are dozens of mail-order sources. So where should you go for your plants?

ANY OLD PLACE

If you have a good eye for healthy plants, you can buy perennials anywhere. Nonspecialist sources—the department store and supermarket gang—are often (but not always) cheaper, although the selection is usually considerably more restricted than in most nurseries. On the other hand, they rarely know plants and you can't ask them questions with any expectation of a reasonable response. Worse yet, their plants can be in poor shape, as they often don't know how to care for them properly.

GARDEN CENTERS AND LOCAL NURSERIES

Garden centers and nurseries usually have a wide selection and a knowledgeable staff. You can obtain almost all the perennials that grow in your climate from a local nursery, although the nursery may not have every cultivar you're looking for.

Although retail nurseries are really set up for impulse purchases, I give them my orders ahead of time (in late winter; for example, for planting in May). I know I'll get the number of plants I want as well as the right varieties. By ordering early, I get the first choice over other customers.

Nurseries give a better guarantee on perennials than do department stores and their ilk. They don't always have a written policy, but most nurseries will guarantee perennials through the plant's first summer and some over the winter as well.

MAIL-ORDER CATALOGS

Then you have plant catalogs. Some are generalist garden catalogs, selling everything from seeds to fertilizer, with a few perennials thrown in. Others specialize in perennials, and some even specialize in a single type of perennial, such as hostas, irises, grasses, or some other specific category of plants.

The advantage of the nurseries producing mail-order catalogs is that they are generally true specialists in their field, often offering rare plants or choice cultivars of more common perennials, plants that you can rarely find locally.

I can't imagine gardening without perennial catalogs on hand. They are often a gold mine of information, and they carry all the choicest plants I hear other gardeners getting excited about; but be careful when ordering a perennial just because you've seen a color photo of it in a catalog or magazine and it just looks fabulous. Such photos often catch a plant at its very peak or in a special lighting situation that you're just not going to see in your garden. Of course, the photo will give you an idea of the plant's outline and an approximation of its color, but it won't always look that good in your garden.

Besides mail-order catalogs that sell plants, there is also a wide range of seed catalogs that carry perennial seeds. Not as many cultivars are offered by seed as in plant catalogs, since many don't come true from seed, but often rare and unusual species perennials are offered, and the prices are unbeatable. But you'll also have to grow the plant from a seedling; and that can take a year or more.

It's easiest to order plants from within your own country because no special permits are required. But it's also relatively straightforward for Americans to order plants from Canada and vice versa: At the time this is being written, import forms are no longer required for perennials, although you do have to pay for a "phytosanitary certificate," which usually costs an extra $25. Seed orders, however, cross international borders with no trouble, no paperwork, and no special fees. Use a credit card or pay by money order in the currency of the country you're buying from.

Beyond Flowers

As gardeners, we tend to be so heavily into flowers that we forget perennials can have other attributes such as an attractive silhouette, beautiful leaves, gorgeous fall colors, the ability to attract butterflies or hummingbirds to the garden, showy seedpods or berries, and so on. In fact, if you choose plants solely on the basis of showy flowers, you may end up with a

garden of "one-season wonders." Once the flowers fade, you'll find yourself looking for someplace to hide them!

SHOWY FRUITS AND SEEDPODS

Besides the colorful berries of plants like baneberries (*Actaea* spp.) and ornamental strawberries (*Fragaria* spp.), there's a wide range of perennials with attractive seedheads. Seedheads range from the fluffy, flowerlike tufts of adonises and common pasque flower to pods that open to reveal brilliantly colored seeds like blackberry lily and stinking iris (*Iris foetidissima*) to the inflated blackish purple pods of baptisias, and the star-shaped capsules (perfect for drying) of gas plant (*Dictamnus albus*).

There are also perennials that bear "extended flowers" like sea hollies (*Eryngium* spp.), globe thistles (*Echinops* spp.), and most grasses. In these species, the flower just seems to go on and on—until you realize that the real blooms faded weeks ago, and what you're looking at is a cluster of maturing seedheads!

PERENNIALS WITH YEAR-ROUND INTEREST

Ornamental grasses are the stars among perennials where winter interest is concerned. Many of them are tall, rising well above even deep snow. Other perennials that add year-round interest where they aren't buried in snow include yuccas, aloes, agaves, astilbes, epimediums, hellebores, lavenders, liriopes, mondo grasses (*Ophiopogon* spp.), and sedums.

There's one important thing to remember, though: Don't cut these perennials back in the fall or you'll miss out on the winter show!

Designing Your Dream Garden

Larry Hodgson

Conventional wisdom says that you should design your garden, then choose the plants for it. But when you love plants as much as I do, you should pick your plants first, then create a design that makes them look good together. This makes especially good sense when you're planting perennials with a purpose: Choose the perennials that suit your purpose, then put them together to make your dream garden.

Basics and Beyond

Although I've planted thousands of perennials in my yard, I'm not an expert on garden design. However, I've picked up a few notions about design during my years of gardening, and I'll share these basics with you here. If I can do it, you can, too! The elements you'll work with are color, texture, and form, and I'll give you some simple guidelines for using them to create pleasing gardens.

Color and Texture

Two of the most important elements in designing a garden are color and texture. If you can get these two elements to click, you're sure to have a beautiful garden. There's a lot of theory about how to combine colors and textures to create pleasing combinations, but remember—it's theory, not law. The color police are not going to arrest you!

Most of us do a fine job choosing colors for our homes. Designing a garden isn't that different. The first color choice is made for you. It's hard to make a major mistake when you have that underlying color pulling your design together.

Keep in mind that your garden is your garden. Don't think for a minute that you have to follow anyone else's color schemes. If you combine colors in a way that seems pleasing to you, you'll be satisfied, and that's what really counts.

COOL AND WARM

When you're thinking about garden design, it's helpful to separate colors into two groups: warm colors and cool colors. Red, orange, and yellow are warm colors. They give a design more excitement and passion. Also, these colors make the garden seem closer. You might want to use warm colors to make a large garden appear more intimate or to attract attention to a distant part of the garden.

Green, blue, and violet are cool colors. They make the garden seem cooler, calmer, and more peaceful. Cool colors also seem farther away. To make a small garden seem larger, use a lot of cool colors. Cool colors will also make an unwanted view less distracting, since they'll make it seem more distant and unobtrusive.

You can plant a garden that's all warm colors, all cool colors, or a mix of both. If you mix cool and warm colors, remember that warm colors dominate. If you want a garden where warm and cool balance, plant more cool-colored perennials. A few spot plantings of warm colors in a sea of blue and green are enough.

When you mix warm and cool colors, don't put the cool colors in the background, or they'll get lost. Plant cool-colored perennials in front, with the warm-colored ones behind.

SINGLE-COLOR GARDENS

Perhaps the easiest garden to design is a single-color garden. You can create a white garden, a yellow garden, a red garden—they're all winning ideas. Choose a color that you like, and use it in various shades and tints. Choose perennials with different sizes, textures, and shapes, all in various shades of the same color, and you can have both variety and harmony at the same time.

Of course, your garden won't truly be one color because it will have a background of green foliage, and there are many shades and tints of green, too. Green leaves can range from nearly black to blue-green to chartreuse to gray or silver. And that's not counting all the variegated foliage! You can even design a green garden just using foliage. It's fun to create striking and beautiful effects with foliage, especially in shade gardens where foliage is a key factor.

Continued →

COMBINING COLORS

If you want to create a garden with more than one color, you can use a color wheel to help decide which colors look good together. On the color wheel, each color is flanked by two other colors. You can move beyond a single-color garden by choosing three colors that appear side by side on the wheel.

If you like violet, for example, you could create an interesting garden using violet flowers with blue-violet or red-violet shades. Or go one step further and combine a primary color with the two secondary colors that are closest together on the wheel: orange with yellow and red, for example.

COMPLEMENTARY COLORS

Colors that are direct opposites on the color wheel are called complementary colors, and they make very vibrant combinations. Yellow and violet are complementary colors, and so are blue and orange. If these combinations strike you as too jarring, you can use tints of the main hue to prevent a clash, such as pink to soften a vibrant red. Or use white flowers or gray or silver foliage between colors that seem too strong. They'll tend to soften the blow.

MULTICOLOR MIXES

Garden designers might call a garden of mixed colors a "polychromatic scheme," but I just call it a mixed-color garden. It can include all the colors in the rainbow. Although considered daring from a design point of view, most home gardens are color mixes, and many of them work very well indeed. A garden with many different colors often creates a light, lively atmosphere, making it a fun place to be—and that's what many people want for their garden.

I'll admit, sometimes I've created a garden of mixed colors just by randomly planting perennials in a bed. When the bed fills in, sometimes I get a rather pleasing meadow garden look, but at other times, I'm not satisfied because many of the individual colors and plants seem lost in the crowd. So now I stick with a technique that usually gives great results.

I group plants together to create spots of color, then I mix the spots together rather than sprinkling individual colors throughout the same garden. How many plants make up a "spot" of color? That varies. When you're planting small perennials like violets, you may need 15 or more to create enough color impact. But with sizable plants like garden phlox (*Phlox paniculata*), 3 plants may be enough. And some perennials are large and imposing enough to stand alone.

TEXTURE

Although we tend to think of color as the mainstay in garden design, texture is just as important. In fact, Japanese gardens often have nothing but shades and tints of green—yet we find them pleasing and harmonious because of the careful choice of textures.

There are three basic textures: fine, medium, and coarse. Plants fit a texture category based on their leaf size and density and their flower placement. For example, bear's breeches (*Acanthus mollis*), with its large, striking leaves, is bold, while peony foliage is medium, and the feathery leaves of artemisias put them in the fine category.

When you create a garden, using a relatively even mix of fine and medium leaves with an accent of larger, bolder leaves is often the safest way to go. You can also design a striking garden using a single texture accented by a contrasting texture every now and then. One classic texture combination is fine-textured ferns with coarse-leaved hostas.

Fine textures tend to have the same effect as cool colors: They're calming and make the garden seem farther away. Coarse textures are almost as exciting and visually stimulating as warm colors and, like them, draw the garden closer. When you're combining textures, you can use the same technique of using "spots" of texture instead of just mixing textures randomly.

Featuring Plant Form

All plants have a natural form: Some plants are vertical, others are spreading, and still others are rounded, open, or prostrate. If a garden mixes too many forms, it can appear chaotic, but repeating a limited number of forms can create a very pleasing garden.

Working with form can be more subtle than color or texture. You can create gardens with gradual changes in form, where low plants melt into spreading ones that in turn give way to vertical shapes. You can also use dramatic contrasts in form, planting a rounded perennial like "Autumn Joy" sedum right next to a vase-shaped perennial like Russian sage (*Perovskia atriplicifolia*). The typical British perennial border is a classic mixture of tall, spiky background plants (verticality with a vengeance!) with rounded plants in the middle and prostrate plants as an edging.

THE FORM OF FLOWERS

Plants have an overall form or shape, and individual flowers or flower heads have a form as well. Large, bold peonies contrast with airy baby's breath blossoms, for example. There are also bell-shaped flowers, upright spikes of flowers, and daisylike blooms. My wife always complains there are too many "daisies" (rudbeckias, purple coneflowers, and perennial sunflowers) in our garden. She's right . . . and I'm trying to do better!

HOW TO HANDLE HEIGHT

The rule of thumb concerning plant height is so simple that most gardeners follow it instinctively: Short plants go in the front of the garden, medium-sized plants in the middle, and tall plants in the back. The deeper the garden, the more varied a range of heights you can use.

This rule is perfect for very formal gardens, but if you're planning a casual garden, don't hesitate to break the rule

occasionally. A few tall plants in the middle of the garden, some medium-sized ones in the front and, every now and again, a low-growing plant inching back into the bed will be more natural looking.

The Role of Repetition

Whether you're thinking about color, texture, form, or height, keep in mind that too much variety randomly tossed together can turn a garden into a total hodgepodge. The way to turn a random mix of plants into a pretty garden is through repetition. Even in a small garden, try to repeat at least three groups of the same plant, or at least the same color or texture, in different parts of the garden. You'll often find even the most unlikely plants suddenly gel perfectly!

Flowers of a Feather Bloom Together

Probably one of the most difficult things to plan for when designing a garden is getting bloom times to coincide. Although perennials can be roughly grouped into spring, summer, and fall bloomers, the actual time when a plant blooms varies from year to year, depending on the growing conditions and the weather. You just don't get guarantees on flowering time from Mother Nature.

The longer the growing season, the more difficult it is to coordinate bloom periods. In the Deep South, where Christmas rose (*Helleborus niger*) really can bloom at Christmas, each season is stretched to its maximum. The spring flowering season often lasts four months or more. By contrast, in my USDA Zone 3 garden, where spring barely lasts a month, you'll see spring and summer bloomers mingling. This makes it much easier to ensure nonstop color.

STAGGER BLOOM TIMES FOR BEST RESULTS

The secret to a perennial garden that always looks good is to stagger bloom times: Combine plants with different flowering seasons so that there's always something in bloom in the garden. One thing that can help is including some everbloomers—perennials that bloom for eight weeks or more—in your design.

Staggering bloom times fits well with my "spots of color" technique. A single perennial blooming on its own might have little impact in the garden, but three or more densely flowered patches of the same plant create the impression that there's color everywhere in the garden. By having at least three different perennials in bloom in three different spots at any given time, you can have that "in full bloom" effect right through the growing season.

Of course, to do so, you'll need to know when different perennials bloom. Once you've planted your garden, you may find that there's a "hole" in it—a particular time of year when there's nearly nothing in bloom. If this happens, take a stroll through your neighborhood at that time of year and see what's blooming in your neighbors' yards. Come fall, order a few of those plants and work them into your garden.

Finally, if you can't guarantee flowering perennials throughout the season, you can count on attractive foliage at all times, so don't hesitate to get some of the color for your garden from foliage.

Beyond Perennials: Branching Out

Perennial gardens can include other plants besides perennials, and adding some annuals, bulbs, and shrubs to your perennial garden can stretch its season of color and interest. For example, while there are perennials that flower in spring, spring bulbs are the true stars of the early spring and midspring gardens. Annuals add consistent color that can tide your garden over if there are periods when perennials aren't at their best, such as during the high heat of midsummer. And shrubs will give your garden some form and interest through the winter.

BULBS FOR SPRING COLOR

From the earliest snowdrops and winter crocuses to May-blooming tulips, not to mention summer-flowering alliums and fall-blooming crocus and colchicums, bulbs ensure color when there is little else around. Spring bulbs are a perfect match for perennials because they produce their foliage in the spring when many perennials are dormant. As spring gives way to summer, the bulb foliage dies back, while the perennials sprout the new season's growth.

Because of this, you can plant bulbs and perennials quite literally in the same space. Just plant the bulbs deeply in the fall (check the bulb package to confirm the planting depth, as it does vary), then plant shallow-rooted perennials literally on top. The bulbs will come up right through the perennials—especially low-growing ones like ajugas and lamiums.

I like to plant rings of early bulbs around slow-to-sprout plants like hibiscus and balloon-flower. I've found that the bulbs serve as markers so I don't accidentally dig up the slow sprouters when I'm working in the garden preparing beds during the spring.

ADDING ANNUALS

Annuals and perennials make a great combination, as long as you give the annuals enough room to spread without crowding the perennials. Planting patches of annuals through a bed of perennials can ensure that "always-in-bloom" look. A ratio of about one annual to five perennials works well.

Annuals also work well as edging plants for a perennial border. It's a job they do marvelously, and if the front edge of the garden—which is the first thing that catches people's attention when they enter the garden—appears to be in full bloom through the summer, the rest of the garden will seem all that much more attractive.

Continued →

SHRUBS TO ANCHOR THE SCENE

Shrubs are excellent backgrounds for perennial beds, "anchoring" the garden to its landscape much better than perennials alone could ever do. Many shrubs bloom in the spring or late summer—two times of year when perennials are rather weak—so the marriage is a good one. Just make sure that each shrub has its own space.

One effective combination is shrubs with perennial groundcovers. You can let the ground-cover creep under the shrubs and create a living carpet that's beautiful and easy to care for.

Of course, not all shrubs belong strictly in the background of the mixed border. Short, dense shrubs, including dwarf conifers, look great in the middle or even the front of the garden as well. Shrubs come in a wide range of forms, textures, and foliage colors, so it's easy to create beautiful combinations of perennials and shrubs. And, of course, many shrubs have beautiful blooms and colorful fruit as well.

The 10 Commandments of Perennial Design

Now that you know the basics of garden design, you can see that there are unlimited possibilities for designing and planting perennial gardens. But before you start, read my list of important lessons learned from years of gardening and designing. My "ten commandments" are some of the best practical advice I can give you, based on some of my own worst mistakes.

1. Leave room for future growth. Don't cram a new garden with perennials, or they'll have no room to spread over time. And you'll end up having to dig some up and move them. Instead, fill in with temporary plants such as annuals for the first couple of years.
2. Change your garden whenever you feel like it. It's a gardener's prerogative to change his (or her!) mind. Once you have a garden design, even one that's been prepared by a professional designer, feel free to change it. After all, it's your garden! Even professional landscapers change plans as they work.
3. Stagger your planting. Don't plant perennials in straight lines because it looks unnatural and static, except when you're planting an edging for a small rectangular or square garden.
4. Don't go with the flow. Be wary of following gardening fads too closely. True, hot pink may be the "hot" trend, but are you sure you'll be able to live with it ten years from now? Experiment with the latest trends using annuals, but make sure your perennial choices are ones you can live with for a long time.
5. Rein in the spreaders. If you plant a potentially invasive perennial in a flower bed, always plant it inside a root barrier. Nothing's harder than trying to dig out an aggressive spreader.
6. Don't be boring. Avoid mirror-image plantings on either side of a walkway or door. They may work in truly formal settings, but they often make for a boring garden.
7. Don't neglect your babies. Remember that all newly planted perennials need extra care for the first year after planting.
8. Show your plants, not your stakes. Stake perennials as discreetly as possible or use stakes that blend in with the plants' foliage. Nothing ruins a nice garden like a forest of ugly stakes.
9. Make big beds. If you're planning a perennial border, make it as wide as you can: Remember, perennials need space to grow! There's nothing more frustrating than having to divide perennials just a year or two after planting them.
10. Don't always follow the rules. Don't follow any design rule too precisely. All rules are meant to be broken, even mine!

Planting & Caring for Perennials

Taking the time to prepare the soil, follow general planting guidelines, weed, and control bad bugs will be well worth the effort. Your payoff? Loads of beautiful blooms that will grace your landscape for years to come.

Sizing Up Your Soil

Good soil is the backbone of any good garden and is key to growing lush plants. Well-prepared soil is fluffy and loose, so water, air, and nutrients can filter down easily and plant roots have room to stretch. Most soils in residential areas are loams—combinations of sand, silt, and clay. If your soil has a high percentage of sand, it's a sandy loam, whereas if your soil has a high percentage of clay, it's a clay loam.

How do you know if you have good loam soil, or too much clay or sand? Try one of these simple tests to find out what's going on down below.

THE WATERING TEST

When you're watering plants in your garden, does the water disappear so fast it looks like only the leaves have gotten wet, rather than the soil surface? And do you find you have to water frequently to keep plants from wilting? If so, you have a lot of sand in your soil.

On the other hand, if water puddles up and seems to take forever to sink into the soil, you have lots of clay. Soil with a high clay content may dry and crack apart in clods or plates between rains, and it becomes sticky or very slippery when it gets wet.

THE SOIL BALL TEST

Try this test after a rain or after you water, when the soil is moist but not soggy. Pick up a handful of soil from the site where you

want to grow perennials and squeeze it. If the soil crumbles apart when you open your hand, the soil is loam. If the soil stays in a ball, it's mostly clay. If it disintegrates easily and you can see and feel gritty little crystals in it, it's a sandy soil. And if the soil crumbles but feels greasy, it's mostly silt.

UNDERSTANDING PH

Soil pH is a measure of acidity or alkalinity. It's measured on a scale from 1.0 (highly acidic) to 14.0 (highly alkaline), with 7.0 considered neutral. Most garden perennials grow best in soil with a pH of 6.0 to 7.0—slightly acidic to neutral. You can test your soil's pH yourself with a home test kit (available from garden centers and through mail-order catalogs).

Bring very acid soils closer to neutral by adding lime (often in the form of limestone); neutralize highly alkaline soils with sulfur. Adding organic matter such as leaves, grass clippings, or compost to your soil will soon bring a soil into balance—and create happier plants.

Amending Your Soil

Soil amendments benefit your garden by supplying the material (humus) that's the basis for good plant growth. Adding amendments loosens the soil, helps the soil retain water better, and improves drainage. All garden soils, even good garden loams, benefit from regular additions of organic material. And you need to apply amendments every season because organic material is constantly being broken down in the soil.

To give your perennial plants the benefits of organic matter, you must give your soil a steady supply: Add compost and mulch to established beds, or incorporate organic material into new beds.

The most commonly available soil amendments are the following:

- Compost
- Aged manure
- Grass clippings
- Shredded leaves
- Hay and straw
- Aged sawdust

Compost and aged manure are balanced amendments, which means that they contain a mix of nutrients and you can add them to the soil as is, at any time. Grass clippings are a good source of fast-release nitrogen, but they decompose quickly, adding little bulk to the soil. However, shredded leaves, hay, straw, and aged sawdust all need time to break down. If you want to add one of those amendments, prepare your beds in fall for spring planting or in spring for fall planting.

Putting in the Plants

You can plant perennials any time the soil is workable, although spring and fall are best for most plants. If the plants arrive or you buy them before you're ready to plant, be sure to care for them properly until you can get them into the ground. Try to plant on an overcast day, and avoid planting during midday heat.

PLANTING CONTAINER-GROWN PERENNIALS

Place container-grown plants on top of the soil according to your design. Start small, removing and planting one plant at a time rather than taking them all out of their pots and leaving them to dehydrate. And don't just grab a plant by the stem and pull it out of its pot. Instead, follow these simple but important steps:

1. Spread your hand over the surface of the soil with your fingers on either side of the plant stem.
2. Invert the pot so it's resting upside down on your hand, then pull off the pot with the other hand. (If the pot doesn't release easily, gently tap it a few times, and try again. If it's really stubborn, cut it off.) If the roots have filled the pot so tightly that they hold their shape once you've removed the pot, gently pull them loose or quarter the rootball before planting.
3. Hold the plant upside down, with your fingers on either side of the stem (as you removed it from the pot). Use a sharp knife or trowel to slice the rootball from the bottom up into four equal sections.
4. Spread out the four quarters in the planting hole to make sure the roots grow into the soil instead of remaining in a ball.

Plant container-grown perennials at the level at which they sat in the pots. If the crowns (where the roots meet the stems) are buried, the plants will have a tough time surviving.

PLANTING BAREROOT PERENNIALS

Right before you plant a bareroot perennial (they arrive with their roots in a protective substance, such as shredded wood, as opposed to actually being planted in a soil-filled container), cut off any dead, damaged, or diseased roots with a sharp knife. Mound soil in the bottom of the planting hole and spread the roots out so the crown of the plant rests on top of the mound. Then add soil around the roots to fill the hole.

Note: On a bareroot perennial, you'll have to determine the depth to which the plant was planted at the nursery or identify the crown. If you see a soil line or notice a spot where stems or leaf bases change color (green to yellow or green to white), plant it at that depth. If not, plant it so the soil comes up to but not past the point where the roots end and the stems begin.

Caring for Perennials

After you've invested time, money, and energy in your perennial garden, you'll want to keep it looking its best. That's where regular (at least a few times a week) attention to watering, mulching, weeding, and grooming comes in.

Continued →

WATERING

When it comes to watering perennials, keep two rules in mind: Water deeply (really soaking the soil, not just sprinkling it), and water the roots (that is, on the ground around the plants, not into the air or onto the plants). If you break these rules, there's a good chance you'll end up with shallow-rooted, wilt-prone plants and mildewed foliage.

With a few exceptions, perennials like consistently and evenly moist soil. In general, water when the top inch or two of soil dries out and Mother Nature isn't planning on providing any rain in the near future. Also, use a hose instead of a sprinkler so you can direct the water to the bases of the plants without wetting the foliage. For best results, don't water in the evening, when the water will stay on your plants all night, encouraging powdery mildew to grow.

MULCHING

After good soil, mulch does more for plants than any technique you could use or any other product you could add to your garden. It helps maintain soil moisture (allowing you to water less often), keeps weeds at bay (giving you more time to enjoy your garden), adds nutrients to the soil (cutting down on the need to add fertilizer), and prevents erosion.

Apply organic mulch—shredded leaves, straw, bark, pine needles, or lawn clippings—around plants you've just planted, leaving about an inch of space around the stem of each plant. (Covering the crowns with mulch encourages crown rot.) If your mulch begins to break down and look thin as summer wears on, add more. After your plants have been killed by a hard frost in the fall, mulch fall transplants or put a winter mulch on your beds. The next spring, pull back the winter mulch until the soil has warmed, then pull it back up around your plants.

WEEDING

Weeding is a fact of life for every gardener, whether you're a beginner or have been gardening for 25 years. The best way to beat these less-than-desirable plants is to start weeding as soon as you see a problem. You'll have a much harder time beating weeds if you let them take over your garden and then try to bring things under control all at once.

Even if you pull 'em as you see 'em, you'll still want to spend as little time as possible fighting weeds. Here are a few ways you can do just that.

- Mulch your garden. Mulch suppresses weed germination and makes the weeds that do appear easier to pull, because the soil stays soft and moist beneath the mulch.
- Remove the whole weed—roots and all—the first time. A lot of weeds can spread from a tiny piece of root or stem left in the ground.
- Don't let weeds set seed. Some perennials, such as coneflowers, self-sow so enthusiastically that they could be considered weeds. If you don't plan on starting your own nursery, cut the flower heads before the seeds ripen and drop.
- Don't compost mature weed seed heads. Although a really hot compost pile will kill weed seeds, you can't guarantee that the seeds will be in the hottest part of the pile or that your pile will get hot enough to kill all of them.

GROOMING

Grooming techniques, such as thinning, pinching, and deadheading, are fast and easy techniques that will put the finishing touches on your perennial garden.

Thinning is removing some of the stems of dense, bushy plants to let in additional light and improve air circulation. This technique helps prevent mildew on susceptible plants such as garden phlox, bee balms, and delphiniums. Thin in spring by cutting or pinching out stems at the soil level. Thin each plant to the four or five strongest shoots, leaving 2 to 4 inches between each stem.

Pinching creates more compact, bushier plants, prevents flopping, and ensures more bloom. Using your forefinger and thumb, pinch out the tips of the stems. From each pinched stem, two branches will grow. Start pinching plants in late spring or early summer. Pinch again a few weeks later to encourage even bushier plants with still more flowers, but don't pinch back after flower buds are set, or you'll discourage (rather than encourage) flowering.

Despite its gory name, deadheading, or removing spent flowers, is a very useful technique. Some perennials deadhead themselves, dropping old flowers to the ground. But the brown, papery ruins of other flowers will spoil the beauty of your garden unless you take them off regularly. Deadheading provides your perennials with more than good looks, though. It's also important for the following reasons:

- The plant can channel energy that would normally be used to produce seed back into flower, leaf, and root production.
- Invasive perennials are kept from self-sowing all over your garden.
- The bloom season often is extended because the plants will keep flowering rather than stopping after the first bloom.

For plants that have more than one flower on a single stalk and the flowers open at different times, like daylilies, carefully snap off or pinch the faded blooms between your fingers. With plants that bear one flower head on the end of each stalk, like yarrow, cut the stalks at or near the ground when the flowers fade.

Perennial Flower Finder

Ellen Phillips and C. Colston Burrell

This is a section of lists—lists that make it easy for you to see at a glance how to put perennials together. If you want to create a

blue color-theme garden or just need a perennial that will add a touch of blue to your garden, turn to the list of blue-flowered perennials. Needless to say, these lists aren't meant to be exhaustive—there will always be many, many more perennials to choose from—but there are enough here to give you a strong start. You can't go wrong with these garden-worthy perennials!

Skim through the lists. Do you need perennials for clay soil, for shade, for full sun? Perennials to attract butterflies or hummingbirds? Drought-tolerant perennials? Flowers that are easy-care? Plants that can take wet feet? Think about what you want, and also see what appeals to you as you look at the lists. You might start out wanting a garden of red-flowered perennials, then decide you'd like a hummingbird garden instead because many hummingbird favorites have red flowers and you'd get the pleasure of the comical little buzzers as well. (Actually, hummingbird enthusiasts call the little birds "hummers," not "buzzers," but since they buzz loudly as they dart and hover, I can't help but call them that.) Enjoy yourself!

Perennials by Flower Color

Most of us play favorites when it comes to color. That's why color-theme gardens are so popular. If you love blue, white, and yellow, you might decide to plant a border featuring one, two, or all three flower colors. Perhaps you planted a bed that blooms in soft shades of lavender and gold, and now you feel that it needs a little pizzazz—maybe a touch of magenta or deep red. In these lists, you'll find perennials arranged by bloom color, so you can quickly check your choices for any given color.

Remember that many perennials have several—or even lots of—flower colors (irises, columbines, lupines, and chrysanthemums spring to mind), so you'll find them on many of these lists. When you don't expect a perennial to bloom in a certain color—for example, a near-white-flowered daylily—we'll give you the cultivar name as well as the genus or species.

White or Cream

Alstroemeria spp. (alstroemerias)
Aster spp. (asters)
Astilbe spp. (false spireas)
Astrantia app. (masterworts)
Campanula spp. (bellflowers, harebells)
Chrysanthemum spp. (chrysanthemums)
Convallaria majalis (lily-of-the-valley)
Delphinium spp. (delphiniums)
Dianthus spp. (pinks, carnations)
Dicentra spp. (bleeding hearts)
Digitalis spp. (foxgloves)
Echinacea spp. (coneflowers)
Gaura lindheimeri (white gaura)
Geranium spp. (geraniums, cranesbills)
Gypsophila paniculata (baby's-breath)
Hedychium coronarium (butterfly ginger)
Hemerocallis cvs., such as 'Gentle Shepherd' (daylilies)
Iberis spp. (candytufts)
Iris spp. (irises)
Lamium maculatum cvs., such as 'White Nancy' (spotted dead nettle)
Leucanthemum maximum (Shasta daisy)
Leucojum spp. (snowflakes)
Lilium spp. (lilies)
Paeonia spp. (peonies)
Papaver spp. (poppies)
Penstemon spp. (beardtongues, penstemons)
Phlox spp. (phlox)
Salvia spp. (sages)
Sanguinaria canadensis (bloodroot)
Tiarella spp. (foamflowers)
Tradescantia spp. (spiderworts)
Trillium spp. (trilliums)
Verbena spp. (verbenas, vervains)
Viola spp. (violets, violas)

Pink

Alstroemeria spp. (alstroemerias)
Armeria maritima (sea pink)
Astilbe spp. (false spireas)
Astrantia spp. (masterworts)
Bletilla striata (Chinese ground orchid)
Campanula spp. (bellflowers, harebells)
Chrysanthemum spp. (chrysanthemums)
Delphinium spp. (delphiniums)
Dianthus spp. (pinks, carnations)
Dicentra spp. (bleeding hearts)
Digitalis spp. (foxgloves)
Echinacea spp. (coneflowers)
Epimedium spp. (fairy wings)
Eupatorium spp. (Joe-Pye weeds, bonesets)
Geranium spp. (geraniums, cranesbills)
Iris spp. (irises)
Lamium maculatum cvs., such as 'Pink Pewter', 'Beacon Silver' (spotted dead nettle)
Lilium spp. (lilies)
Lobelia spp. (lobelias)
Monarda spp. (bee balms, bergamots)
Oenothera speciosa (showy evening primrose)

Paeonia spp. (peonies)

Papaver spp. (poppies)

Phlox spp. (phlox)

Salvia spp. (sages)

Thalictrum spp. (meadow rues)

Verbena spp. (verbenas, vervains)

Red and Scarlet

Aquilegia spp. (columbines)

Astilbe spp. (false spireas)

Astrantia spp. (masterworts)

Canna spp. (cannas)

Chrysanthemum spp. (chrysanthemums)

Coreopsis 'Limerock Ruby' ('Limerock Ruby' corepsis)

Crocosmia spp. (crocosmias, montbretias)

Dianthus spp. (pinks, carnations)

Gaillardia spp. (blanket flowers)

Hemerocallis spp. (daylilies)

Heuchera cvs. (alumroots, coral bells)

Lilium spp. (lilies)

Lobelia spp. (lobelias)

Monarda spp. (bee balms, bergamots)

Paeonia spp. (peonies)

Papaver spp. (poppies)

Persicaria amplexicaule (mountain fleece flower, mountain knotweed)

Salvia spp. (sages)

Silene spp. (campions, pinks)

Spigelia marilandica (Indian pink)

Veronica spicata (spike speedwell)

Purple, Lilac, Mauve, and Maroon

Agapanthus spp. (lilies of the Nile, African lilies)

Allium spp. (ornamental onions)

Alstroemeria spp. (alstroemerias)

Aquilegia spp. (columbines)

Aster spp. (asters)

Astrantia spp. (masterworts)

Callirhoe involucrata (purple poppy mallow)

Campanula spp. (bellflowers, harebells)

Chrysanthemum spp.(chrysanthemums)

Delphinium spp. (delphiniums)

Digitalis spp. (foxgloves)

Echinacea spp. (coneflowers)

Eupatorium spp. (Joe-Pye weeds, bonesets)

Geranium spp. (geraniums, cranesbills)

Hemerocallis cvs., such as 'Plum Perfect' (daylilies)

Iris spp. (irises)

Knautia macedonica (knautia)

Lavandula spp. (lavenders)

Liatris spp. (gayfeathers, blazing-stars)

Liriope spp. (lily turfs)

Lobelia spp. (lobelias)

Monarda spp. (bee balms, bergamots)

Nepeta spp. (catmints, nepetas)

Papaver spp., such as *P. orientale* 'Patty's Plum', *P. somniferum* 'Lauren's Grape' (poppies)

Phlox spp. (phlox)

Salvia spp. (sages)

Tradescantia spp. (spiderworts)

Verbena spp. (verbenas, vervains), such as *Verbena bonariensis* (Brazilian vervain)

Vernonia spp. (ironweeds)

Veronica spp. (speedwells)

Viola spp. (violets, violas)

Blue

Agastache foeniculum, such as 'Blue Fortune' (fragrant anise hyssop)

Amsonia spp. (blue stars, amsonias)

Aster spp. (asters)

Baptisia australis (blue false indigo)

Brunnera macrophylla (Siberian bugloss, forget-me-not)

Campanula spp. (bellflowers, harebells)

Ceratostigma plumbaginoides (plumbago)

Clematis spp. (clematis)

Corydalis flexuosa (blue fumeroot)

Delphinium spp. (delphiniums)

Iris spp. (irises)

Linum perenne (blue flax)

Lobelia spp. (lobelias)

Meconopsis spp. (meconopsis)

Muscari spp. (grape hyacinths)

Phlox divaricata (wild blue phlox, woodland phlox)

Phlox paniculata cvs., such as 'Blue Paradise' (garden phlox)

Platycodon grandiflorus (balloon flower)

Pulmonaria saccharata (Bethlehem sage)

Salvia spp. (sages)

Stokesia laevis (Stokes' aster)

Tradescantia spp. (spiderworts)

Verbena spp. (verbenas, vervains)

Veronica spp. (speedwells)

Yellow

Achillea spp. (yarrows)

Alstroemeria spp. (alstroemerias)

Aquilegia spp. (columbines)

Aurinia saxatilis (basket-of-gold)

Canna spp. (cannas)

Chrysanthemum spp. (chrysanthemums)

Chrysogonum virginianum (goldenstar, green-and-gold)

Coreopsis spp. (tickseed, coreopsis)

Crocosmia spp. (crocosmias, montbretias)

Digitalis spp. (foxgloves)

Doronicum spp. (leopard's banes)

Epimedium spp. (fairy wings, barrenworts)

Euphorbia polychroma (cushion spurge)

Hemerocallis spp. (daylilies)

Iris spp. (irises)

Kniphofia spp. (torch lilies, red-hot pokers)

Ligularia spp. (ligularias, groundsels)

Lilium spp. (lilies)

Lysimachia vulgaris (yellow loosestrife)

Oenothera spp. (evening primroses)

Paeonia spp. (peonies)

Papaver spp. (poppies)

Primula auricula (auricula primrose)

Ranunculus spp. (buttercups)

Rudbeckia spp. (black-eyed Susans, coneflowers)

Solidago spp. (goldenrods)

Viola spp. (violets, violas)

Peach, Orange, and Coral

Agastache spp. (anise hyssops)

Alstroemeria spp. (alstroemerias)

Asclepias tuberosa (butterfly weed)

Canna spp. (cannas)

Chrysanthemum spp. (chrysanthemums)

Crocosmia spp. (crocosmias, montbretias)

Diascia vigilis (twinspur, diascia)

Eremurus spp. (foxtail lilies, desert-candles)

Gladeolus spp. (gladioli, sword lilies)

Hedychium spp. (ginger lilies, garland lilies)

Hemerocallis spp. and *cvs.* (daylilies)

Iris spp. (irises)

Kniphofia spp. (torch lilies, red-hot pokers)

Lilium spp. (lilies)

Paeonia spp. (peonies)

Papaver spp. (poppies)

Schizostylis coccineus (crimson flag)

Zephyranthes spp. (rain lilies)

Green and Chartreuse

Chrysanthemum spp. (chrysanthemums)

Euphorbia spp. (spurges, euphorbias)

Helleborus spp. (hellebores), especially *H. foetidus* (stinking hellebore)

Iris spp. (irises)

Kniphofia spp. (torch lilies, red-hot pokers)

Sedum spp. (stonecrops, sedums). Note: Most sedum flower heads mature to white, pink, red, maroon, or rust, but they remain green for a very long time first, giving the presence of green flowers in your garden until they color up.

"Black"

Alcea rosea 'Nigra' (black hollyhock)

Aquilegia cvs., such as 'Black Barlow' (columbines)

Geranium phaeum var. phaeum (mourning widow hardy geranium)

Helleborus cvs. (hellebores)

**Ipomoea barbatus* 'Blackie' and 'Ace of Spades' (sweet potato vine)

Iris spp. (irises)

Tulipa cvs. (tulips)

Viola cvs. (Johnny-jump-ups, pansies)

Perennials for Long Bloom

Unlike annuals, perennials don't bloom nonstop from planting to frost because they need to put most of their energy into their roots so they'll live through the winter and have the strength to come up the following spring. Some perennials bloom for only a week or two, then the show's over until next year. Luckily for gardeners, other perennials bloom for weeks on end. (Others, like most ornamental grasses, bear showy plumes of flowers that turn into long-lasting seedheads.) If you enjoy a good show, choose from this list.

Acanthus spp. (bear's breeches)

Achillea spp. (yarrows)

Agastache spp. (anise hyssops)

Alchemilla spp. (lady's-mantles)

Armeria spp. (thrifts)

Aster spp. (asters)

Bergenia spp. (bergenias, winter begonias)

Calamintha nepeta (calamint)

Callirhoe spp. (winecups, poppy mallows)

Continued ➔

Campanula spp. (bellflowers, harebells)
Canna spp. (cannas)
Centranthus ruber (red valerian)
Coreopsis spp. (tickseeds, coreopsis)
Corydalis spp. (corydalis, fumeroots)
Dianthus spp. (pinks, carnations)
**Diascia vigilis* (twinspur)
Digitalis spp. (foxgloves)
Echinacea spp. (coneflowers)
Echinops spp. (globe thistles)
Euphorbia spp. (spurges, euphorbias)
Gaura lindheimeri (white gaura)
Geranium spp. (geraniums, cranesbills)
Gypsophila spp. (baby's-breaths)
Helianthus spp. (sunflowers)
Helleborus spp. (hellebores, Christmas roses, Lenten roses)
Hemerocallis spp. (daylilies)
Kalimeris pinnatifida (Mongolian aster)
Liatris spp. (gayfeathers, blazing-stars)
Limonium spp. (sea lavenders, statices)

Thalictrum spp. (meadow rues)
Tradescantia spp. (spiderworts)
Verbena spp. (verbenas, vervains)
Veronica spp. (speedwells)
*tender perennial

Perennials By Season

Knowing what perennials bloom when can be especially helpful when you're planning your garden. Maybe you want plants in bloom in every season, or you're trying to add color at a specific time—fall, for example—because you realize that you've planted all spring and summer bloomers. If you have a summer home, you may want to design a bed that blooms in a single season so you can enjoy the color while you're there. (Of course, some perennials bloom from one season into the next; these lists capture the season when the plants bloom longest.) We haven't included spring-blooming bulbs or summer-blooming grasses here, but check these lists for other seasonal showstoppers.

Spring-Flowering

Amsonia spp. (blue stars, amsonias)
Aquilegia spp. (columbines)
Aurinia saxatilis (basket-of-gold)
Cerastium tomentosum (snow-in-summer)
Chrysogonum virginianum (goldenstar, green-and-gold)
Corydalis spp. (corydalis, fumeroots)
Crocus spp. (crocuses)
Dicentra spp. (bleeding hearts)
Epimedium spp. (fairy wings, barrenworts)
Helleborus spp. (hellebores, Christmas roses, Lenten roses)
Iris spp. (irises)
Lamium maculatum (spotted dead nettle)
Oenothera speciosa (showy evening primrose)
Paeonia spp. (peonies)
Primula spp. (primroses, cowslips)
Trillium spp. (trilliums)

Summer-Flowering

Achillea spp. (yarrows)
Alstroemeria spp. and hybrids (alstroemerias)
Anemone x *hybrida*, *A. tomentosa* (Japanese anemones)
Asclepias tuberosa (butterfly weed)
Aster spp. (asters)
Calamintha nepeta (calamint)
Callirhoe involucrata (purple poppy mallow)
Ceratostigma plumbaginoides (plumbago)
Coreopsis spp. (tickseed, coreopsis)
Crocosmia x *crocosmiiflora* (crocosmia)
Digitalis spp. (foxgloves)
Echinacea spp. (coneflowers)
Eupatorium spp. (Joe-Pye weeds, bonesets)
Geranium spp. (geraniums, cranesbills)
Heliopsis spp. (oxeyes)
Hemerocallis spp. (daylilies)
Heuchera spp. (alumroots, coral bells)
Kalimeris spp. (Mongolian asters, Japanese asters)
Kniphofia spp. (torch lilies, red-hot pokers)

Leucanthemum maximum (Shasta daisy)
Liatris spp. (gayfeathers, blazing-stars)
Lilium spp. (lilies)
Linaria vulgaris (toadflax)
Lobelia spp. (lobelias)
Monarda spp. (bee balms, bergamots)
Nepeta spp. (catmints, nepetas)
Oenothera spp. (evening primroses)
Penstemon spp. (beardtongues, penstemons)
Platycodon grandiflorus (balloon flower)
Prunella grandiflora (large-flowered self-heal)
Rudbeckia spp. (black-eyed Susans, coneflowers)
Scabiosa spp. (pincushion flowers)
Tanacetum parthenium (feverfew)
Tradescantia spp. (spiderworts)
Veronica spp. (speedwells)

Fall-Flowering

Aconitum spp. (monkshoods)
Anemone hupehensis (Chinese anemone)
Aster spp. (asters)
Boltonia asteroids (boltonia)
Chelone lyonii (pink turtlehead)
Chrysanthemum x *morifolium* (garden chrysanthemum)
Cimicifuga simplex (Kamchatka bugbane)
Colchicum spp. (colchicums, meadow saffrons)
Coreopsis spp. (tickseeds, coreopsis)
Cyclamen hederifolium (ivy-leaf cyclamen)
Hedychium spp. (ginger lilies, garland lilies)
Helenium spp. (sneezeweeds, Helen's flowers)
Helianthus spp. (sunflowers)
Kirengeshoma spp. (yellow bells, wax bells)
Leucanthemum nipponicum (Nippon daisy)
Lycoris spp. (spider lilies, surprise lilies)
Lysimachia vulgaris (yellow loosestrife)
Patrinia scabiosafolia (patrinia)
Physostegia virginiana (obedient plant)
Salvia spp. (sages)
Sedum spp. (stonecrops, sedums)
Solidago spp. (goldenrods)
Tricyrtis spp. (toad lilies)

Winter Interest

Acanthus spp. (bears-breeches)
Achillea spp. (yarrows)
Arum spp. (arums)
Asarum spp. (wild gingers)
Aster spp. (asters)
Astilbe spp. (false spireas)
Baptisia spp. (false indigos, wild indigos)
Bergenia spp. (bergenias, winter begonias)
Cyclamen coum (hardy cyclamen)
Echinacea spp. (coneflowers)
Eupatorium spp. (Joe-Pye weeds, bonesets)

Ferns
Galanthus spp. (snowdrops)
Helleborus spp. (hellebores, Christmas roses, Lenten roses)
Hibiscus spp. (rose mallows, hibiscus)
Hosta spp. (hostas)
Lespedeza spp. (bush clovers)
Lilium formosanum (Formosa lily)

Ornamental grasses
Rudbeckia spp. (black-eyed Susans, coneflowers)
Vernonia spp. (ironweeds)

Perennials with Showy Foliage

Attractive foliage can hold its own with flowers in the perennial garden, providing interest when plants aren't in bloom, complementing or contrasting with flower color, or enhancing a color-theme bed. Foliage can brighten shady gardens and cool down sunny ones, create tropical effects in temperate gardens, or weave a tapestry of colorful groundcover under other plantings. Some plants have such showy foliage that they can stand alone as specimen plants. Foliage is a fact of perennial life, so why not make the most of it? The choices below will get you off to a good start.

White or Silver; Solid, Mottled, or Variegated

Ajuga reptans 'Silver Carpet' ('Silver Carpet' common bugleweed)
Artemisia spp. (artemisias, wormwoods)
Arum italicum 'Pictum' ('Pictum' Italian arum)
Asarum spp. (wild gingers)
Athyrium niponicum 'Pictum' ('Pictum' Japanese lady fern)
Carex morrowii '*Variegata*' (variegated morrow sedge)
Cerastium tomentosum (snow-in-summer)
Heuchera americana cvs. (alumroots, rock geraniums)
Hosta cvs., such as 'Patriot' (hostas)
Lamium maculatum cvs., such as 'White Nancy', 'Beacon Silver' (spotted dead nettles)
Liriope spicata 'Silver Dragon' ('Silver Dragon' creeping liriope)

Continued →

Miscanthus sinensis 'Caberet', 'Cosmopolitan' (variegated Japanese silver grasses)

Phalaris arundinacea cvs., such as 'Feesey's Variety' (ribbon grass)

Polygonatum odoratum 'Variegatum' (variegated Japanese Solomon's seal)

Pulmonaria spp. (lungworts, Bethlehem sages)

Sedum cvs., such as 'Frosty Morn' (stonecrops, sedums)

Stachys byzantina (lamb's ears)

Vinca spp. and cvs., such as *V. minor* 'Ralph Shuggart' (vincas, periwinkles)

Yucca filamentosa 'Variegata' (variegated Adam's needle)

Gold or Chartreuse; Solid or Variegated

Acanthus mollis 'Hollard's Gold' ('Hollard's Gold' bear's-breeches)

Agastache 'Golden Jubilee' ('Golden Jubilee' anise hyssop)

Arachnoides simplisior 'Variegata' (variegated holly fern)

**Canna* x *generalis* 'Bengal Tiger' ('Pretoria') ('Bengal Tiger' canna)

Carex elata 'Aurea' (Bowles' golden sedge), *C. dolichostachya* 'Kaga Nisiki' (Kaga brocade sedge), *C. morrowii* 'Goldband' ('Goldband' morrow sedge)

Dicentra spectabilis 'Gold Heart' ('Gold Heart' old-fashioned bleeding heart)

Filipendula ulmaria 'Aurea' (European queen of the meadow)

Geranium 'Ann Folkard' ('Ann Folkard' geranium)

Hakonechloa macra 'Aureola', 'All Gold' (golden hakone grass, Japanese fountain grass)

Heliopsis helianthoides 'Loraine Sunshine' ('Loraine Sunshine' oxeye)

Heuchera 'Amber Waves' ('Amber Waves' coral bells)

Hosta cvs., such as 'Gold Standard', 'Tokudama', 'Sum and Substance' (hostas)

**Ipomoea batatas* 'Margarita' ('Margarita' sweet potato vine)

Iris variegated selection such as *I. ensata* 'Variegata', (variegated Japanese iris), *I. pallida* 'Aureo-Variegata' (variegated sweet iris)

Lamium maculatum 'Aureum' ('Aureum' spotted dead nettle)

Ligularia tussilaginea 'Aureomaculata' (leopard plant)

Liriope muscari 'Pee Dee Gold Ingot' (blue lily turf)

Lysimachia nummularia 'Golden Globe' ('Golden Globe' creeping Jenny); *L. clethroides* 'Geisha' ('Geisha' gooseneck loosestrife)

Miscanthus sinensis 'Strictus' ('Strictus' Japanese silver grass)

**Pelargonium* cvs. (zonal geraniums)

Phlox paniculata 'Goldmine' and others (garden phlox)

**Solenostemon scotellarioides* cvs. (coleus)

Tanacetum vulgare 'Isla Gold' ('Isla Gold' tansy)

Tradescantia 'Blue and Gold' ('Blue and Gold' spiderwort)

Tricyrtis formosana 'Gates of Heaven' ('Gates of Heaven' Formosa toad lily)

Veronica repens 'Sunshine', *V. prostrata* 'Aztec Gold' (harebell speedwells)

Yucca 'Golden Sword', 'Color Guard' (varie gated yuccas)

*tender perennial

Blue or Gray-Blue

Achillea 'Moonshine' ('Moonshine' yarrow)

Corydalis flexuosa, C. ochroleuca (blue and white fumeroots)

Crambe maritima (sea kale)

Dicentra cvs. (bleeding hearts)

Festuca cinerea, such as 'Elijah Blue', 'Skinner's Blue', 'Solling' (blue fescue)

Helictotrichon sempervirens (blue oat grass)

Hosta cvs., such as 'Eatoi Blue', 'Krossa Regal', 'Blue Mammoth', 'Big Daddy' (hostas)

Panicum virgatum 'Heavy Metal', 'Dallas Blues' ('Heavy Metal' or 'Dallas Blues' switchgrass)

Ruta graveolens cvs., such as 'Blue Beauty', 'Blue Mound' (rues)

Yucca rostrata (beaked blue yucca)

Purple or Purple Variegations

Ajuga reptans 'Atropurpurea' or 'Purpurea' ('Atropurpurea' or 'Purpuea' common bugleweed)

Angelica gigas (Korean angelica, purple parsnip)

**Anthriscus* 'Ravenswing' (cow parsley)

Aster lateriflorus 'Lady in Black' ('Lady in Black' calico aster)

**Canna* x *generalis*, such as 'Pink Futurity', 'King Humpert', 'Wyoming', 'Australia', 'Intrigue', 'Pacific Beauty' (cannas)

**Colocasia esculenta* 'Black Magic' ('Black Magic' elephant ear)

Corydalis flexuosa 'Purple Leaf' ('Purple Leaf' blue fumeroot)

Dahlia 'Bednall Beauty', 'Yellow Hammer', 'Bishop of Llandaff' (dahlias)

Eupatorium rugosum 'Chocolate' ('Chocolate' white snakeroot)

Geranium pratense 'Midnight Reiter' ('Midnight Reiter' meadow cranesbill)

Heuchera cvs., such as 'Palace Purple', 'Cathedral Windows', 'Velvet Night' (alumroots, coral bells)

**Ipomoea batatas* 'Blackie', 'Black Heart' ('Blackie' and 'Black Heart' sweet potato vines)

Lysimachia ciliata 'Atropurpurea' ('*Atropurpurea*' fringed loosestrife)

Persicaria microcephala 'Red Dragon' ('Red Dragon' knotweed)

Polemonium yezoense 'Purple Rain' ('Purple Rain' Jacob's ladder)

**Ricinus communis* (castor bean)

Sedum 'Matrona', 'Vera Jameson' ('Matrona' and 'Vera Jameson' sedums)

**Solenostemon scotellarioides* cvs. (coleus)

*tender perennial

Glossy

Ajuga reptans (common bugleweed)

Asarum europaeum (European wild ginger)

Astilbe spp. (false spireas)

Bergenia cordifolia (heart-leaved bergenia)

Chelone spp. (turtleheads)

Colchicum spp. (colchicums, meadow saffrons)

Darmera peltata (umbrella plant)

Epimedium spp. (fairy wings, barrenworts)

Helleborus spp. (hellebores, Christmas roses, Lenten roses)

Heuchera micrantha var. *diversifolia* 'Palace Purple' ('Palace Purple' alumroot)

Hosta spp. (hostas)

Liriope muscari (blue lily turf)

Pachysandra spp. (pachysandras, spurges)

Paeonia spp. (peonies)

Phygelius spp. (cape fuchsias, cape figworts)

Polystichum spp. (holly ferns, sword ferns)

Stokesia laevis (Stokes' aster)

Specimen

Acanthus spp. (bear's-breeches)

Angelica spp. (angelicas, archangels)

Aralia spp. (spikenards)

Astilboides tabularis (astilboides)

**Canna* x *generalis* (canna)

Crambe spp. (crambes, kales)

Cyathea cooperi (lacy tree fern)

Darmera peltata (umbrella plant)

Filipendula spp. (meadowsweets, queen of the meadows)

Hedychium spp. (ginger lilies, garland lilies)

Hosta spp., such as 'Great Expectations', 'Krossa Regal', 'Sum and Substance', 'Blue Mammoth', 'Big Daddy' (large-leaved hostas)

Inula spp. (elecampanes, inulas)

Kirengeshoma palmata (Japanese yellow bells)

Lespedeza spp. (bush clovers)

Ligularia spp. (ligularias, groundsels), *Matteuccia struthiopteris* (ostrich fern)

Miscanthus spp. (Japanese silver grasses)

Onoclea sensibilis (sensitive fern)

Osmunda spp. (flowering ferns)

Rheum spp. (rhubarbs)

Rodgersia spp. (rodgersias, Roger's-flowers)

Silphium spp. (rosinweeds, compass plants)

Symphytum x *uplandicum* (Russian comfrey)

Telekia speciosa (telekia)

Yucca spp. (yuccas, Adam's needles)

Perennials By Care Requirements

If you're a busy gardener or you have extensive gardens, you probably want to look for the easy-care perennials and avoid those fussy types that require tons of coddling, primping, and other maintenance. If a perennial you're considering isn't on one list or the other, consider it to require moderate care—maybe some deadheading, watering during dry spells, cutting back, or dividing occasionally—and plant or avoid accordingly.

Easy Care

Acanthus spp. (bear's-breeches)

Aconitum spp. (monkshoods)

Actaea spp. (baneberries)

Agapanthus spp. (lilies of the Nile, African lilies)

Alchemilla spp. (lady's-mantles)

Amsonia spp. (blue stars, amsonias)

Armeria spp. (thrifts)

Aruncus spp. (goat's beards)

Astilbe spp. (false spireas)

Baptisia spp. (false indigos, wild indigos)

Bergenia spp. (bergenias, winter begonias)

Cimicifuga spp. (bugbanes, cohoshes, snakeroots)

Dicentra spp. (bleeding hearts)

Dictamnus albus (gas plant)

Digitalis spp. (foxgloves)

Echinacea spp. (coneflowers)

Echinops spp. (globe thistles)

Epimedium spp. (fairy wings, barrenworts)

Eryngium spp. (sea hollies, eryngos)

Euphorbia spp. (spurges, euphorbias)

Gaura lindheimeri (white gaura)

Geranium spp. (geraniums, cranesbills)

Gypsophila spp. (baby's-breaths)

Helleborus spp. (hellebores, Christmas roses, Lenten roses)

Continued →

Hemerocallis spp. (daylilies)
Heuchera spp. (alumroots, coral bells)
Hosta spp. (hostas, plaintain lilies, funkias)
Kirengeshoma spp. (yellow bells, wax bells)
Kniphofia spp. (torch lilies, red-hot pokers)
Liatris spp. (gayfeathers, blazing-stars)
Limonium spp. (sea lavenders, statices)
Lysimachia spp. (loosestrifes)
Paeonia spp. (peonies)
Papaver orientale (Oriental poppy)
Pennisetum spp. (fountain grasses)
Perovskia atriplicifolia (Russian sage)
Platycodon grandiflorus (balloon flower)
Rheum spp. (rhubarbs)
Thalictrum spp. (meadow rues)
Thermopsis spp. (bush peas, thermopsis)
Veronicastrum virginicum (Culver's root)
Yucca spp. (yuccas, Adam's needles)

Intensive Care

Delphinium cvs. (delphiniums)
Eremurus spp. (foxtail lilies, desert-candles)
Fritillaria spp. (fritillaries, checkered lilies)
Lewisia spp. (lewisias)
Lupinus cvs. (lupines)
Meconopsis spp. (meconopsis)
Penstemon spp. (beardtongues, penstemons)
Primula spp. (primroses, cowslips)

Perennials By Preferred Conditions

Sun or shade. Hot or cool. Wet or dry. Like us, perennials have their preferences. Check this section to find perennials that match your garden's conditions.

Hot and Dry, Sunny

Achillea spp. (yarrows)
Agapanthus spp. (lilies of the Nile, African lilies)
Agastache spp. (anise hyssops)
Agave spp. (agaves)
Allium spp. (ornamental onions)
Anthemis tinctoria (golden marguerite)
Artemisia spp. (artemisias, wormwoods)
Asclepias tuberosa (butterfly weed)
Calamintha nepeta (calamint)
Callirhoe involucrata (purple poppy mallow)
Centranthus ruber (red valerian)
Chrysopsis spp. (golden asters)
Delosperma spp. (ice plants)
Dianthus gratianopolitanus (cheddar pinks)
Echinacea spp. (coneflowers)
Echinops spp. (globe thistles)
Eryngium spp. (sea hollies, eryngos)
Euphorbia spp. (spurges, euphorbias)
Festuca glauca (blue fescue)
Gaillardia spp. (blanket flowers)
Gaùra lindheimeri (white gaura)
Helianthus spp. (sunflowers)
Helictotrichon sempervirens (blue oat grass)
Iris bearded hybrids (bearded irises)
Knautia macedonica (knautia)
Lavandula spp. (lavenders)
Limonium latifolium (sea lavender)
Nepeta spp. (catmints, nepetas)
Oenothera spp. (evening primroses)
Opuntia spp. (prickly pears)
Penstemon spp. (beardtongues, penstemons)
Perovskia atriplicifolia (Russian sage)
Phlomis spp. (Jerusalem sages)
Phormium spp. (phormiums, New Zealand flax)
Romneya coulteri (matilja poppy)
Salvia spp. (sages)
Santolina chamaecyparissus (lavender cotton)
Schizachyrium scoparium (little bluestem)
Verbascum spp. (mulleins)
Verbena spp. (verbenas, vervains)
Veronicastrum virginicum (Culver's root)
Yucca spp. (yuccas, Adam's needles)

Moist Soil, Sunny

Agastache spp. (anise hyssops)
Alstroemeria spp. and hybrids (alstroemerias)
Amsonia spp. (blue stars, amsonias)
Anemone x *hybrida* (Japanese anemone)
Aster x *frikartii* (Frikart's aster)
Astrantia major (masterwort)
Baptisia spp. (false indigos, wild indigos)
Calamagrostis x *acutiflora* (feather reed grass)
Canna x *generalis* (canna)
Coreopsis spp. (tickseed, coreopsis)
Crocosmia x *crocosmiiflora* (crocosmia)
Digitalis spp. (foxgloves)

Geranium spp. (geraniums, cranesbills)
Hedychium spp. (ginger lilies, garland lilies)
Helianthus angustifolius (swamp sunflower)
Hemerocallis spp. (daylilies)
Heuchera x *brizoides* (hybrid coral bells)
Kalimeris spp. (Mongolian asters, Japanese asters)
Kniphofia spp. (torch lilies, red-hot pokers)
Lespedeza spp. (bush clovers)
Leucanthemum x *superbum* (Shasta daisy)
Liatris spp. (gayfeathers, blazing-stars)
Molinia caerulea (purple moor grass)
Paeonia spp. (peonies)
Patrinia spp. (patrinias)
Penstemon digitalis (foxglove penstemon)
Phlox spp. (phlox)
Platycodon grandiflorus (balloon flower)
Silphium spp. (rosinweeds, compass plants)
Solidago spp. (goldenrods)
Tanacetum parthenium (feverfew)
Veronica spp. (speedwells)

Wet Soil, Sunny

Acorus spp. (sweet flags)
Alchemilla spp. (lady's-mantles)
Asclepias incarnata (swamp milkweed)
Boltonia asteroides (boltonia)
Caltha palustris (marsh marigold, cowslip)
Canna spp. (cannas)
Carex elata 'Aurea' (Bowles' golden sedge)
Chelone spp. (turtleheads)
Darmera peltata (umbrella plant)
Eupatorium spp. (Joe-Pye weeds, bonesets)
Filipendula spp. (meadowsweets, queen of the meadows)
Helenium spp. (sneezeweeds, Helen's flowers)
Hibiscus moscheutos (common rose mallow)
Iris ensata, I. pseudacorus, I. versicolor, I. virginica (Japanese iris, yellow flag iris, blue flag iris, southern blue flag iris)
Juncus spp. (rushes)
Ligularia spp. (ligularias, groundsels)
Lobelia spp. (lobelias)
Matteuccia struthiopteris (ostrich fern)
Monarda spp. (bee balms, bergamots)
Myosotis scorpioides (water forget-me-not)
Osmunda spp. (flowering ferns)
Panicum virgatum (switchgrass)
Physostegia spp. (obedient plants)
Rodgersia spp. (rodgersias, Roger's-flowers)
Sanguisorba spp. (burnets)
Sarracenia spp. (pitcher plants)
Stokesia laevis (Stokes' aster)
Thalictrum spp. (meadow rues)
Thelypteris spp. (river ferns, marsh ferns)
Veratrum spp. (false hellebores, Indian pokes)
Vernonia spp. (ironweeds)
Zephyranthes spp. (rain lilies)

Dry Shade

Anemonella thalictroides (rue anemone, windflower)
Aquilegia spp. (columbines)
Arum italicum 'Pictum' (Italian arum)
Carex morrowii and cvs., such as 'Variegata' (morrow sedges)
Covallaria majalis (lily-of-the-valley)
Chasmanthium latifolium (Northern sea oats)
Cyclamen spp. (hardy cyclamens)
Dicentra spp. (bleeding hearts)
Dodecatheon spp. (shooting-stars)
Dryopteris spp. (shield ferns, wood ferns)
Epimedium spp. (fairy wings, barrenworts)
Euphorbia amygdaloides (wood spurge)
Helleborus spp. (hellebores, Christmas roses, Lenten roses)
Hepatica spp. (*hepaticas*, liverleafs, harbingers of spring)
Heuchera americana (alumroot, rock geranium)
Pachysandra spp. (pachysandras, spurges)
Polygonatum odoratum and cvs., such as 'Variegatum' (Japanese Solomon's seals)
Polystichum spp. (holly ferns, sword ferns)

Moist Shade

Aconitum spp. (monkshoods)
Actaea spp. (bane berries)
Arisaema spp. (Jack-in-the-pulpits)
Asarum spp. (wild gingers)
Astilbe spp. (false spireas)
Astrantia spp. (masterworts)
Begonia grandis (hardy begonia)
Brunnera macrophylla (Siberian bugloss, forget-me-not)
Cimicifuga spp. (bugbanes, cohoshes, snakeroots)
Corydalis lutea (golden fumeroot)
Dicentra spp. (bleeding hearts)
Ferns

Continued ➔

Helleborus spp. (hellebores, Christmas roses, Lenten roses)
Heuchera spp. (alumroots, coral bells)
x *Heucherella alba* (white foamy bells)
Hosta spp. (hostas, plantain lilies, funkias)
Iris cristata (crested iris)
Kirengeshoma spp. (yellow bells, wax bells)
Ligularia spp. (ligularias, groundsels)
Mertensia virginica (Virginia bluebells)
Myosotis spp. (forget-me-nots)
Omphalodes spp. (navel seeds, blue-eyed Marys)
Phlox divarciata (wild blue phlox, woodland phlox)
Polygonatum spp. (Solomon's seals)
Primula spp. (primroses, cowslips)
Pulmonaria spp. (lungworts, Bethlehem sages)
Smilacina racemosa (Solomon's plume)
Tiarella spp. (foamflowers)
Tricyrtis spp. (toad lilies)
Trillium spp. (trilliums)
Trollius spp. (globeflowers)
Uvularia spp. (bellworts, merrybells)
Viola spp. (violets, violas)

Perennial Favorites

With so many beautiful, dependable perennials to choose from, deciding which ones to plant in your garden can be tough. In this section, you'll learn about 50 outstanding plants—perennials that have been loved by gardeners for years and are just waiting to grace your flowerbeds.

Choose Carefully

Once you start flipping through the following pages, you'll probably want to plant at least one of each kind of perennial listed here. But hold on a minute before you rush gung ho to your local garden center. Take the time to read the "Plant Particulars" listed for each entry—especially the appropriate USDA Plant Hardiness Zones (see chapter 1) for each perennial that interests you. Then, consider the available light as well as the soil characteristics in each area of your yard that you want to plant. The perennials you choose should be those best suited to growth in your region and under the conditions specific to your landscape.

Plant shape, spread, height, color, and bloom time also are important factors to consider when choosing perennials. If you have limited room, rule out plants that spread aggressively, or they'll quickly invade the rest of your space. Also, make sure that the shapes, heights, and colors of your chosen plants work with the overall design you have in mind.

Express Yourself

Now go ahead—turn the page and start dreaming about the art you'll create in your garden. Remember, anyone can create a masterpiece with perennials!

Achillea

(Yarrow)

PLANT PARTICULARS

Zones: 3 to 9

Height: 1 to 4 feet

Spread: Strong spreaders; depending on species, can spread between 1 and 5 feet

Shape: Spreading clumps of stiff, upright flowerstalks

Color: White, pink, red, or yellow flowers; green or gray leaves

Bloom time: Late spring or summer to early fall

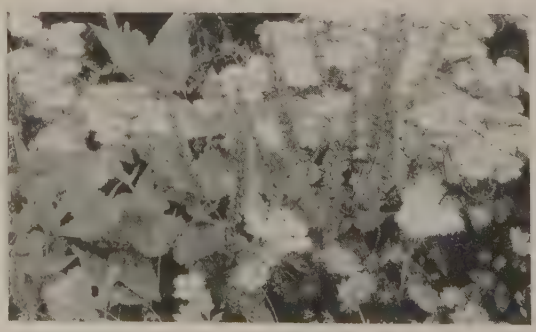
Light needs: Full sun to partial shade

Soil: Average to poor; dry but well drained

Yarrows are the perfect perennials to add some spice to your garden—literally—because their foliage has a spicy aroma. In addition to smelling good, yarrows are also attractive. Their showy, flattened flower heads are made up of many tiny, tightly packed flowers and their leaves are feathery. These extremely versatile plants work well in formal or informal borders and soften bold textures. Definitely plant yarrows along a walkway, where you'll be sure to brush against them, releasing their fragrance.

These low-maintenance plants thrive with little care. However, they do spread rapidly, so divide your plants every 3 to 5 years. In early spring or fall, dig up a clump, remove any dead stems from its center, break up the clump, and relocate the new plants.

Yarrows are excellent for cutting and for use in fresh and dried flower arrangements. To enjoy the flowers after the growing season has ended, cut the blooms before their color starts to fade; tie the stems in bunches; and hang them upside down in a dark, airy room (such as an attic) until dry.



Achillea x 'Moonshine'

Alchemilla

(Lady's-Mantle)

PLANT PARTICULARS

Zones: 3 to 8

Height: 6 to 12 inches

Spread: 1 to 2 feet

Shape: soft mounds

Color: Chartreuse flowers; gray-green leaves

Bloom time: Spring, early summer

Light needs: Sun to partial shade

Soil: Rich, moist

The leaves of lady's-mantle have an interesting feature: downy hairs. When water beads up on the leaves, the effect is an enchanting, jeweled display that's hard to beat. The plant also will reward you with clouds of lovely flowers and lush clumps of soft, fan-shaped foliage. This perennial works well at the front of the perennial border, along a wall, or edging a walk. Try pairing it with upright perennials, such as Siberian iris and astilbes. The small variety of lady's-mantle (*A. alpina*) is perfect for rock gardens and containers.

By midsummer, the leaves of lady's-mantle can look rather tired. To perk up the plant and encourage new foliage growth, cut it back to the ground. (The plants will quickly produce a new set of leaves.) If you live in a region where the temperature really climbs during the summer, choose a partially shaded site for best growth and flowering.

Lady's-mantle will often self-sow; cut off spent flowers to prevent reseeding. Relocate new seedlings to extend an edging all along a bed. Divide overgrown clumps in spring or fall.

Anemone

(Anemone, Windflower)

PLANT PARTICULARS

Zones: 3 to 9

Height: 4 inches to 5 feet

Spread: 18 to 24 inches

Shape: Varies among species

Color: White, pink, red, purple, or blue flowers with yellow centers; deep green foliage

Bloom time: Spring, summer, fall

Light needs: Full sun to partial shade

Soil: Fertile but well drained

One of the great things about anemones is that they come in spring-, summer-, and fall-blooming varieties—which means you can have a full season of anemone color. Anemones have fragile, five-petaled flowers with fuzzy, bright yellow centers. These perennials can work well as mass plantings, in combination with spring bulbs, under shrubs, or as a groundcover, depending on the variety.

If you have room for only one anemone, make it a Japanese anemone (*Anemone x hybrida*). This fall-blooming beauty has single or double flowers on 3- to 5-foot stems. Combine Japanese anemones with bleeding hearts and other early bloomers; the anemone foliage will fill the space when the other plants go dormant.

To increase your anemone collection, divide spring-blooming types after flowering and summer and fall bloomers in spring.

Note: All anemones are poisonous if eaten, so you might want to avoid planting them if small children frequently visit your garden.

Aquilegia

(Columbine)

PLANT PARTICULARS

Zones: 3 to 9

Height: 6 inches to 4 feet

Spread: 1 foot

Shape: Open clumps

Color: Blue, maroon, pink, purple, red, white, or yellow flowers; blue-green to green leaves

Bloom time: Late spring to early summer

Light needs: Full sun to partial shade

Soil: Average to rich; moist but well drained

If you want to attract hummingbirds to your garden, then add columbine to your beds. Each blossom has five petals, which form a tube that holds the nectar that hummingbirds desire. These delicate-looking perennials come in shades of blue, maroon, pink, purple, red, white, or yellow that add charm to borders, woodland gardens, and rock gardens and also bridge the spring and summer bloom seasons. Combine them with late-blooming tulips to finish the spring show, and with irises and peonies to start your summer display. They also look super around the base of tall, shrubby perennials, such as baptisias and delphiniums.

In mid- to late summer, the urn-shaped seedpods will drop lots of seed and self-sow. To prevent self-sowing, pinch off spent flowers. Otherwise, relocate the seedlings in spring.

Squiggly lines on your columbine leaves indicate that leafminers are at work. Immediately pinch off and destroy the damaged leaves, and check the plants frequently for more signs of damage. If the problem is severe, spray the plants weekly with insecticidal soap.

Continued →

Artemisia

(Artemisia, Wormwood)

PLANT PARTICULARS

Zones: 3 to 9

Height: 10 inches to 6 feet

Spread: Strong spreaders; depending on species, can spread between 6 and 30 inches

Shape: Varies among species

Color: Yellowish or grayish flowers; green to silver leaves

Bloom time: Summer, fall

Light needs: Full sun

Soil: Average, dry but well drained

These aromatic plants are indispensable for adding year-round foliage interest to beds and borders. Artemisias have showy green or gray foliage and yellowish or grayish flowers, which appear late in the season. Some varieties form shrubby, mounding clumps. Plant artemisias to contrast with bright colors in your garden (especially hot pinks, reds, and oranges) or to cool pastels (such as soft pinks, purples, and blues).

If you prefer low-maintenance plants, then artemisias are the perennials for you. And once established, most of them are extremely drought tolerant. If you live in a warm, humid region, plant upright varieties instead of the mounding ones, because the mounding varieties tend to fall open from the center. All artemisia varieties should be pruned back hard if they start to lose their form.

Aster

(Aster)

PLANT PARTICULARS

Zones: 2 to 8

Height: 6 inches to 8 feet

Spread: Varies among species

Shape: Varies among species

Color: Blue, purple, red, pink, or white flowers; green leaves

Bloom time: Late summer to late fall

Light needs: Full sun to light shade

Soil: Average; moist but well drained

Bushy and beautiful, asters offer masses of showy, daisylike blooms that are ideal for edgings, containers, meadow and woodland gardens, and at the backs of beds and borders. Although you might think of asters as being primarily fall plants, many varieties begin blooming in late summer—and they come in a rainbow of colors. To create layers of texture and color, try backing pink asters with Russian sage and yellow coneflowers. Asters also pair well with ferns and wildflowers.

Tall asters probably will need staking. You also can cut them back by half in midsummer to promote sturdier stems and more branching. For bushier fall plants, pinch or shear asters in the spring or early summer. Divide plants every year or two to control their spread, rejuvenate overgrown clumps, or increase your plantings. To avoid powdery mildew, avoid wetting the leaves when watering.

Astilbe

(Astilbe, False Spirea)

PLANT PARTICULARS

Zones: 3 to 9

Height: 8 inches to 5 feet

Spread: 1 to 3 feet

Shape: Clumps of upright or cascading flowerstalks

Color: Red, magenta, rose, pink, lavender, lilac, cream, or white flowers; leaves are green or reddish

Bloom time: Late spring, summer

Light needs: Full sun to deep shade

Soil: Average; moist but well drained

If you're looking for a way to add some color to a moist, shady area of your yard, then astilbes are the perennial for you. These regal plants have airy plumes of densely packed, tiny flowers that range in color from red through all shades of magenta, rose, and pink to lavender, lilac, cream, and white. The shape of the flower clusters differs by variety; some are stiff and upright, others are open plumes, and still others cascade outward like fireworks. Astilbe leaves are fernlike and have a coppery or reddish sheen in spring.

These long-lived, low-maintenance plants are perfect companions to ferns, irises, and other moisture-loving plants. You might want to try a mass of astilbes around a water garden, where the water will reflect the flower's colorful blooms.

During the summer, snip a few of the flowers to enjoy in arrangements indoors; leave the rest to mature on the plants for winter interest.

Baptisia

(Baptisia, False Indigo)

PLANT PARTICULARS

Zones: 3 to 9

Height: 1 to 5 feet

Spread: 3 to 4 feet

Shape: Clumps of upright flowerstalks

Color: Blue, yellow, cream, or white flowers; gray-green or bluish leaves

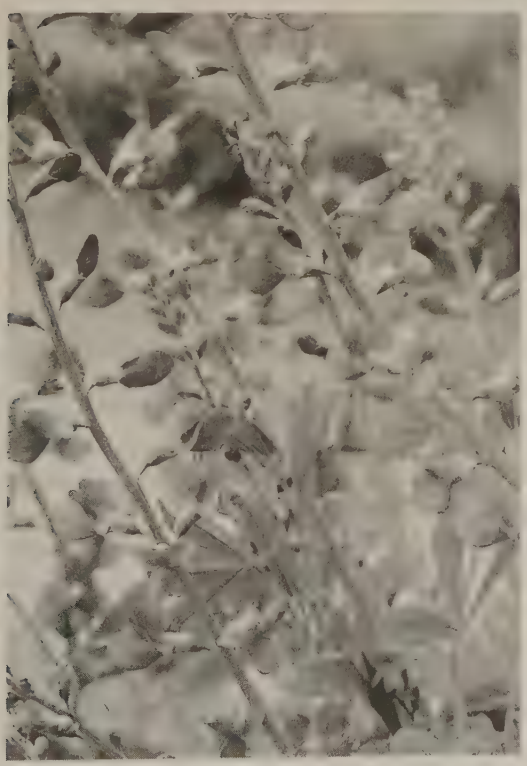
Bloom time: Late spring to early summer

Light needs: Full sun to partial shade

Soil: Rich; moist but well drained

Plant them and forget them—that's the key to growing baptisias. These durable plants can live in the same spot for years without division, slowly forming shrublike clumps. Baptisias have colorful spikes of pealike flowers in blue, yellow, cream, and white with gray-green or bluish leaves. They're excellent border plants; use them toward the back of the border in the company of bold flowers such as peonies, oriental poppies, and irises. After flowering, baptisias make a good background for late-blooming perennials. Baptisias also produce showy gray or brown seedpods; cut them for arrangements or leave them on the plants for off-season interest.

Have patience when growing baptisias; they grow slowly at first and may require at least 5 years to reach their full growth. In some spots, baptisias may need staking; place rounded peony hoops over the clumps as they emerge in early spring to keep the plants from toppling over.



Baptisia australis (blue false indigo)

Boltonia

(Boltonia)

PLANT PARTICULARS

Zones: 3 to 9

Height: 4 to 6 feet

Spread: 3 to 4 feet

Shape: Tall, rounded

Color: Pink, purple, or white flowers with yellow centers; blue-green leaves

Bloom time: Late spring to midfall

Light needs: Full sun to light shade

Soil: Rich; moist or dry

Add a cool touch to late summer and early fall borders and wildflowers gardens with boltonia. This elegant perennial has blue-green leaves and purple, pale pink, or snowy white flowers with yellow centers. It's easy to grow, and it will deliver blooms in poor, dry soil as well as rich, moist soil. (Just keep in mind that the plant will be smaller in dry soil than it would be in moist soil.) For an elegant, all-white combination, try 'Snowbank' boltonia with a white-variegated ornamental grass and a white-flowered Japanese anemone.

Cut back boltonias by half in early to midsummer to encourage bushiness and flowering. You can leave the stems standing after they've finished blooming to add interest and texture to your winter garden. If you want more boltonia plants, divide them in spring. Remove the dead centers and replant the vigorous outer portions.

Campanula

(Bellflower)

PLANT PARTICULARS

Zones: 2 to 8

Height: 4 inches to 5 feet

Spread: Varies among species

Shape: Varies among species

Color: Purple, blue, white, or pink flowers; green leaves

Bloom time: Spring, summer

Light needs: Full sun to partial shade

Soil: Average to rich; well drained

These easy-care perennials have bell- or star-shaped flowers. They come in many different varieties, which range from low, mat-forming creepers to tall, upright plants. Choose the low-growing varieties for rock gardens and informal rock walls. The blue and purple flowers contrast well with rocks and will soften

Continued ➔

even the harshest rock surface. Use the taller varieties in beds and borders, or along walls and fences. They're also lovely in large drifts. Create stunning color combinations by grouping blue bellflowers with bright yellow yarrow, pure white peonies, and/or pretty pink astilbes.

Divide bellflowers in early spring or fall to control their spread or rejuvenate crowded clumps. Slugs are the only serious threats to bellflowers; use a dish of beer as bait to drown these pests.

Chrysanthemum

(Chrysanthemum)

PLANT PARTICULARS

Zones: 3 to 11

Height: 1 to 5 feet

Spread: Varies among species

Shape: Varies among species

Color: White, yellow, orange, red, pink, or purple; leaves various shades of green

Bloom time: Summer to fall

Light needs: Full sun

Soil: Average to rich; well drained

With so many different varieties of this perennial, you could have some sort of chrysanthemum (often shortened to "mum") blooming in your garden from early summer 'til frost. The daisylike flowers are available in shades of white, yellow, orange, red, pink, or purple. Shasta daisies and garden (hardy) mums are both types of chrysanthemums.

Mums are so varied in bloom time, color, size, and adaptability that they have a place in almost every garden. Shasta daisies, for example, are classics for the early summer garden. These white blooms create quite a pretty sight when paired with Siberian irises. And what would fall be without bright garden mums? They're perfect for tucking into bare spots in the garden left by worn-out annuals or for grouping in containers when most plants have stopped blooming for the season. Other mums work well as edging plants and at the back of beds or borders.

Coreopsis

(Coreopsis)

PLANT PARTICULARS

Zones: 3 to 9

Height: 1 to 9 feet

Spread: Varies among species

Shape: Varies among species

Color: Yellow or pink flowers; green leaves

Bloom time: Early summer to midfall

Light needs: Full sun

Soil: Average to poor; dry but well drained

Cheerful coreopsis is a dependable, easy-care plant that will bloom for months as long as you remove the spent flowers. The daisylike blooms are a welcoming sight in summer beds and borders. Coreopsis combines well with asters, irises, blanket flowers, purple coneflowers, and phlox. 'Moonbeam' (*c. verticillata*) is a particularly outstanding variety; its light yellow flowers look beautiful paired with other soft colors, such as pink, blue, and lavender. For brighter yellow blooms, look for 'Zagreb'.

Coreopsis is an especially good choice for beginning gardeners. The plants grow rapidly from seed and, once established, are quite drought-tolerant and even thrive under stress. However, they do need well-drained soil and may rot if planted in a location where water puddles. They may also flop over in soil that's too rich. Divide overgrown or declining plants in spring or fall.

Delphinium

(Delphinium, Larkspur)

PLANT PARTICULARS

Zones: 3 to 8

Height: 1 to 6 feet

Spread: Varies among species

Shape: Varies among species

Color: Blue, purple, pink, or white flowers; green leaves

Bloom time: Late spring, summer; fall rebloom

Light needs: Full sun

Soil: Rich; moist but well drained

These tall, sturdy, old-fashioned perennials are perfect for adding vertical accents to your garden. Their towers of showy flowers are traditional favorites for early summer color in beds, borders, and cottage gardens. Try placing them at the rear of a border, where their spikes can be highlighted against a wall or hedge. Create eye-catching contrasts by pairing delphiniums with bushy, mounded perennials such as peonies and baby's breath. To accent a wall or a fence, plant bold masses of mixed colors.

Encourage plants to rebloom by cutting off the spent flowers just above the top leaves. When the leafy stems begin to die back, cut them down to the new growth at the base of the plant.

Delphiniums are short-lived perennials, which means they fade out after 2 or 3 years in the garden. To propagate them, sow seeds outdoors in late summer; the seeds will grow and bloom the following season.

Dianthus

(Pinks, Carnation)

PLANT PARTICULARS

Zones: 3 to 9

Height: 3 inches to 2 feet

Spread: 8 to 18 inches

Shape: Mounds or mats

Color: White, pink, or red flowers; blue-green leaves

Bloom time: Spring, summer

Light needs: Full sun to light shade

Soil: Average; moist to dry

Pinks are beloved for their old-fashioned charm and delightful spicy-sweet fragrance. Their delicate flowers have fringed petals that complement their slender leaves. What's more, the foliage holds its color year-round, making this perennial attractive even when it's not blooming.

Most varieties of pinks are low-growing, clump-forming plants that are perfect additions to rock gardens and border edgings, and great for use as ground covers. Plant them on top of a retaining wall so you won't have to kneel down to enjoy their scent. Silvery-leaved plants, such as lamb's-ears and artemisias, make striking companions for pinks' bright blooms.

Pinks spread quickly and are often short-lived, so divide the clumps every 2 or 3 years to keep the plants vigorous. If you remove the spent flowers regularly, you'll usually be able to keep your pinks in bloom for 6 weeks or more.

Dicentra

(Bleeding Heart)

PLANT PARTICULARS

Zones: 2 to 9

Height: 8 inches to 2½ feet

Spread: Varies by species

Shape: Soft mounds

Color: Pink or white flowers; green to blue-green leaves

Bloom time: Spring, summer

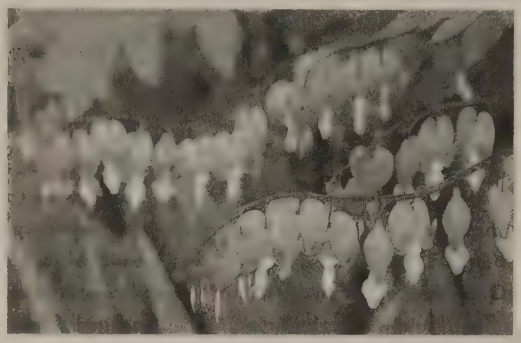
Light needs: Full sun to full shade

Soil: Rich; moist but well drained

The unique flowers of this perennial, which resemble pink or white hearts with drops of blood on their tips, add splashes of color to any shade or woodland garden. Its feathery, fernlike foliage is a nice contrast to the plant's blooms. Some varieties are tall (common bleeding heart, *D. Spectabilis*) and bloom in the spring, whereas others (fringed bleeding heart, *D. eximia*) are much smaller and bloom in summer.

Because common bleeding heart often goes dormant by midsummer, pair it with bushy plants, such as asters and baby's breath, that will fill the space it leaves. Common bleeding heart also works well with daffodils, tulips, peonies, irises, and primroses. For a steady display of flowers from spring until frost, plant fringed bleeding heart with ferns, wildflowers, and shade-loving hostas.

Divide overgrown clumps of bleeding hearts in the fall or as they go dormant. The plants often self-sow; either remove spent flowers to prevent self-sowing or transplant the seedlings.



Dicentra spectabilis 'Alba'

Digitalis

(Foxglove)

PLANT PARTICULARS

Zones: 3 to 8

Height: 2 to 5 feet

Spread: 1 to 2 feet

Shape: Erect flower spikes

Color: Pink, rose, white, or yellow flowers; green leaves

Bloom time: Summer

Light needs: Full sun to partial shade

Soil: Rich; moist but well drained

Here's a plant that deer seem to avoid. These stout perennials have leafy stems and tall spikes of funnel-like flowers in shades of pink, rose, white, and yellow. The insides of the plants are often spotted. Most foxgloves are either biennials (they live 2 years) or short-lived perennials (they live about 3 years).

These striking blooms perfectly punctuate the summer border, and their upright form is a welcome contrast to mounded plants such as hostas and peonies. They also look super with ferns and hostas in shade and woodland plantings. For compact, easy-care color, try perennial yellow foxglove (*D. grandiflora*). Its 2- to 3-foot spikes of soft yellow flowers combine beautifully with blues, pinks, and whites.

Continued ➔

Common foxglove (*D. purpurea*) reaches 5 feet high when in bloom. Although it's a biennial, common foxglove acts like a perennial because it produces lots of self-sown seedlings. You can also lift the clumps after flowering, remove the bloom stalks that are spent, and replant the new rosettes in the same spot or somewhere new.

Echinacea

(Purple Coneflower)

PLANT PARTICULARS

Zones: 2 to 8

Height: 1 to 6 feet

Spread: Varies by species

Shape: Loose clumps of erect stalks

Color: Purple, pink, or white flowers; green leaves

Bloom time: Summer

Light needs: Full sun to light shade

Soil: Average; moist to dry

Butterflies love to visit purple coneflower during the blooming season, and seed-eating birds are attracted to its seedheads long after the blooms are gone. This showy perennial with daisylike flowers is also extremely heat- and drought-tolerant because the plant's thick, deep taproots store moisture in lean times. What's more, purple coneflower is about the easiest perennial to care for.

This plant is a natural choice for meadow gardens, along with ornamental grasses, goldenrods, and yarrows. In beds and borders, try pairing the bright blooms with artemisias, daylilies, coreopsis, and lamb's-ears. For a colorful late-summer display, pair purple coneflowers with black-eyed Susans.

You'll rarely need to divide purple coneflowers. (In fact, once divided, plants tend to become bushy and produce fewer flowers.) If you leave the seedheads on for winter interest, plants may self-sow.

Epimedium

(Epimedium, Barrenwort)

PLANT PARTICULARS

Zones: 3 to 8

Height: 6 to 15 inches

Spread: Varies by species

Shape: Spreading mats

Color: White, yellow, pink, or red flowers; green, yellow, or reddish leaves

Bloom time: Spring

Light needs: Partial to full shade

Soil: Average to rich; moist to dry

These tough perennials, once established, will perform admirably in dry shade or under mature trees where nothing else will grow. Most people grow epimediums as groundcovers. However, they also work well in beds, borders, and rock gardens—even in a shade garden with astilbes, hostas, primroses, wildflowers, bulbs, and ferns.

Their heart-shaped green leaves often have red highlights; their flowers bloom in early spring before the new leaves open. Although they're often touted as evergreens, epimediums tend to look tattered by midwinter. Cut them to the ground in early spring; the plants will look neater and the dainty flowers will be more visible. New leaves will emerge with or just after the flowers.

Epimediums form spreading clumps that seldom need division. But, if you want to divide your plants, do so in late summer or early fall.

Euphorbia

(Spurge, Euphorbia)

PLANT PARTICULARS

Zones: 3 to 9

Height: 6 inches to 4 feet

Spread: Varies by species

Shape: Spreading clumps

Color: Yellow flowers; green or blue-green leaves

Bloom time: Spring, summer

Light needs: Full sun to partial shade

Soil: Average to rich; dry but well drained

If you want an outstanding foliage perennial, then euphorbia is for you. Euphorbias are succulent perennials with leafy stems and milky sap that flows freely when the leaves or stems are picked or damaged. (This sap is irritating to skin, so wear gloves while working around these plants.) Combine them with other perennials or flowering shrubs at the rear of a bed or border, or use them as container plants, as a groundcover, or in a rock garden.

Cushion spurge (*E. epithymoides*) is one of the most popular species. It forms a mound of bright yellow flowers in early spring, and the leaves turn red and orange in fall. Combine its green leaves and glowing yellow petal-like bracts with brightly colored tulips for a spectacular spring display.

Euphorbias are long-lived perennials that require little care. If you live in a zone where winters are cold but you don't get a lot of snow, provide winter protection (mulch or plant covers) to prevent leaf burn and stem damage. Divide plants in spring to rejuvenate old clumps or fill out plantings.

Gaillardia

(Blanket Flower)

PLANT PARTICULARS

Zones: 2 to 10

Height: 2 to 3 feet

Spread: Varies by species

Shape: Spreading clumps

Color: Yellow, orange, red, and brown flowers; green or blue-green leaves

Bloom time: Spring, summer

Light needs: Full sun to partial shade

Soil: Average to rich; well drained

These salt- and drought-tolerant perennials are perfect for seaside gardens and seem to thrive on neglect and heat. (Surprisingly, the only place they don't grow well is in rich, moist soil, which makes them floppy and shortens their life expectancy.) Blanket flowers produce mounds of showy daisylike flowers from early summer through fall. Plant them with other warm-colored perennials such as coreopsis, butterfly weeds, and yarrows for a harmonious display. Add interest and excitement to blanket flowers by teaming them with the spiky yellow leaves of Spanish bayonet and with purple flowers, such as sage. Gaillardia is also a great cutting flower, so make sure to add some to fresh bouquets.

Pinch off spent flowers at the tip of the stem to keep plants looking tidy and to prolong the bloom season. Blanket flowers tend to be short-lived, so divide them every 2 or 3 years in early spring to keep the clumps thriving. Sow seeds outdoors in fall or sow them indoors in winter. Seedlings may bloom the first year.

Geranium

(Cranesbill, Hardy Geranium)

PLANT PARTICULARS

Zones: 3 to 8

Height: 4 inches to 3 feet

Spread: Varies by species

Shape: Soft mounds

Color: White, blue, purple, rose, or pink flowers; green leaves that turn burgundy-red, scarlet, or orange in the fall

Bloom time: Spring, early summer

Light needs: Full sun to partial shade

Soil: Rich; moist but well drained

Cranesbills will give you a long season of interest in the garden, thanks to their attractive foliage that turns colors in the fall. These geraniums have small, pretty flowers in shades of purple, rose, pink, white, or blue; the plants come in an array of heights that can fit into any planting scheme. (Don't confuse cranesbills with the tender bedding geraniums that you'll find at your local garden center—those geraniums won't survive a frost.)

A summer border wouldn't be complete without cranesbills. Combine them with bold colors and spiky forms or use them as "weavers" to tie together different combinations. Siberian iris, garden phlox, bellflowers, evening primroses, and ornamental grasses are all good companions.

It's nearly impossible to have too many of these versatile, easy-to-grow perennials, so divide and transplant existing plants in fall or early spring. Many cranesbills will also self-sow. If you catch the seeds before they're catapulted toward the neighbor's yard, sow them outdoors.

Helleborus

(Hellebore, Lenten Rose)

PLANT PARTICULARS

Zones: 3 to 9

Height: 10 inches to 2 feet

Spread: 10 to 18 inches

Shape: Clumps of flowerstalks

Color: Green, pink, purple, red, yellow, or white flowers; dark green leaves

Bloom time: Late winter to spring

Light needs: Partial shade

Soil: Rich; moist but well drained

This perennial is what you want to plant for winter and early spring bloom and lasting foliage interest. Some hellebores have noticeable stems, and others have leaves and flowers that seem to rise directly from the ground. Their flowers come in shades of green, pink, purple, red, yellow, and white, and their leathery foliage is attractive throughout the summer, long after the blooms have faded.

Try combining hellebores with flowering shrubs that have attractive bark and early flowers; red- and yellow-stemmed dogwoods, serviceberries, and purple-leaved shrubs are good choices. The smaller bulbs, such as early crocus, reticulated iris, and species forms of daffodils and tulips are also good companions. The mottled, heart-shaped foliage of spring- or fall-blooming hardy cyclamen combines nicely with the dark green of the hellebore leaves. (Take care not to plant large floppy perennials near hellebores, which may smother the hellebores and block out the sun.)

Hellebores tend to self-sow where they are happy; transplant seedlings to other parts of the garden.

Continued →

Helleborus x orientalis

Hemerocallis

(Daylily)

PLANT PARTICULARS

Zones: 2 to 9

Height: 1 to 6 feet

Spread: 1 to 5 feet

Shape: Mounds of arching leaves with clumping flowerstalks

Color: Cream, yellow, orange, red, maroon, or pink flowers; green leaves

Bloom time: Spring, summer

Light needs: Full sun to partial shade

Soil: Average to rich; dry but well drained

Tough, adaptable daylilies are easy to grow. These popular perennials have colorful flowers that each last only a day—but a profusion of new buds keeps plants in bloom for 2 to 4 weeks.

Daylilies make great companion plants for spring bulbs, such as daffodils. The bulbs bloom as the daylily leaves emerge; then, the daylily foliage takes over as the bulb leaves turn yellow in summer. These versatile 1-day wonders are great for mass plantings, especially along walls or banks, or in combination with shrubs and trees. Use daylilies as accent plantings around foundations or with groundcovers.

Once established, daylilies spread quickly to form dense, broad clumps. Although you can leave the plants in place for years, some varieties produce so many stalks that the flowers get too crowded if the clumps aren't divided every 3 years or so. Lift the entire clump in late summer, pull or cut the thick tangled roots apart, and replant.

Heuchera

(Alumroot, Coral Bells)

PLANT PARTICULARS

Zones: 3 to 9

Height: 1 to 3 feet

Spread: 12 to 18 inches

Shape: Mounds of leaves with taller flower spikes

Color: White, pink, or red flowers; green to dark red leaves

Bloom time: Spring, summer

Light needs: Full sun to partial shade

Soil: Rich; moist but well drained

This group of perennials is made up of lovely foliage plants, many of which also have showy flowers. The evergreen leaves of heuchera are rounded, heart-shaped, or triangular and have long slender leafstalks. The white, pink, or red flowers hang daintily in clusters from the leafstalks.

Plant these versatile perennials in containers, in rock or woodland gardens, as groundcovers, or in a mixed border. The flower clusters add an airy look to summer beds and borders, and the mounds of green foliage are excellent for edging. Make the most of heuchera leaves by pairing them with bright flowers, like red pansies.

Prolong heuchera bloom by removing the spent flowerstalks at the base of the plants. As heucheras grow, they produce woody crowns. Divide the crowns every 3 or 4 years in spring or fall.

In warm regions, provide shade from the hot afternoon sun to keep the leaves from bleaching.

Hosta

(Hosta, Plantain Lily)

PLANT PARTICULARS

Zones: 3 to 8

Height: 6 inches to 3 feet

Spread: Varies by species

Shape: Wide mounds of leaves with taller flower spikes

Color: Lilac, white, or purple flowers; green, yellow, blue-green, and/or cream leaves

Bloom time: Summer to fall

Light needs: Light to full shade

Soil: Average to rich;moist

The bold, dramatic foliage of hostas is perfect for brightening up a shady area of your landscape. Their leafy clumps vary greatly in size, and come in a range of colors from deep green through chartreuse, yellow, and gold to blue. Leaves are oval, heart-shaped, or lance-shaped with smooth or wavy edges. Some varieties even produce spiky bloom stalks with white, lilac, or purple flowers.

Plant hostas with ferns, wildflowers, and other shade-loving perennials on the north side of your house or under the canopy of large trees. Or, interplant them with ferns and wild ginger for a beautiful shady groundcover. You can also plant them with early spring bulbs. The hostas will unfurl their leaves just when the bulb foliage starts to look shabby.

Hostas grow slowly and may take 2 to 4 years to reach their full size. Allow plenty of room when you plant them to accommodate for their mature size. Small varieties spread three times as wide as they are tall. Medium-sized varieties spread twice their height, and the large ones are at least as wide as they are tall.

Iberis

(Candytuft)

PLANT PARTICULARS

Zones: 2 to 9

Height: 3 to 12 inches

Spread: Varies by species

Shape: Low creeping mats

Color: White flowers; shiny evergreen leaves

Bloom time: Early spring

Light needs: Full sun to light shade

Soil: Average; well drained

Lovely long-flowering perennials are a must for the spring garden. And that includes perennial candytuft (*I. sempervirens*), which offers tidy mounds of evergreen leaves that are covered in flat clusters of white flowers in early spring.

Candytuft is the consummate edging plant. Its low and compact growth, early flowers, and evergreen foliage make it perfect for planting along stairs or walks, or in the front of a bed or border. In rock gardens, combine candytuft with spring bulbs, bleeding hearts, rock cresses, and purple rock cress. In a border, plant it with tulips, columbines, forget-me-nots, and spring bulbs. Planted in raised beds or atop retaining walls, it can cascade over the side.

After the plants have bloomed for the season, cut them back by about one-third to remove the spent flowers to encourage compact growth and good foliage. Prune them hard, at least two-thirds back, every 2 to 3 years to encourage new stem growth and to promote flower production. These plants seldom need division.

Iris

(Iris)

PLANT PARTICULARS

Zones: 2 to 10

Height: 4 inches to 4 feet

Spread: Varies by species

Shape: Upright spiky clumps

Color: White, yellow, orange, brown, pink, purple, or blue flowers; green leaves

Bloom time: Spring, summer

Light needs: Full sun to light shade

Soil: Varies widely by species

An iris exists for every garden situation: sun or shade, moist or dry soil, early or late bloom. In addition, you're sure to find a color to suit your taste, because bloom colors include white, pink, red, purple, blue, yellow, and brown. You can choose from a host of different species, which include bearded irises, Siberian irises, reticulated irises, and yellow flag irises. Different species bloom at different times from winter through summer, so you can enjoy this perennial practically year-round. Many irises are excellent for cutting.

Bearded and Siberian irises are well suited to beds and borders with spring and early-summer perennials. Combine their strap-shaped foliage with peonies, hostas, cranesbills, and columbines. Plant moisture-loving yellow flag irises with ferns, hostas, and other lush perennials along the sides of ponds. Smaller iris species are perfect in rock gardens or at the front of a border.

If you want to divide your irises, do so after they've finished flowering in summer or early fall. Replant them immediately.

Liatris

(Gayfeather, Blazing-Star)

PLANT PARTICULARS

Zones: 3 to 9

Height: 6 inches to 3 feet

Spread: 18 to 24 inches

Shape: Clumps of upright flowerstalks

Color: Purple, pink, or white flowers; green leaves

Bloom time: Summer

Light needs: Full sun

Soil: Average to rich; well drained

Plant some of these perennials, and you're sure to attract butterflies, which love the upright, fuzzy spikes and profusion

Continued ➔

of small red-violet to purple flowers. The spikes of gayfeathers open from the top down, unlike those of most other spike-flowering perennials, which open from the bottom up.

These native American perennials are a natural choice for meadow gardens, prairie plantings, and borders. In a border, combine them with yarrows, purple coneflowers, artemisias, Shasta daisies, garden phlox, and ornamental grasses. If you want to tone down pinkish purple varieties, pair them with silvery lamb's-ears. To jazz them up, plant them with coreopsis or yellow coneflower. And don't forget to include gayfeathers in your cutting garden; they're great for fresh-flower arrangements.

You don't need a green thumb to grow gayfeathers because they're tough, low-maintenance, long-lived perennials. If you leave them alone, they'll form large clumps; if you want to create new plants, divide the clumps in the fall.

Liatris spicata 'Kobold'

Lilium

(Lily)

PLANT PARTICULARS

Zones: 2 to 9

Height: 1 to 7 feet

Spread: Varies by species

Shape: Tall, slender stalks topped with a cluster of flowers

Color: White, yellow, orange, red, or pink flowers, green leaves

Bloom time: Spring, summer

Light needs: Full sun to partial shade

Soil: Average; well drained

This large group of plants offers such a wide range of sizes, colors, and shapes that you're sure to find some to suit your garden. These perennials grow from bulbs that lack the papery brown covering (tunic) of bulbs such as tulips and daffodils. From the center of the bulb rises a tall stalk, which is clothed in leaves that may be narrow and grasslike, or wide and more swordlike. Nodding or upright flowers may be trumpet-, star-, or bowl-shaped. Lilies are available in various bloom colors, many of which have dark spots or streaks on the petals.

Combine lilies with baby's breath, hostas, asters, and other bushy perennials that will hide the bases of the lily stems. Or, plant generous groupings with ornamental grasses and vines.

If you plant tall lilies, you'll probably need to stake them. Insert a stake near the stem, taking care not to spear the bulb when you put the stake in the ground. Tie the stem loosely to the stake.

Lobelia

(Lobelia)

PLANT PARTICULARS

Zones: 2 to 9

Height: 2 to 4 feet

Spread: 1 to 2 feet

Shape: Erect spikes

Color: Red, purple, blue, white, or pink flowers; green leaves

Bloom time: Summer, fall

Light needs: Full sun to partial shade

Soil: Rich; constantly moist

Hummingbirds love these perennials, particularly *L. cardinalis*, or cardinal flower. (Butterflies love them, too.) Lobelias produce erect spikes of irregularly shaped tubular flowers that come in many colors including blue and pink.

Lobelias are best suited to gardens with moist soil, especially along ponds and streams. They are good border plants, as long as the soil doesn't dry out. Plant them in the company of Siberian and Japanese irises, astilbes, ferns, and bold foliage plants such as hostas. Combine them with other moisture-tolerant border perennials such as daylilies, spiderworts, garden phlox, and sneezeweed. Great blue lobelia (*L. siphilitica*) has subtle blue flowers that mix well with goldenrods and ornamental grasses.

Although they tend to be short-lived, lobelias can produce many seedlings for transplanting; remove the flower spikes after blooming if you want to prevent self-sowing. Divide clumps in early fall to help plants perform well for several seasons.

Lupinus

(Lupine)

PLANT PARTICULARS

Zones: 2 to 7

Height: 18 inches to 5 feet

Spread: 1 to 2 feet

Shape: Mounds of leaves with tall flower spikes

Color: White, pink, purple, blue, or red flowers; green leaves

Bloom time: Spring, summer

Light needs: Full sun to light shade

Soil: Rich; moist but well drained

These perennials are a good choice for zones where summers are cool. (Lupines suffer in hot temperatures.) Lupines' tall, dense flower spikes produce pea-shaped flowers that come in shades of white, pink, purple, blue, and red.

Plant lupines for early summer color in cottage gardens and meadow gardens. Use them as an accent with flowering shrubs or in a border with irises, peonies, bellflowers, Oriental poppies, and annuals. They also make a wonderful accent in groundcovers such as common periwinkle.

Cut off spent flower spikes to promote possible regrowth, or let the seeds mature so plants can self-sow. For propagation, separate sideshoots from the clumps in fall. Or, if you aren't looking for a specific color (lupine seeds usually are sold in packets of mixed colors), sow seed in pots outdoors in late summer or indoors in winter. (Soaking the seed in warm water overnight can speed germination.) Place flats of seeds sown indoors in a refrigerator for 4 to 6 weeks before moving to a warm place.

Monarda

(Bee Balm, Bergamot)

PLANT PARTICULARS

Zones: 3 to 9

Height: 1 to 4 feet

Spread: 3 feet

Shape: Spreading patches of upright stems

Color: Red, pink, white, purple, or yellow-green flowers; green leaves

Bloom time: Summer

Light needs: Full sun to partial shade

Soil: Rich; moist

Put out the welcome mat for bees, butterflies, and hummingbirds with generous clumps of bee balm. This perennial has round heads of tightly packed flowers and aromatic leaves that add a splash of color to the landscape. Combine bee balms with lilies, phlox, yarrows, cranesbills, and astilbes. *M. didyma*, a wild species of bee balm, works well in the moist wild garden among bonesets, queen-of-the-prairie, hibiscus, and ferns.

Many bee balms are prone to powdery mildew, a fungal disease that appears as a dusty white coating on leaves and stems. Help avoid powdery mildew problems by planting resistant varieties, such as bright pink 'Marshall's Delight'; choosing a site with good air circulation; and thinning bee balm stems as needed.

Bee balms spread rather quickly, so you'll probably want to divide the clumps every 2 or 3 years (in spring or fall) to keep them from taking over. Relocate the new transplants, or share them with friends.

Nepeta

(Catmint)

PLANT PARTICULARS

Zones: 3 to 8

Height: 1 to 2 feet

Spread: Varies by species

Shape: Soft, sprawling mounds

Color: Violet to lavender-blue flowers; gray-green leaves

Bloom time: Spring, early summer

Light needs: Full sun to light shade

Soil: Average; well drained

This perennial is simply one of the best edging plants. Its misty mounds of soft gray-green leaves and wiry stems crowned with clusters of violet to lavender-blue flowers are lovely in the garden. Catmint also offers a long season of bloom—about 2½ months.

Plant catmint along walks, as an edging for beds, as a groundcover, or in a rock garden. The gray-green leaves and lavender-blue flowers look great with pale yellow coreopsis or yarrow, or with bright yellow evening primroses and daylilies. It also works well in front of peonies and roses.

Deer and rabbits seem to avoid catmint, so try planting it as a barrier to keep these critters away from plants they do love.

After the first flush of bloom, shear off the spent flower heads to promote rebloom (they'll quickly grow back again). To propagate catmint, dig up, divide, and transplant rooted stems.

Continued →

Paeonia

(Peony)

PLANT PARTICULARS

Zones: 2 to 8

Height: 1 to 5 feet

Spread: 30 to 36 inches

Shape: Loose, flower-topped mounds

Color: White, yellow, cream, pink, rose, and scarlet flowers; green leaves

Bloom time: Spring, early summer

Light needs: Full sun to light shade

Soil: Rich; moist

Peonies are prized for their variety of form and color, exceptional hardiness, and ease of care. They can have single, semidouble, or double blooms that range in color from white, cream, and yellow to pink, rose, and scarlet.

A row of peonies can make a glorious early-summer hedge. Mix several varieties (with different bloom times) together to extend the bloom season as long as possible. Classic companions include irises, foxgloves, and columbines. Hosta foliage and pink peonies make a pretty combination that's also practical: The hostas serve as natural support for the floppy peonies.

Speaking of support, taller peonies and those with double flowers usually need staking to keep their blooms out of the mud. Use hoop stakes or straight stakes and string to support floppy stalks. Single-flowered peonies generally have self-supporting stems that stand up to wind and rain.

Papaver

(Poppy)

PLANT PARTICULARS

Zones: 2 to 7

Height: 1 to 3 feet

Spread: 2 feet

Shape: Loose clumps

Color: Orange, red, pink, white, or yellow flowers; dark green leaves

Bloom time: Spring, early summer

Light needs: Full sun

Soil: Rich; well drained

These delightful flowers are wonderful for adding vibrant color to your beds. Their crepe paper-like petals come in shapes of orange, red, pink, white, or yellow. The flowers sit atop stems and open from nodding buds.

To get the most eye-popping color, plant the orange-scarlet, black-centered Oriental poppy (*P. orientale*). Bushy perennials that bloom after early summer, such as Russian sage and boltonia, make good companions. Other more subtle perennials that work well paired with bold-colored poppies include speedwells, bellflowers, baptisias, and blue stars. Use long-blooming cranesbills, perennial salvia, or spreading baby's breath to fill in the gaps after the poppies have finished flowering.

Rejuvenate crowded clumps (probably only once every 5 or 6 years) by dividing the plants just as the new leaves emerge in late summer. Lifted plants will invariably leave behind a few broken roots, which will grow into new plants. To propagate, take root cuttings while you're dividing the clumps.

Penstemon

(Penstemon, Beardtongue)

PLANT PARTICULARS

Zones: 2 to 9

Height: 4 inches to 3 feet

Spread: Varies by species

Shape: Tall spikes

Color: White, pink, rose, lavender, or violet flowers; evergreen leaves

Bloom time: Early summer through fall

Light needs: Full sun to partial shade

Soil: Average; very well drained

To bring a touch of wildflowers to your beds, try penstemon. It produces slender, single-branched spikes with tiers of irregularly shaped flowers. The flowers vary in color from white to pink, rose, lavender, and violet. This airy-looking plant has lush rosettes of evergreen leaves that form wide patches and make attractive groundcovers when the plants aren't in bloom.

Use penstemon in container plantings, as an edging, as a groundcover, in a mixed border, or in a rock garden. Combine it with cranesbills, spiderworts, yarrows, evening primroses, lamb's-ears, yuccas, and ornamental grasses.

Success with penstemon depends on choosing the right species for your growing conditions. Species native to the western mountains, for example, often cook in the heat of midwestern gardens and rot in the humidity and dampness of eastern gardens. However, many excellent eastern natives and other adaptable species are available. Good drainage is essential for all varieties except *P. digitalis*, which tolerates moist soil.

Perovskia

(Russian Sage)

PLANT PARTICULARS

Zones: 4 to 9

Height: 3 to 5 feet

Spread: 2 to 4 feet

Shape: Airy, shrublike mound

Color: Powder blue flowers; gray-green leaves

Bloom time: Summer

Light needs: Full sun

Soil: Average; well drained to dry

This tough, trouble-free perennial laughs at heat, drought, and pests. Its shrubby, branching habit supports gray-green leaves and airy sprays of tiny powder blue flowers. In addition to being tough, Russian sage earns its keep year-round by producing soft shoots in spring, flowers that bloom for more than a month in summer, and seedheads that dry in fall for winter interest.

The soft blue flowers of Russian sage complement pink, yellow, deep blues, and purples. Plant it in the middle or back of the perennial border with yarrows, phlox, balloon flowers, gayfeathers, and ornamental grasses. Also, try it as a low-maintenance landscape feature or as an accent in a cottage garden.

Perovskia atriplicifolia 'Blue Spire'

Cut the woody stems of this plant down to about 1 foot in late fall or early spring to promote new growth. In the North, plants often die back to the soil but resprout from the roots. Russian sage seldom needs dividing.

Phlox

(Phlox)

PLANT PARTICULARS

Zones: 2 to 9

Height: 4 inches to 5 feet

Spread: 24 to 30 inches

Shape: Varies among species

Color: White, pink, rose, red, violet, blue, or bicolored flowers; dark green leaves

Bloom time: Spring, summer

Light needs: Full sun to full shade

Soil: Varies among species

They're favorites among perennial gardeners, and rightly so. Phlox are easy to grow, bloom prolifically, and produce a heady fragrance. Depending on the variety, phlox may produce tall, leafy stems crowned with dense, domed heads of five-petaled flower clusters, or short, creeping stems that form an attractive groundcover.

One variety gardeners prefer is garden phlox (*P. poniculoto*). Its mounded flower clusters combine well with other summer bloomers. Place garden phlox in the middle or rear of the garden, and give it ample room to spread. Combine it with perennials such as bonesets, bee balms, Shasta daisy, astilbes, meadowsweets, cranesbills, delphiniums, daylilies, and ornamental grasses.

To help prevent powdery mildew, choose a site with good air circulation, thin the stems of dense clumps, and water the plants from below to avoid wetting their leaves.

Platycodon

(Balloon flower)

PLANT PARTICULARS

Zones: 3 to 8

Height: 1 to 3 feet

Spread: 24 inches

Shape: Loose clumps

Color: Blue, pink, or white flowers; green leaves

Bloom time: Summer

Light needs: Full sun to light shade

Soil: Average to rich; well drained

Continued →

Plant it now; enjoy it forever. A real showstopper, balloon flower flaunts star-shaped flowers that open from inflated round buds that resemble balloons.

These blooms look lovely with bright or pastel flowers and green or silvery foliage plants. Combine them with summer-blooming perennials such as yellow yarrows, alliums, violet sage, bee balms, and garden phlox. Use silvery foliage, such as lamb's-ears and artemisias, along with ornamental grasses to set off the bright flowers. Enjoy the blooms indoors as well as out; they last long as fresh-cut flowers if you singe the stem ends with a match to stop the milky sap from flowing.

The new shoots of balloon flowers are slow to emerge in spring, so be sure to mark their location so you don't dig into their clumps by mistake. The plants bloom for a month or more; removing the spent flowers will encourage the plants to continue blooming as well as keep them looking neat.

Polygonatum

(Solomon's Seal)

PLANT PARTICULARS

Zones: 3 to 9

Height: 1 to 3 feet

Spread: 1 to 2 feet

Shape: Arching stems with dangling flowers

Color: Greenish or white flowers; green or variegated leaves that turn yellow-brown in fall

Bloom time: Spring

Light needs: Partial to full shade

Soil: Rich; moist

For the areas of your garden in deep shade, try Solomon's seal. This graceful, arching plant has broad oval leaves and bell-shaped greenish or white flowers that hang below the foliage. In summer, it produces waxy, blue-black berries; in fall, the foliage turns yellow-brown.

Use Solomon's seal as edging, in a rock or a woodland garden, or at the back of a bed or a border. Combine it with bold foliage plants such as hostas, ferns, alumroots, wild ginger, and lady's-mantle. Most species will also do well under mature shade trees.

Although Solomon's seal prefers moist, rich soil, it will tolerate dry, stony soil. Divide plants whenever they start to outgrow their boundaries. To propagate, divide clumps in spring or fall and replant into amended soil. Or, remove the seeds from the berries in fall and immediately plant the seeds outdoors. (The seeds may take 2 years to germinate, and seedlings will grow slowly.)

Primula

(Primrose)

PLANT PARTICULARS

Zones: 2 to 8

Height: 2 inches to 2 feet

Spread: Varies by species

Shape: Rosettes of leaves with taller flowering stems or open, branched clusters

Color: Yellow, white, pink, purple, or red flowers; green leaves

Bloom time: Very early spring, early summer

Light needs: Full sun to partial shade

Soil: Rich; moist

Perky primroses have a place in every garden (they perform well in containers, too). These beloved five-petaled spring flowers bloom with flowering bulbs when the earth is reawakening, so plant them in clumps or drifts with spring bulbs such as tulips, snowdrops, and daffodils.

Some primrose varieties produce a tall stem, whereas others sport open, branched clusters close to the ground. Japanese primroses (*P. japonica*) love a spot with dependably damp soil, so combine them with irises, hostas, ferns, and lady's-mantle. If you live in a northern USDA plant hardiness zone that has erratic snowfall, mulch or cover your primroses for the winter to help them survive. In the South, provide consistent moisture and shade from the hot afternoon sun in summer; if the plants get too hot or dry, they will go dormant early—meaning you lose out on bloom time.

Pulmonaria

(Lungwort, Bethlehem Sage)

PLANT PARTICULARS

Zones: 2 to 8

Height: 9 inches to 2 feet

Spread: 1 to 2 feet

Shape: Loose clumps

Color: Pink, blue, red, or white flowers; green or variegated leaves

Bloom time: Spring

Light needs: Partial to full shade

Soil: Rich; moist

Some lungwort varieties do double duty: They not only produce pretty flowers in early spring but also sport showy silver-spotted leaves that make a bold statement the rest of the year. Some varieties of these low-growing plants have flowers that do a mid-bloom costume change: They open pink and turn to blue.

Combine lungworts with daffodils and other spring bulbs in a bed or a border or under flowering trees or shrubs. The tough and attractive summer foliage is outstanding as a groundcover. In the perennials garden, plant lungworts in drifts with hellebores, anemones, bleeding hearts, and irises. And planted singly or in groups, they brighten up shady spots under trees and shrubs.

Once lungworts are established, they are fairly drought-tolerant. However, they'll go dormant early if the soil dries out. Divide overgrown clumps after flowering or in fall, and replant into amended soil.

Rudbeckia

(Coneflower, Black-Eyed Susan)

PLANT PARTICULARS

Zones: 3 to 9

Height: 18 inches to 2 feet

Spread: Varies by species

Shape: Broad clumps of stiff, branched stalks

Color: Orange or yellow flowers; green leaves

Bloom time: Summer

Light needs: Full sun to light shade

Soil: Average to rich; well drained

Tough, adaptable coneflowers are the perfect perennials to grow if your thumb is more brown than green. Their daisylike blooms have golden yellow petals and brown or green centers that are either domed or flat.

These plants are invaluable for adding bright, long-lasting color to perennial gardens. Plant them with other summer-blooming flowers such as purple coneflowers, Russian sage, garden phlox, sedums, bee balms, and ornamental grasses, such as blue oat grass. Coneflowers also make good, long-lasting cut flowers, so you can enjoy them indoors as well as out in your garden.

Pinch off spent flowers to promote rebloom, or let the seedheads form to add winter interest to your garden. To propagate, divide clumps in spring, or dig up self-sown seedlings. You can sow seed outdoors in spring or fall.

Rudbeckia 'Goldsturm'

Salvia

(Salvia, Sage)

PLANT PARTICULARS

Zones: 3 to 10

Height: 1 to 4 feet

Spread: Varies by species

Shape: Mounded to shrubby

Color: Blue, purple, pink, or red flowers; silver-gray, green, or variegated leaves

Bloom time: Summer, fall

Light needs: Full sun to light shade

Soil: Average; well drained to dry

Like coneflowers, these perennials are easy to grow and will tolerate a wide variety of conditions (although they typically prefer well-drained soil). These plants are mounded to shrubby mints with tubular blue, purple, red, or pink flowers and square stems. Many salvias also have aromatic foliage.

Spiky salvias are super mid-border or edging plants for sunny gardens. Their upright habit contrasts beautifully with mounded plants, such as cranesbills and threadleaf coreopsis. They also look great combined with yuccas, yarrows, sedums, coneflowers, daylilies, daisies, mums, and ornamental grasses.

Plant salvias in full sun or light shade; they'll get leggy and flop in too much shade. Overly rich or moist soils also encourage flopping. Cutting the spent flower stems off your salvias can promote a second bloom in late summer. In fall or early spring, cut the plants back to the ground.

Scabiosa

(Scabious, Pincushion Flower)

PLANT PARTICULARS

Zones: 3 to 7

Height: 18 inches to 2 feet

Spread: Varies by species

Shape: Clumps with long flower stems

Color: Blue, pink, or white flowers; gray-green leaves

Bloom time: Summer

Light needs: Full sun to light shade

Soil: Rich; well drained to dry

Want the perfect cutting flower? This old-fashioned perennial has fuzzy foliage and broad, flat flower heads with tiny, lacy flowers on tall stems. What's more, it blooms for a long time. The quaint look of pincushion flower makes it a charming

Continued ➔

addition to cottage gardens and informal borders. Daylilies, yarrows, and coreopsis are wonderful companions. Blue pincushion flowers and yellow heliopsis make a great pair, both in the garden and cut for indoor arrangements. To create a significant display of pincushion flowers, plant them together in groups of three or more.

Pincushion flowers will form good-sized clumps under ideal conditions but are sensitive to heat and excess soil moisture. If you live in a southern zone, place these plants where they will be shaded in the afternoon. Remove spent flowers to keep plants looking neat and encourage repeat blooms. Divide clumps in spring only if they become overcrowded.

Sedum

(Sedum, Stonecrop)

PLANT PARTICULARS

Zones: 3 to 9

Height: 2 inches to 2 feet

Spread: 12 to 18 inches

Shape: Spreading mats to upright clumps

Color: Yellow, pink, or white flowers; green, red, yellow, or silver leaves

Bloom time: Spring, summer

Light needs: Full sun to partial shade

Soil: Average; well drained to dry

Thick, succulent, waxy leaves and fleshy, often trailing stems make these perennials drought-tolerant plants. Sedums come in lots of shapes and sizes, providing interesting foliage and yellow, pink, or white showy flowers with little or no fuss. Plus, the seedheads of many varieties retain their color after flowering and hold their form when dried.

"Autumn Joy" is one popular sedum variety that looks great in several seasons. Its neat mounds are topped with green buds that open to reddish pink flowers in late summer. The flower heads hold their shape well into winter. Sedums are versatile plants for beds, borders, and rock gardens and as groundcovers under open trees. The low, spreading species works well along paths.

All sedums are tough, low-maintenance plants. Once established, they generally won't require much care from you. Just divide them in spring or fall to control their spread.

Solidago

(Goldenrod)

PLANT PARTICULARS

Zones: 3 to 9

Height: 1 to 5 feet

Spread: Varies by species

Shape: Clumps of upright stalks

Color: Yellow flowers; green leaves

Bloom time: Late summer, fall

Light needs: Full sun

Soil: Average; moist but well drained

Goldenrods are a welcome sight in the garden, blooming at a time when many other flowers are going dormant for the season. The lemon yellow or golden flowers are carried in spikelike, flat-topped, or plume-like clusters; the leafy stems may be smooth or hairy.

These easy-care perennials look as good in beds and borders as they do in meadows and wildflower gardens. Combine them with coneflowers, balloon flowers, gayfeathers, bonesets, lavender, sages, asters, and ornamental grasses. Most species of goldenrod prefer average soil (rich soils cause rampant spread and cause the flowers to flop over). All species of goldenrod hold up well under drought conditions.

Regardless of whether you choose to include goldenrod in your perennial garden, rest assured that goldenrods aren't responsible for your fall hay fever. They're mistakenly blamed for the irritating pollen that's produced by ragweed. Because goldenrod pollen isn't released into the wind (the plants are pollinated by insects), it can't be blamed for upper respiratory tract allergies.

Stachys

(Lamb's-Ears, Betony)

PLANT PARTICULARS

Zones: 2 to 8

Height: 6 inches to 2 feet

Spread: 1 foot

Shape: Spreading mats with upright flower stems

Color: Purple, pink, or white flowers; silver-gray leaves

Bloom time: Spring, summer

Light needs: Full sun to light shade

Soil: Varies among species

Delightful lamb's-ears are extremely versatile in any landscape. Their soft, fuzzy leaves just beg to be touched, and their tiny flowers add an accent of color to the silvery foliage.

Use them at the front of a border or an herb garden—or along a path, where you'll brush by them frequently. Their foliage and flower spikes are a perfect complement to green leaves and both bright and pastel flowers. Plant lamb's-ears in formal or informal gardens with irises, goat's beards, alumroots, bergenias, and lung worts.

In hot, humid conditions, the leaves may die back because the woolly foliage traps water and encourages rot. If this happens, cut the leaves and stems to the ground; new foliage should sprout when things cool off. Also, you can cut the flower stems to the ground after bloom to keep the plants looking tidy.

All species of lamb's-ears spread well when grown in the conditions they like best. Divide and replant overgrown clumps in the fall to control their spread, if you wish.

Stachys byzantina

Verbena

(Verbena, Vervain)

PLANT PARTICULARS

Zones: 4 to 10

Height: 4 inches to 5 feet

Spread: 1 foot

Shape: Varies among species

Color: Pink, purple, white, or blue flowers; green leaves

Bloom time: Summer

Light needs: Full sun to light shade

Soil: Average; well drained to dry

The popularity of these perennials stems from their different shapes, from tall upright plants to low, creeping, mat-forming ones. Surely, at least one variety will work well in your landscape. The brightly colored flowers have five flat petals that are carried in flat or spiky clusters on top of wiry stems.

The mat-forming varieties are excellent for tying together mixed plantings. Let them creep among foliage plants such as yuccas, artemisias, mulleins, and ornamental grasses. They also serve to fill in gaps between tall flowering perennials such as coneflowers, butterfly weeds, and yarrows. Contrary to usual practice, plant upright varieties at the front of a border, because the verbenas' tall, airy stems will allow you to see the plants behind.

These tough, heat- and drought-tolerant perennials bloom tirelessly throughout the summer. The creeping varieties spread quickly to form showy groundcovers, whereas the upright varieties spread slowly.

Veronica

(Veronica, Speedwell)

PLANT PARTICULARS

Zones: 3 to 8

Height: 4 inches to 6 feet

Spread: Varies among species

Shape: Varies among species

Color: White, pink, purple, or blue flowers; green leaves

Bloom time: Spring, summer

Light needs: Full sun to light shade

Soil: Average to rich; moist but well drained

Dependable, long-blooming speedwells are available in both upright and creeping varieties. The blooms are spikes of small flowers in shades of white, pink, rose, purple, and blue. Speedwells' leaves may be narrow and lance-shaped, oblong, oval, or wedge-shaped.

Practically maintenance-free, speedwells are very heat- and drought-tolerant—perfect for beds, borders, and rock gardens. You can also use them as edging, in a wildflower meadow, or along a path. Combine their colorful spiky flowers with mounded plants such as coreopsis, butterfly weeds, yarrows, cranesbills, daylilies, and ornamental grasses.

Pinch off the dead flower spikes to keep the plants blooming, and divide the plants in spring or fall for propagation or to control spread. (The creeping types tend to spread quite widely, so watch them carefully, or you may end up with plants in unwanted areas—like your neighbor's yard.)

Perennial Pest and Disease Control

Ellen Phillips and C. Colston Burrell

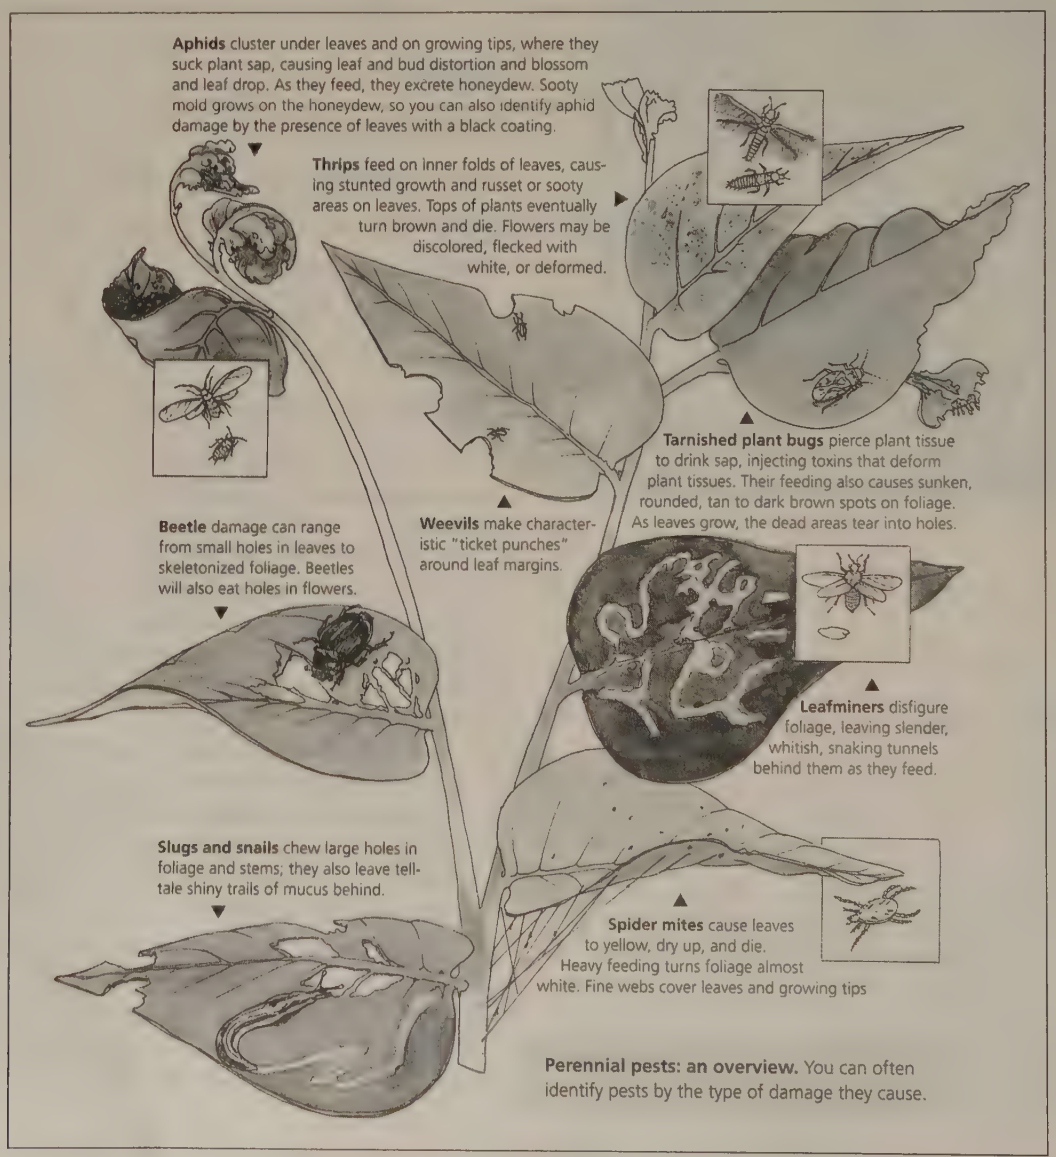
Effective pest and disease control is a three-step process for the perennial gardener: observe, refer, react. You'll apply the right preventives and controls at the right time if you watch your plants for signs of pests or diseases, check your references to identify pests or symptoms, and then use the recommended control for that particular problem.

In this section, you'll find out which pests and diseases attack perennials, what they look like, and what to do about them. But first, you'll learn how to prevent pests and diseases from becoming a major problem through wise plant selection and good cultural practices.

Start with Resistant Plants

Some species and cultivars of perennials are resistant to certain pests and diseases that plague similar plants. Some of these plants are naturally resistant; others were bred for resistance. Using these plants is one of the easiest ways to solve pest and disease problems. Either look for and choose resistant plants when you're starting a new garden, or replace susceptible plants with resistant species or cultivars when problems arise.

Resistant plants are the best way to solve potential garden problems like powdery mildew. Garden phlox (*Phlox paniculata*) is notoriously susceptible to powdery mildew, which disfigures the foliage with a powdery white coating and reduces plant vigor. But phlox is a staple of many summer gardens, with its tall, showy panicles of red, white, pink, or salmon flowers.



Aphids cluster under leaves and on growing tips, where they suck plant sap, causing leaf and bud distortion and blossom and leaf drop. As they feed, they excrete honeydew. Sooty mold grows on the honeydew, so you can also identify aphid damage by the presence of leaves with a black coating.
Thrips feed on inner folds of leaves, causing stunted growth and russet or sooty areas on leaves. Tops of plants eventually turn brown and die. Flowers may be discolored, flecked with white, or deformed.
Tarnished plant bugs pierce plant tissue to drink sap, injecting toxins that deform plant tissues. Their feeding also causes sunken, rounded, tan to dark brown spots on foliage. As leaves grow, the dead areas tear into holes.
Weevils make characteristic "ticket punches" around leaf margins.
Beetle damage can range from small holes in leaves to skeletonized foliage. Beetles will also eat holes in flowers.
Leafminers disfigure foliage, leaving slender, whitish, snaking tunnels behind them as they feed.
Slugs and snails chew large holes in foliage and stems; they also leave telltale shiny trails of mucus behind.
Spider mites cause leaves to yellow, dry up, and die. Heavy feeding turns foliage almost white. Fine webs cover leaves and growing tips

Perennial pests: an overview. You can often identify pests by the type of damage they cause.

If you feel that you simply must have phlox in your perennial bed or border, you have two choices: You can battle mildew with good cultural practices and preventive spraying, or you can plant mildew-resistant cultivars like 'Bright Eyes', a pink-flowered phlox with crimson centers, or 'David', a sparkling white-flowered form. Wild sweet William (*P. maculata*), which looks like garden phlox, is also mildew-resistant and an excellent substitute; there are pink, white, and rose-colored cultivars.

Growing Plants Right

Good gardening practices result in vigorous, healthy perennials. Careful site selection and soil preparation, adequate irrigation, and preventive mulching are some of the ways you can make sure your plants are ready to resist pest and disease attacks. Just as we're less able to resist a cold when our bodies are already run down, stressed plants succumb more quickly to infection. Research has shown that weakened plants are the first to be attacked by pests.

Make sure your plants aren't water-stressed or waterlogged. Keep weeds, which are often alternate hosts for both pests and diseases, away from your garden. Add plenty of organic matter—especially compost—to your beds to enhance water and nutrient retention and fight nematodes. Space plants far enough apart for good air circulation. And grow a variety of species: Many pests and diseases are species-specific, or are confined to a few related species.

Pests in the Perennials

Pests build up most quickly when just one or two kinds of plants are grown. A bed of mixed perennials is less likely to be decimated than a bed of roses or petunias because the pests that prefer specific plants will have a harder time finding them when they're "hidden" among all those other perennials. That doesn't mean perennials are pest-free, though, as gardeners who've encountered borers in their bearded irises, Japanese beetles on their hollyhocks, or slugs on their hostas can attest.

One cause of pests in perennial beds is the nature of perennials themselves: The plants are in place a long time, giving pest populations a chance to establish themselves over many growing seasons. Fortunately, there are five ways to keep pests at an acceptable level in your garden.

1. Grow resistant species and cultivars when available.
2. Use good cultural practices.
3. Apply biological controls, which are alive and often self-perpetuating.
4. Use manual controls, including barriers and traps.
5. Use insecticidal sprays and dusts when required.

These five tactics should keep perennial pests at the "few and far between" state so your plants can bloom and thrive unmolested.

Here's an overview of biological controls, manual controls, and sprays and dusts. But first, there are two techniques that are more important than any control: monitoring and using common sense.

LOOKING FOR TROUBLE

The best and easiest way to keep pests under control is to find them when they've just arrived and there still aren't many of them, so monitor your plants. If you can start control early, your perennials will suffer minimal damage, and you can usually use a simple control. Handpicking a few Japanese beetles is far better than coping with bug sprays and stripped plants. Become a garden detective: When you're weeding, watering, or just out strolling in your garden, check your plants for pests and signs of feeding injury. Make sure you're in the garden every day—pest populations can build up fast. Try to familiarize yourself with the major perennial pests so you'll know what you're looking for, then apply appropriate controls.

Japanese beetles. These ½-inch-long, metallic blue-green beetles consume the leaves, stalks, and flowers of many perennials. The ¾-inch-long, C-shaped grub larvae feed on the roots of lawn grasses. Handpick adults into a can of soapy water. Traps will attract these pests to your yard unless your neighbors set up traps, too. Use milky disease or parasitic nematodes on lawn areas to control beetle larvae.

Continued ➔

USING COMMON SENSE

Don't panic at the first sight of a slug or a ragged leaf. Unless you're growing perennials for the florist industry or a flower show, a little damage is as acceptable as it is inevitable. The techniques we recommend will ensure that you have lush, healthy plants and plenty of perfect flowers. Your garden is a natural system, so be prepared for the occasional flaw. Use good sense; don't overreact.

The second time to let common sense come to your rescue is at the other end of the control spectrum. If, in spite of your best efforts, certain perennials are decimated every year, give up the fight. No matter how much you love columbines, if leafminers make them unsightly every season, it's time to throw in the trowel. There are plenty of other lovely perennials to choose from. Give it your best shot, but then let reason be your guide. Don't let pest-pocked perennials ruin the looks of your perennial garden.

If you can't live without them, remember this: You can always hide favorite but pest-plagued perennials in the cutting garden, where the colorful chaos will make pest damage less noticeable.

USING BIOLOGICAL CONTROLS

Biological controls are microscopic living organisms that infest or attack pests. They are usually pest-specific, attacking only one kind of insect, and are thought to be harmless to the environment and nontargeted species. To be effective, biological controls must be applied early because the infection takes several days to kill the pest. All are available from garden suppliers; apply according to directions.

BT. *Bacillus thuringiensis*, known as BT, is a bacterial disease that infects insect larvae. Different strains of BT have been isolated for different pests: One infects caterpillars, a second attacks the grubs of Colorado potato beetles, and a third infects mosquito and blackfly larvae. (However, the strain of BT that kills pest caterpillars will kill all caterpillars, and so on, so please don't apply a biological control unless you're sure you have or will have a problem based on past years' infestations.) Make sure you buy the strain of BT that targets your pest problem.

Milky disease. *Bacillus popilliae*, milky disease, attacks Japanese beetle grubs. Apply this bacterial disease, often sold as milky spore, to the lawn where these grubs live. Milky disease is most effective in providing grub control if everyone in your neighborhood applies it to their lawns; one application will be effective for years.

Parasitic nematodes. These microscopic roundworms parasitize and kill insect larvae, including ground-dwelling caterpilllars (like cutworms) and grubs. The nematodes feed on a dead insect; about 10 to 20 days after the first infection, huge numbers of nematodes leave the carcass in search of new victims. Because nematodes perish in sunlight or dry places, they are most useful against pests in soil or hidden locations. Although the larval stage can survive for long periods in the soil, for the greatest effect you need to release more nematodes each year.

USING MANUAL CONTROLS

Manual controls are simple, low-tech methods like handpicking pests or putting barriers around plants. Some manual controls are preventive, like cutworm collars; their aim is to keep pests from reaching your plants. Others, like handpicking, come into play once pests attack. When you notice a pest problem, try these controls first; they're often all you'll need. If pest populations are too great for effective manual control, move on to dusts and sprays.

Handpicking. This is a simple technique that merely involves plucking a pest off a plant and squashing it or drowning it in a can of soapy water. (Soap breaks the surface tension of the water so the pests can't climb out.) It's not for the squeamish, but it is highly effective when used early when populations are light.

Copper barriers. Slugs and snails get an electric shock when their slimy bodies touch copper, so these copper strips keep them out of your beds. They're easiest to use if you have wood-sided raised beds and can nail the strip around the outside of the bed. This works on a barrel garden, too. Copper strips are available from garden supply companies and are sold as Snail-Barr.

Cutworm collars. Make your own "collars" to keep cutworms from attacking your seedlings and transplants. Use cardboard cylinders like toilet paper or paper towel rolls, or roll your own. Make each collar 2 to 3 inches tall and 1½ to 2 inches wide; push them into the soil so that about half the collar is below the soil surface. Remove the collars once plants are past the seedling stage.

Diatomaceous earth. This mineral dust is composed of fossilized diatom shells. The microscopic fossil shells have razor-sharp edges that pierce the skin of soft-bodied pests like caterpillars, slugs, and snails. The pests dehydrate and die. Diatomaceous earth also works as a repellent: Use it as a barrier on the soil around plants or around the outside of beds.

Traps. Shallow pans of beer will lure slugs and snails to a watery death. (Alcohol-free beer is even more effective, and you can use a brew of yeast and water, too.) Set the pans into the soil, placing the lip flush with the soil surface, and fill with stale beer; empty the traps daily. Snail traps are also commercially available. Other traps, like Japanese beetle traps, are available commercially but are less relevant to perennial gardeners; in fact, studies have shown that Japanese beetle traps often act as a lure, drawing pests into your garden.

USING SPRAYS AND DUSTS

The best control for a severe pest outbreak is sometimes a spray or dust. A number of sprays and dusts are harmless (like water); some

are relatively harmless (like insecticidal soap); and others may be highly toxic for a short time (pyrethrins are toxic for about a day, rotenone for about a week). Don't underestimate the potential toxicity of organically acceptable insecticides like pyrethrins. If you choose to use them, wear protective clothing, a face mask, and gloves when handling or applying them. Whichever spray or dust you use, make sure you coat the undersides of the leaves; many pests congregate there, out of sight of potential predators.

Water. A forceful spray of water is often enough to control aphids and spider mites. It knocks them off the plants, and these slow-moving pests can't find their way back.

Insecticidal soap. Soap sprays are contact poisons that are effective against outbreaks of soft-bodied pests like aphids and whiteflies. You can buy insecticidal soap commercially (Safer is a commonly available brand) and dilute it according to directions, or make your own by mixing 1 to 3 teaspoons of liquid dish soap (not laundry or dishwasher detergent) in 1 gallon of water. For best control, spray plants every 2 or 3 days for 2 weeks.

Pyrethrum. Pyrethrum is made from the pulverized dried flowers of pyrethrum daisies (*Chrysanthemum cinerariifolium* and *C. coccineum*). Pyrethrum can be appplied as a dust or used as a spray and is efffective against a wide range of insects. For best control, apply pyrethrum in early evening; two applications 2 hours apart may be most effective. Because pyrethrum is not pest-specific, don't use it near water (it's extremely toxic to fish) or pets. Make sure you buy plant-derived pyrethrum, not synthetic pyrethrins or pyrethroids, which are more toxic and break down more slowly.

A Plague of Perennial Diseases

Perennials are more likely to be disease-free than annuals or vegetables because perennnial beds usually contain a mixture of plants rather than a single species or cultivar (a monoculture). Monocultures draw diseases—and the pests that often spread them—like a magnet. Good cultural practices, like adding plenty of compost and other organic matter to the soil, mulching, and cleaning up plant debris in fall, also reduce the likelihood of diseases getting a foothold in your garden.

No matter how careful you are, though, you'll probably encounter diseases in your perennials from time to time. An especially hot, wet summer might provoke an outbreak of powdery mildew, a friend might inadvertently give you a peony division with botrytis blight, or an unusually high leafhopper population might spread aster yellows to your chrysanthemums. Familiarize yourself with disease symptoms so when your plants show signs of infection, you can take prompt action to save them.

There are three types of diseases that infect perennials—bacteria, fungi, and viruses—as well as a related category of pests and problems that cause diseaselike symptoms in plants. These include microscopic nematodes; nutrient deficiencies, and other disorders like herbicide drift.

Iris borers. In spring, borer larvae enter a fan of iris leaves at the top and burrow down to the rhizome. Pale, irregular tunnels in the leaves mark their travels. Borers also spread soft rot bacteria as they feed. To control borers, pinch and crush them in the leaves, or inject BT or parasitic nematodes into their holes. Also, remove dead leaves in fall and destroy infested fans in spring. If you've had serious borer problems, grow Siberian iris (Iris sibirica), *which is usually borer-free, rather than bearded iris.*

PREVENTING DISEASES

Prevention is the best—and often the only—cure for plant diseases. There is no cure for viral diseases, and once your garden soil becomes infested with nemaatodes, you may have to remove all the plants in your perennial bed and solarize the soil before trying again with new plants. Even fungi like *Verticillium* can survive for 20 years in the soil. So good gardening practices and commonsense precautions can be critical in keeping diseases out or minimizing their damage.

You can start with resistant species and cultivars, especially if a disease has been a problem in the past. For example, if powdery mildew has been a plague on your bee balm (*Monarda*), try 'Marshall's Delight', which is mildew-resistant. You might

Continued ➔

have to search for disease-resistant cultivars; breeding for resistance in perennials is a fairly new phenomenon. Resistant species and cultivars are mentioned in encyclopedia entries when a disease is a particular problem for a perennial.

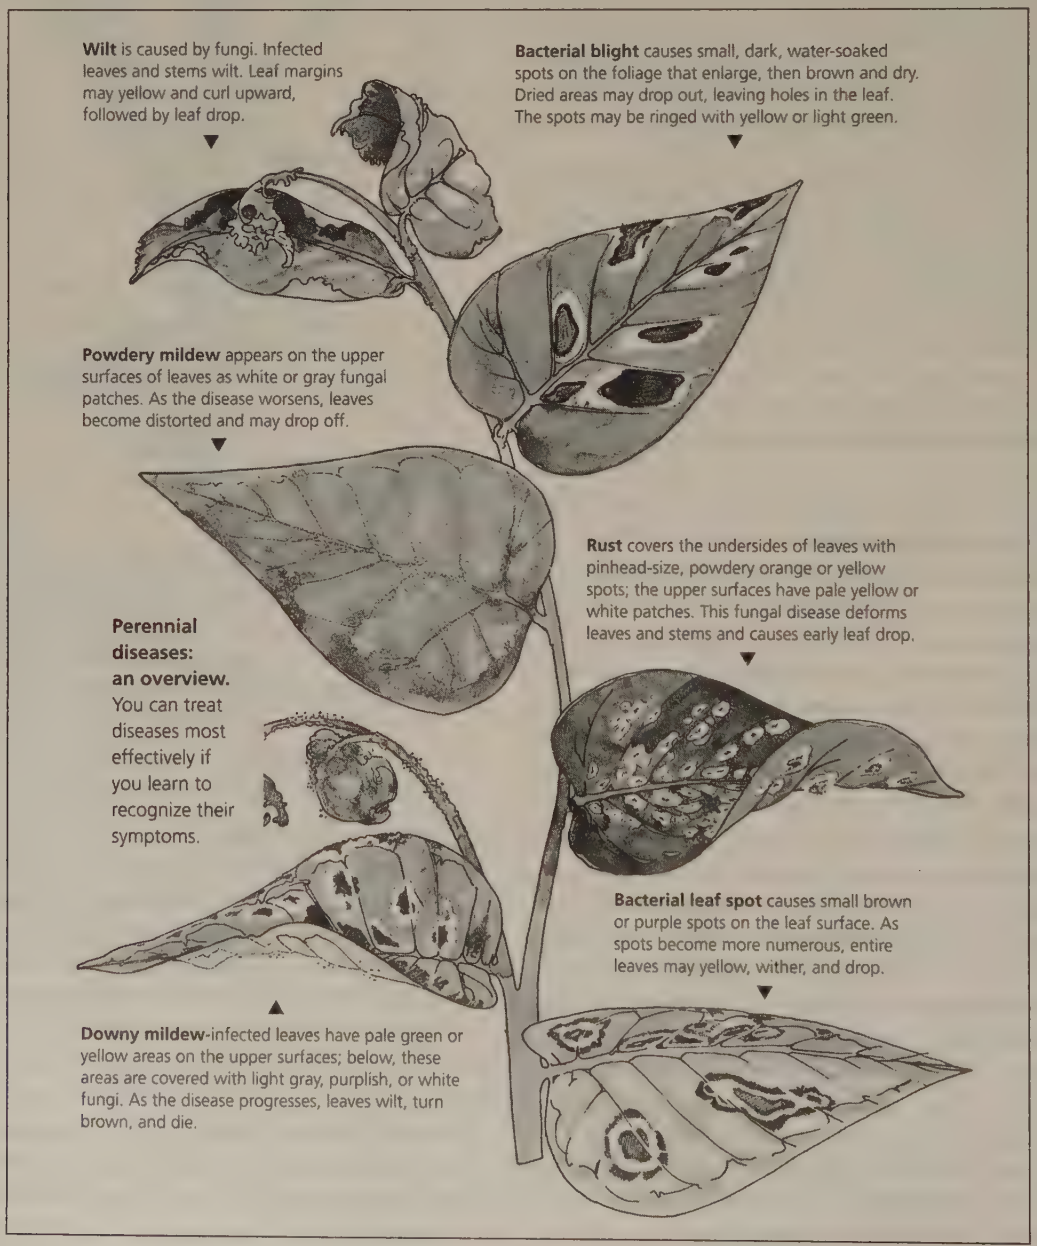
Site selection is also important. If you're planning a new perennial bed, site it in well-drained soil in full sun and where it will get good air circulation. Don't overcrowd plants; space them far enough apart so air can circulate between them. If you have an established bed that has become overcrowded, thin plants to improve circulation.

Fungal and bacterial diseases and nematodes can all spread by water. You can avoid encouraging infections by careful watering. Water your perennials in the morning so they'll dry before night; water the ground around the plants, not the foliage; and don't work in your perennial beds when the foliage is still wet from a rain.

Another time-honored preventive tactic is to practice good garden hygiene: Wash your hands and tools after working with diseased plants. Keep the garden clean of potentially diseased plant debris, and weed religiously to remove alternate hosts of diseases and their carriers. Cut plants to the ground at the end of the growing season. Compost healthy trimmings, but destroy any that look diseased.

CURING OR CONTROLLING DISEASE

If disease strikes in spite of your attempts to prevent it, take prompt action to curtail its development and spread.



Wilt is caused by fungi. Infected leaves and stems wilt. Leaf margins may yellow and curl upward, followed by leaf drop.
Bacterial blight causes small, dark, water-soaked spots on the foliage that enlarge, then brown and dry. Dried areas may drop out, leaving holes in the leaf. The spots may be ringed with yellow or light green.
Powdery mildew appears on the upper surfaces of leaves as white or gray fungal patches. As the disease worsens, leaves become distorted and may drop off.
Rust covers the undersides of leaves with pinhead-size, powdery orange or yellow spots; the upper surfaces have pale yellow or white patches. This fungal disease deforms leaves and stems and causes early leaf drop.
Perennial diseases: an overview. You can treat diseases most effectively if you learn to recognize their symptoms.
Bacterial leaf spot causes small brown or purple spots on the leaf surface. As spots become more numerous, entire leaves may yellow, wither, and drop.
Downy mildew-infected leaves have pale green or yellow areas on the upper surfaces; below, these areas are covered with light gray, purplish, or white fungi. As the disease progresses, leaves wilt, turn brown, and die.

The simplest but most painful control is to promptly remove and destroy infected foliage, flowers, or entire plants, if necessary. It's heartrending to pull out prized perennials, but sometimes that's the only alternative, especially if they have viral diseases or foliar nematodes; better to lose a plant or two than an entire bed. This technique will help control fungal and bacterial diseases as well. A more specialized technique that can be quite effective is called soil solarization.

Soil Solarization

If soilborne problems like wilts and nematodes have plagued your perennials in the past few seasons, try soil solarization. This is an easy technique, but it does require planning because it takes several months to be effective. If you're starting a new bed, prepare the bed a season before you plan to use it if you live in the North; in the South and Southwest, you can dig the bed, solarize it, and be ready to plant the same growing season.

In spring in the South and midsummer in the North, rake the new bed smooth and water it well. Dig a trench several inches deep around the outside of the bed. Spread a thin (1 to 4 mils) clear plastic sheet over the bed and press it down against the soil surface. Press the edges of the sheet into the trench, and seal the plastic by filling the trench with soil. Leave the sheet in place for 1 to 2 months.

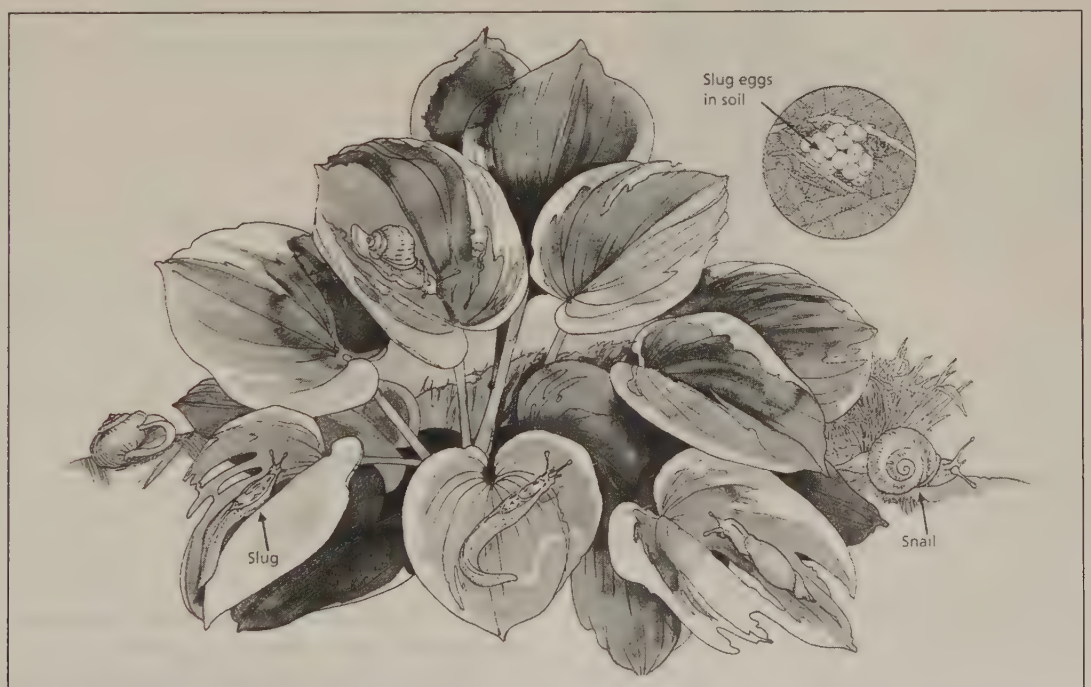
The technique works because heat builds up under the plastic sheet, essentially cooking the top 6 to 12 inches of soil in the bed. In addition to killing nematodes and diseases, solarization will also kill weeds, weed seeds, and insect pests. The drawback is that you need bare soil; if you have a serious nematode infestation in an existing bed, you may have to dig out and discard all the perennials, solarize the soil, and replant in fall.

BATTLING BACTERIAL DISEASES

Bacteria are microscopic organisms. Most are beneficial decomposers—vital to the decay cycle and to composting—and some are major pest controls, like Bacillus thuringiensis. A few bacteria cause diseases in perennials. Bacterial infections can be spread by wind, water, and contact with contaminated tools or carrier pests. Once contracted, these diseases are difficult to control. Use preventive tactics and treat signs of disease promptly.

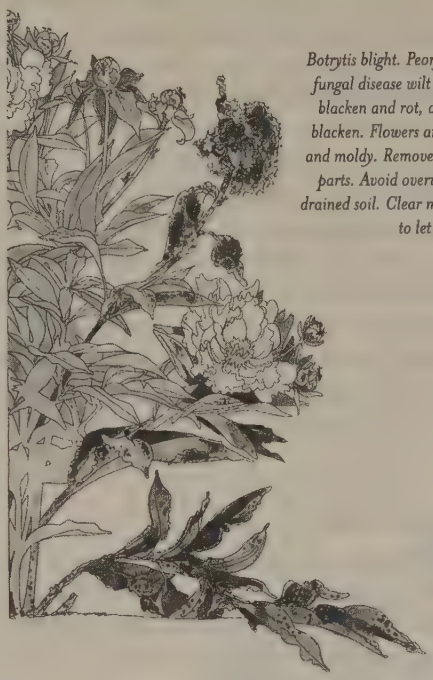
Controlling Bad Bacteria

To control bacterial diseases, remove and discard infected plant parts. Thin plants and avoid crowding future plantings. Wash your tools and hands after handling infected plants. Avoid overhead watering. Clean up plant debris to remove overwintering sites. The most common bacterial diseases of perennials are bacterial soft rot of iris, and leaf spot, which infects a number of plants. If you live in the South, your perennials may also be infected by pseudomonas wilt, which causes leaves and stems to wilt and may kill infected plants. Keep



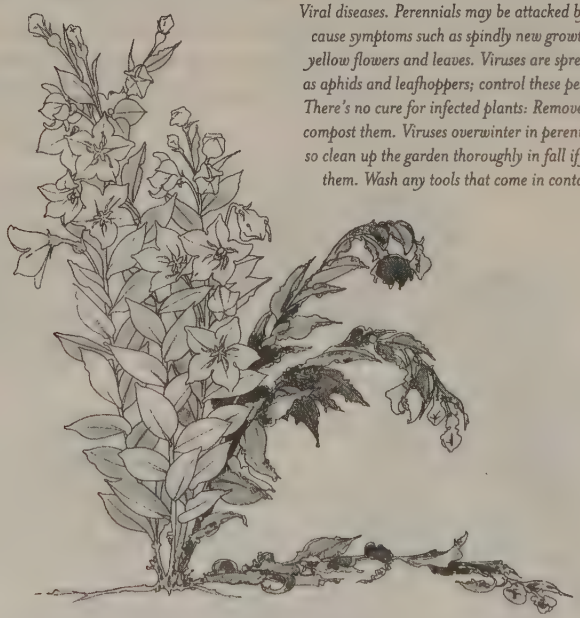
Slugs and snails. These pests thrive in the cool, moist soil preferred by many perennials like hostas. Mulches and plants with low-growing leaves provide shady hiding places from which slugs and snails emerge to feed at night. They rasp large holes in leaves and stems and leave a characteristic shiny slime trail. To control these pests, drown them in beer traps or sprinkle bands of coarse, dry, scratchy materials such as wood ashes or diatomaceous earth around plants or beds.

Continued ➔



Botrytis blight. Peony shoots afflicted with this fungal disease wilt and fall over. Stem bases blacken and rot, and buds may wither and blacken. Flowers and leaves may turn brown and moldy. Remove and destroy infected plant parts. Avoid overwatering and wet, poorly drained soil. Clear mulch from crowns in spring to let the soil dry.

Crown rot. Overcrowded plants and wet, poorly drained soil are the main causes of crown rot. The leaves and stems of afflicted plants turn brown or black at the base, and black spores may appear on stems. Plants may wilt suddenly or yellow and wilt slowly. Prevention is the best control: Avoid sites with poorly drained, wet soil; divide plants regularly; don't damage crowns when digging near plants; and keep winter mulch away from the base of the plant. Remove and destroy infected plants.



Viral diseases. Perennials may be attacked by several viral diseases that cause symptoms such as spindly new growth and distorted, greenish yellow flowers and leaves. Viruses are spread by sucking insects such as aphids and leafhoppers; control these pests to limit virus problems. There's no cure for infected plants: Remove and destroy them; do not compost them. Viruses overwinter in perennials and perennial weeds, so clean up the garden thoroughly in fall if you've had problems with them. Wash any tools that come in contact with infected plants.

pseudomonas wilt from spreading by digging and destroying infected plants.

FIGHTING FUNGAL DISEASES

Most perennial diseases are fungal. Fungi are organisms like mushrooms that reproduce by spores, lack cholorphyll, and live on organic matter. Most fungi are beneficial, but parasitic fungi cause diseases, sapping the strength of host plants by growing and feeding on them. These fungi are microscopic, but they produce visible spores that are often easy to identify, like the white, cotttony spores of powdery mildew or the orange spores of rust.

Controlling Fatal Fungi

Fortunately, because they're the diseases you're most likely to encounter in your garden, fungal diseases are the easiest to control. Besides growing resistant species and cultivars and using cultural practices to reduce the likelihood of infection, you can choose from a number of organic fungicides to treat stricken plants. These fungicides won't cure disease on infected plant parts, but they will keep the disease from spreading to healthy parts of the plant once you've removed the infected portions. Always follow label directions. Remember that some of these sprays may leave an unattractive coating on foliage, but this is a temporary effect—and it certainly looks no worse than fungus-covered leaves. Here are some of the most effective fungicide sprays.

- **Antitranspirants.** Sprays like Wilt-Pruf that are intended to keep leaves from dehydrating have also been proven effective in preventing powdery mildew. Use one-third of the recommended summer rate and reapply to cover new growth and after rain.
- **Baking soda.** One homemade spray that tests have shown to be effective in controlling a wide range of fungal diseases, including leaf spot, anthracnose, and powdery mildew, is a 0.5 percent solution of baking soda and water. Mix 1 teaspoon of baking soda in 1 quart of water, add a few drops of liquid dish soap or cooking oil to help the mixture adhere to the leaves, and spray on infected plants.
- **Copper.** Copper is also a powerful broad-spectrum fungicide. Use copper fungicides sparingly: Repeated applications may stunt or damage plants.
- **Fungicidal soap.** Safer Garden Fungicide, which contains sulfur in a soap emulsion, controls fungi—including powdery mildew, leaf spot, and rust—on perennials. You can buy it in ready-to-spray or concentrate form.
- **Sulfur.** Milder than copper, sulfur still prevents fungi from growing on perennials. You can apply elemental sulfur as a dust, or spray wettable or liquid sulfur onto your plants. Apply sulfur only when temperatures will stay below 85°F; higher temperatures make sulfur toxic to plants.

VIRUSES AND VIRUSLIKE DISEASES

Even though viral diseases aren't as common in perennials as fungal and bacterial infections and nematodes, it's still important to recognize the symptoms of viral infection and eliminate infected plants before they can spread disease. There is no cure for viral infection. Symptoms can vary from plant to plant, but infected plants tend to show certain characteristic traits like greenish flowers, ring spotting (concentric rings on the foliage), and rosetting (a deformed, tight clump of leaves that resembles a rosebud). Mosaic virus and aster yellows are common.

Viruses are spread from plant to plant by direct contact rather than by wind or water. The virus must be either rubbed against or injected by pests into a susceptible plant for it to contract the disease. You can spread viral diseases to your perennials by brushing against infected plants and then healthy plants, especially when plants are wet. Smokers can transmit tobacco mosaic virus from touching cigarettes or other tobacco products and not washing up before heading out to the garden. If you inadvertently propagate infected plants, you may also be spreading viral diseases.

Controlling Vile Viruses

Because there is no cure for plants that are infected by viruses, try to keep your garden virus-free. Plant resistant species and cultivars when possible. Viruses are carried by sucking insects such as aphids, whiteflies, and leafhoppers, which spread the diseases as they feed. Control these pests by spraying plants with a mixture of insecticidal soap and 70 percent isopropyl alcohol (1 tablespoon alcohol to 1 pint soap solution) to reduce the risk of infection. Wash tools used around infected plants. Viruses overwinter in perennials and weeds such as daisies and plantains; a good fall cleanup will reduce the chances of reinfection.

Viruses infect entire plants; you can't control their spread by removing infected leaves or stems. Once perennials show viral symptoms, remove and destroy them. Do not compost infected plants.

NEMATODES: MICROSCOPIC MENACE

Nematodes are microscopic roundworms, but when they attack plants, they produce disease-like symptoms rather than the damage typical of other insects. Three types of nematodes—root knot, foliar, and stem-and-bulb—attack a wide range of perennials. Nematodes are more likely to be a problem in the South or in perennial beds that were previously used for growing susceptible vegetables.

Controlling Nasty Nematodes

Nematodes travel over wet plants on a film of water, or on garden tools and gardeners moving among plants. Promote natural nematode controls by increasing soil organic matter. You can control root knot nematodes by applying chitin (ground seafood shell wastes) or parasitic nematodes to the soil; both are available from garden-supply companies. In severe cases, remove plants, solarize the soil, and replant with nematode-free stock.

There is no cure for either stembulb or foliar nematodes. Remove and destroy infested plants and the surrounding soil; do not compost the debris. Clean up debris in fall to destroy overwintering nematodes. Mulch in spring to keep nematodes from climbing up plants; avoid wetting leaves when watering.

Your Seasonal Perennial-Care Calendar

This month-by-month calendar is a handy reference guide to help you create and maintain your perennial garden. When using the calendar, keep in mind that these are only general guidelines. What you do specifically in your beds each month depends on what your climate and growing season are like.

JANUARY

Just because it's winter doesn't mean your landscape has to be bare and boring. Here are some things you can do this year to perk up your landscape for next winter.

- Go outside and take a look at your perennial garden (or where you'd like to put perennials).
- Are there places where shrubs, ornamental grasses, or plants with interesting winter seed pods might add structure and improve your garden's winter appearance?
- If so, make a list of those plants—or put your thoughts on paper in the form of a winter garden design to refer to later.

FEBRUARY

Read perennial gardening books and catalogs for ideas about what you want to plant and for design suggestions. Order new plants and seeds from mail-order catalogs now. Start counting down the days until spring is scheduled to arrive in your zone.

MARCH

Clean up existing perennial garden beds. Rake out fallen leaves and winter mulch as spring growth begins, adding the leaves and mulch to your compost pile so it doesn't go to waste. When the soil is dry enough to dig, prepare new garden areas, amending the soil with compost.

APRIL

The arrival of spring means there's plenty for you to do to get ready for a new season of growing perennials.

- Cut back woody perennials such as Russian sage and butterfly bush as they begin to show new growth.
- Begin a garden journal; note what plants are in bloom when, what you like and don't like, and what ideas you have for changing things.
- Don't rely on plant labels to remember where everything is and what it is. (Plant labels have a habit of disappearing over time.) Instead, make a garden plan on paper or on your computer, if you don't already have one, and keep it updated as your garden evolves.

MAY

Now you can really start to go to town in your beds. Dig up and divide summer- and fall-blooming plants, and share some of your divisions with family and friends. Plant perennials, and after danger of frost has passed, fill in empty spots with annuals for all-season colorful bloom.

JUNE

Mulch the perennial garden with compost, chopped leaves, or shredded bark to help control weeds. Add new plants as desired. Continue to keep a detailed journal, noting any problem spots in your garden.

JULY

During these dog days of summer:

- Watch for signs of pests or disease, and research organic ways to prevent them in the first place.
- Look through mail-order catalogs for disease resistant varieties to replace problem plants next spring.
- Water your garden during dry spells.
- Keep things looking neat by weeding and deadheading regularly.
- Cut back plants that have finished blooming to promote new growth.
- Cut perennials to use in fresh-flower bouquets and arrangements indoors.

AUGUST

Your late-season garden can still look great during this month; you just need to stay on top of things.

- Take a good look at your beds, noting colorless areas.
- Research possible substitutions, relocations, or additions and jot them down in your garden journal.
- The end of this month is a good time to move or add plants, particularly those that bloom in spring and early summer.
- Dig up and divide early-blooming plants, keeping the new divisions well watered until they become established.

SEPTEMBER

Take cuttings of tender plants (such as salvias) and root them in moist perlite for next year's garden. Prepare new perennial beds. Amend the soil with compost; take a soil test, and adjust the pH if necessary. Cover the bare soil with a mulch of chopped leaves to prevent erosion.

OCTOBER

Clean up existing beds after the first hard frost, and throw the spent plants on your compost pile. Leave upright seedheads and pods in the garden for winter interest (the birds will thank you, too). Cover the beds with a 3- to 4-inch layer of mulch for winter protection.

NOVEMBER

Pot the now-rooted cuttings you took back in September and place them on a bright windowsill for the winter.

DECEMBER

Lay evergreen boughs over your perennials to provide an additional layer of insulation. Page through your garden journal and dream about the new perennials you'd like to try the next year.

Perennials Glossary

Acidic soil. Soil with a pH value lower than 7.0.

Alkaline soil. Soil with a pH value higher than 7.0.

Amendment. Material that improves soil condition and aids plant growth.

Annual. A plant that completes its life cycle in one growing season and then dies.

Biennial. A plant that completes its life cycle in 2 years and then dies.

Bulb. An underground stem that stores energy in modified leaves, as in the bulbs of daffodils or tulips.

Compost. Decomposed and partially decomposed organic matter that's dark in color and crumbly in texture. Used as a soil amendment, compost increases the water-holding capacity of sandy soil, improves the drainage of clay soil, and is an excellent nutrient source for microorganisms, which later release nutrients to your plants.

Corm. An underground stem that stores energy in modified stem tissue. as in a crocus stem.

Crown. The part of a plant where the stem meets the roots, usually at or just below the soil line.

Cultivar. Short for "cultivated variety." Any plant that's bred for specific characteristics, such as color, fragrance, disease resistance, or other desirable qualities.

Cutting. Removing a piece of stem or root from an existing plant to grow into a new plant.

Deadheading. Removing spent flowers from a growing plant.

Disbudding. Removing some of a plant's buds to encourage the remaining buds to grow larger.

Disk flowers. The small, tube-shaped blooms located in the center of the flowering heads of plants such as asters and daisies.

Division. A method of propagation by which a plant clump is separated or split apart into two or more plants.

Evergreen. A plant that keeps its green foliage through the winter.

Hardy (perennial). A perennial plant that tolerates frost.

Herbaceous. A plant that dies back to the ground each year; not woody.

Humus. A dark-colored, stable form of organic matter that remains after most of the plant and animal residues in it have decomposed; the organic component of soil.

Insecticidal soap. A specially formulated solution of fatty acids that kills insect pests such as aphids, mites, and whiteflies.

Life cycle. The germination, growth, flowering, seed production, and death of a plant.

Mulch. A layer of organic or inorganic material (such as shredded leaves, straw, bark, pine needles, lawn clippings, or black plastic) that's spread on the ground around plants to conserve soil moisture and discourage weeds. As organic mulches decompose, they help to build the soil.

Neutral soil. Soil with pH of 7.0—that is, neither acidic not alkaline.

Perennial. A plant that flowers and sets seed for two or more seasons.

pH. A number from 1.0 to 14.0 that's a measure of the acidity or alkalinity: 7.0 is neutral, below 7.0 is acidic, and above 7.0 is alkaline. Soil pH greatly affects the availability of nutrients to plants.

Pinching. Removing the tips of stems to encourage more compact, bushier plants; prevent flopping; and ensure more bloom.

Propagate. To make new plants from existing ones. Some methods of propagation include saving seed from plants and then planting the seed, taking cuttings from plants, and dividing clumps of plants.

Rhizome. A horizontal underground stem modified and often enlarged for food storage.

Semiwoody. A perennial plant that forms woody stems but is less substantial than a shrub.

Succulent. Having thick, fleshy, water-holding leaves or stems.

Taproot. The central, often thickened root of a plant.

Tender (perennial). A perennial plant from a tropical or subtropical region that won't survive the winter outside in North America, except in subtropical regions such as Florida and southern California.

Terminal bud. The bud borne at the tip of a stem.

Thinning. Removing some stems of dense, bushy plants to let in light and improve air circulation, often to help prevent mildew on susceptible plants.

Tuber. A swollen, underground stem modified to store large quantities of food.

Variegated. Striped, spotted, or otherwise marked with a color other than green; often used to describe leaves.

Woody. A perennial plant such as a shrub or tree that doesn't die down to the ground each year.

Picking the Perfect Annuals

Larry Hodgson

I have the secret to end all secrets when it comes to growing annuals: Discover which annuals are considered easy to grow under your growing conditions—then plant lots of them! There's little use trying to grow cool-weather annuals in a Florida summer, or moisture-loving annuals where summers are always dry. But if you pick the right plants for your conditions, they'll practically grow themselves!

What Is an Annual?

As the very name "annual" suggests, true annuals are plants that go through their entire life cycle—from seed to bloom to seed production to death—within one calendar year.

Actually, though, only a few of the plants we know as annuals really do go through their full cycle in just one year (on their own, at least). The other "annuals" are actually biennials, perennials, or shrubs that we can trick into blooming the first year by extending their growing season artificially. In other words, we start them indoors to encourage early bloom. We then treat them as annuals because they give the results we expect of an annual; that is, they come into bloom quickly and remain in bloom over the whole summer. When they die in the fall, it's not because they couldn't have lived longer, but because they can't take the cold or damp winters common in much of North America.

From Hardy to Tender

Since they have different origins, the plants we group together as annuals have somewhat different needs. It's easy to tell these needs at a glance if you just understand three terms: hardy, half-hardy, and tender.

- Hardy annuals are extremely fast-growing plants that you can sow directly outside in all climates. They are tough enough to sow outdoors in very early spring, before the last frost date, although you can also start them indoors a few weeks before the last frost date for even earlier bloom. Many are so tough you can sow them the previous fall for germination the following spring.
- Half-hardy annuals can be started indoors in short-season climates, 6 to 8 weeks before the last frost date. Where summers last 4 months or more, they grow fast enough that you can sow them directly outdoors. Set out transplants or direct-sow around the last frost date.
- Tender annuals are usually tender biennials, perennials, or shrubs. Unless you live in a frost-free climate, you'll sow these indoors, usually 10 or more weeks before the last frost. These plants don't like cold temperatures, so keep them indoors until 2 or 3 weeks after the last frost date.

10 Things to Look For in an Annual

Most gardeners probably first choose a particular annual for its color or flower shape—but that can be a mistake. Even the most beautiful flowers can be fleeting if you try to grow a plant in conditions it doesn't like. To get the best results, first pick out annuals that adapt well to your conditions, then look at the flower colors and forms of the plants in that group. I suggest choosing your annuals according to the following 10 criteria:

1. The plant should be adapted to a wide range of general conditions (sun and shade, rain and drought, and so on).
2. It should also be well adapted to any particularities in your climate (hot summers or humid air, for example).
3. It should bloom all summer.
4. It should grow from seed to full bloom in no more than 3 months.
5. It should be resistant to insects and diseases.
6. It should grow more strongly than most weeds, yet not strongly enough to become a weed.
7. It should need little in the way of fussy maintenance (such as pruning, staking, or deadheading).
8. It should be widely available.
9. It should come true from seed.
10. It should transplant readily at all stages of growth.

Of course, no annual meets all 10 of my criteria (wouldn't that be wonderful, though?). The best most can usually manage is 7 out of the 10, which are very good plants. And 5 out of 10 is really not that bad. However, if the plant rates less than 4, you're better off looking for something else.

Buying Annuals

There was a time when you had only two choices when purchasing annuals: Either you bought wooden boxes of ready-to-plant annuals, or you bought seed packs. Well, those wooden boxes (and the fiber ones that followed) have pretty much gone the way of the dinosaur, having been replaced by plastic containers. Seed packs still exist, of course, and in many ways, they've scarcely changed from a century ago. Let's take a quick look at the options:

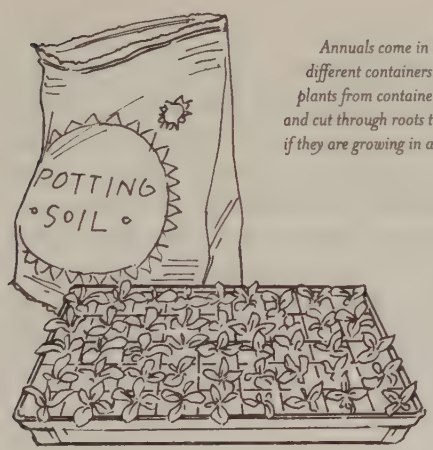
Seed Packs

You'll find these for sale both in local stores and in seed catalogs, but the latter have by far the widest choice. Seed packs are relatively inexpensive, so they're a great choice if you are on a limited budget. In most cases, each annual you grow from seed costs you only a few cents! The downside of seed packs is that they do mean extra work.

Boxes, Flats, and Cell Packs

The standard containers for nursery-grown annuals include boxes, flats, and cell packs. Single pots—usually 4 inches (10 cm) in diameter for annual plants—are the most costly, and cell packs (4 to 6 plants) and six packs are the most commonly sold. In the United States, flats usually contain 8 to 12 cell packs and are the cheapest, most surefire route to a lush, full garden. Outside the states, annual containers hold anywhere from 4 to 36 plants.

The plants grown in these containers are generally raised from seed; in fact, it's the same seed you could have bought from a seed rack or a catalog, but someone else has done all the work. Container-grown seedlings can be a big plus if you're really busy; just pop the plants into the ground and water. In return, you pay a bit more, but most annuals come in at less than 50 cents a plant, so that's not exorbitant.



Annuals come in a variety of different containers. Just pop out plants from containers of peat pots, and cut through roots to separate plants if they are growing in an undivided flat.

Plugs

For years, nurseries have been buying the more-delicate annuals prestarted in trays with tiny little compartments. Normally, they pot them up into larger containers, then jack up the price. Some nurseries, however, are now selling these "plugs" (as the tiny seedlings are called) directly at greatly reduced prices. I buy all my "difficult" annuals (such as begonias and impatiens) this way. Of course, you'll have to pot up the plugs yourself, but the savings are considerable: less than one-quarter the cost of buying the same plant in a cell pack. Buy plugs early and pot them into 2½-inch (6.5 cm) pots or sectioned trays, then grow them indoors until planting-out time.

You can also buy larger plugs (in this case, starter plants) of the usually expensive annuals grown from rooted cuttings—such as Australian fan flower (*Scaevola aemula*)—once again with the idea of potting them up yourself.

Individual Pots

Rooted cuttings of container annuals are usually sold in individual pots at quite a cost: $2 or more per pot. And the larger the pot, the more you pay! If you only need a few plants for a container, though, the cost won't seem so bad. Since all these plants can be propagated by cuttings, I suggest you buy just one plant and multiply it by rooting the cuttings yourself. That will bring the price down!

Preplanted Pots and Baskets

These "finished" container plantings are the most expensive option of all. Plus, they limit your creativity since you're stuck with choosing from the available color combinations and plant choices. Personally, I prefer to plan my own mixed containers. But hey, if you find a preplanted container that you like and it's at a reasonable price, go for it!

Buying Smart

You can tell true gardeners by the annuals they purchase. Everyone around them is picking up plants in full, gorgeous-bloom, yet the true gardeners select plants with nary a blossom. Why?

They know that blooming plants kept in cramped quarters all their lives are overmature. When you put these plants in the ground, they are slow to produce new roots and tend to grow poorly or even die back. Slightly younger plants—perhaps in bud, but not yet in bloom—react differently; put them in the garden and they immediately send out new roots in all directions, then new branches and new leaves. Soon, they are far larger, healthier, and more floriferous than the planted-when-blooming annuals will ever be.

Unfortunately, already-flowering plants sell quickest, so nurseries have no reason to set out younger, not-yet-blooming plants. If you must buy container-grown seedlings already in bloom, you can still get good results if you pinch out all the flowers and all the buds at planting time. This extra step encourages the plant to sprout new roots and shoots galore, giving you blooming plants of top quality in no time.

Going for Quality

Besides choosing annuals that are not yet in full bloom, watch out for any that have been mistreated. Yellowed leaves, leaf spots, straggly growth, wilting stems, and visible insects are not good signs. Instead, look for plants with dense, lush, dark green foliage.

Designing with Annuals

Larry Hodgson

Boy, are you in luck! There is no plant group easier to design with than annuals. For one thing, most bloom throughout the growing season. That means you don't need to account for "downtime," as you would in a perennial garden, or to plan on a color scheme that changes constantly. And annuals let you experiment! You wouldn't dare try a bold design or color combination with permanent plants like perennials or shrubs unless you're sure it will work. With annuals, though, anything goes! You don't like it? Just try something different the following year!

Design Basics

I don't consider myself an expert on design. Like most gardeners, I just follow a few basic rules and change things when I don't like them. And I confess to breaking the rules every now and then: sometimes with great results, sometimes not. Oh well, that's what I use annuals for—to experiment! Three of the basic keys to a beautiful garden are color, texture, and form. Get them to mesh and you'll be doing just fine.

Color

Of the three, color is probably the most influential factor when you choose the annuals you grow. Cool colors, like green and blue, make the garden seem calmer and more peaceful, and they can make a small garden look larger.

Warm colors, like yellow and red, stimulate the eye. They make a garden seem vibrant and alive and can make a large garden seem more intimate.

How you use warm and cool colors is up to you. You can use only one or mix the two groups. If you do choose to mix them, use about half again as many cool-colored annuals as warm-colored ones; if you use equal numbers, the warm colors will dominate. And in general, put cool colors in front of warm colors; otherwise, they'll hardly be visible.

Color Combinations

There is nothing wrong with mixing colors at random, especially if you enjoy an all-mixed-up, everything-goes appearance. If so, you'll find white flowers (and silver and gray foliage) make great moderators. You can use them to separate and soften excessively strong impacts and dilute overbearing colors.

Texture and Form

While flower color is undeniably important when planning a garden, you'll want to consider texture and form as well.

Texture can refer to either flowers or foliage. Just think fine, medium, and coarse, and you'll have a handle on it. Fine foliage creates a soft, intimate look, whereas a few spots of bold, coarse foliage can wake up a humdrum border.

Form refers to a plant's general outline; it may be vertical, rounded, open, spreading, or prostrate (practically flat). The most successful gardens usually include some of each form, with spreading or prostrate plants in the foreground, rounded plants to the middle, and vertical ones at the back or standing tall here and there as "vertical accents."

Beyond "Borders"

Most modern flower gardens feature a broad bed backed by a tall background element, such as a hedge or fence, and are laid out with plants of graduating height (shortest in the front to tallest in the back). Or if the border is to be seen from both sides, the tallest plants are in the middle with shorter plants to either side. But with annuals offering so many possibilities, why not try going beyond the border?

Carpet Bedding

This type of formal bedding is back in style. You've probably seen it in parks or in front of corporate offices: neatly trimmed, low-growing plants set out in precise geometrical patterns or even in company or municipal logos. You can adapt simpler carpet-bedding styles to the home garden. Just choose low-growing plants of contrasting colors, and set them out in relatively geometric patterns. Often a tall, upright centerpiece plant, like castor bean (*Ricinus communis*), will give carpet beds more impact.

Flower Meadows

The ultimate in informality! Best suited for vast spaces you don't have the time (or the money!) to cover with individual bedding plants, a flower meadow involves simply sowing seeds of mixed, fast-growing annuals. In fall or early spring, simply till or plow under whatever was there before. (Don't bother worrying about weeds; the nice thing about a flower meadow is that weeds fit right in!) Then sow annual wildflower seed by hand or with a spreader. Don't think flower meadows are self-maintaining, though. You'll have to till the meadow under and resow it annually; otherwise, weeds and grasses will dominate and flowers will be few.

Cut-Flower Gardens

If you're fond of gathering flowers and foliage for fresh and dried arrangements, consider growing an area of annuals just for that purpose.

The 10 Commandments of Annual Design

Over the years, I've learned a lot both from my successes and my failures. Here are the best tips I know about gardening with annuals.

1. Mix 'em up! Gone are the days when annuals had to be in a bed of their own. You can—and should—plant them among shrubs and perennials.

2. Don't plant too densely. A newly planted garden always looks barren at first, but annuals fill out in only a few weeks.
3. Plan before you plant. It's always wise to take a few minutes to make a rapid sketch of a garden plan and then pencil in a few plant names you've chosen. Next, trace the plan on the garden surface with flour or powdered lime before planting. If you make a mistake, you just have to rake the lines out and redraw. It's much easier than having to dig plants up and replant them!
4. Use annuals abundantly for new gardens. Even if you plan to have a garden mostly based on shrubs or perennials, use annuals until the permanent plants fill in.
5. Avoid straight lines whenever possible. Lines are too hard to maintain and rarely look their best; it takes only one dead plant to destroy the whole effect. Instead, go for curves and undulations when planning edges and for spots of color inside the garden. Save planting in lines for very formal styles, such as carpet bedding.
6. Repeat spots of color. You can mix any colors you like with total impunity, as long as you repeat them. One spot each of a dozen different plants will seem discordant, but if you repeat the spots (each at least twice and preferably more), the whole garden will "pull together" visually. And while you're at it, write down your successful combinations so you'll remember the following year.
7. Stake discreetly or not at all. A few twiggy branches, a bit shorter than the plants themselves, will look much nicer than a forest of upright stakes. And if possible, grow plants that don't require staking.
8. Watch out for self-sowing annuals. They have many good qualities, but that doesn't mean you should let them grow anywhere they want! Pull or dig out any annuals that appear where you don't want them.
9. Don't be afraid to experiment. One of the great advantages to annuals is that they are temporary, so you can easily replace plants that don't work with others when you replant next year.
10. Don't always follow the rules. All rules are meant to be broken, especially in design. Break or bend a few—and watch your garden come alive!

Garden Designs with a Purpose

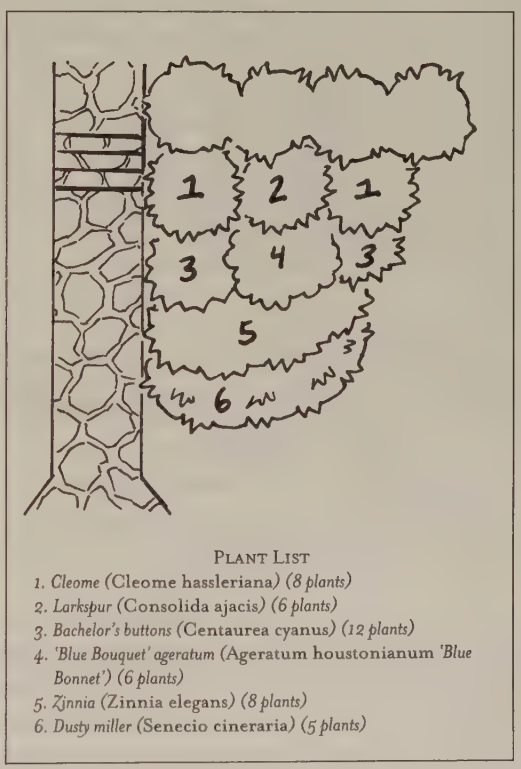
Still not sure you're ready to design a garden on your own? I've included four annual garden designs created by professionals especially for home gardeners like you.

Look over the design layouts on the next several pages to see how the designers combine color and texture, use repetition, and choose plants that have different habits. You may find a plan that's just perfect for your yard or one that inspires you to take the plunge to design a garden of your own. Good luck and have fun!

Grandmother's Backdoor Garden

Heirloom flowers are enjoying a resurgence of popularity—and with good reason. The annuals our grandmothers and great-grandmothers knew and grew are colorful, sturdy, easy-to-grow plants. Many of these old-time favorites are also wonderful in cut-flower arrangements. Designed by heirloom-flower aficionado Sarah Wolfgang Heffner, this backdoor garden in shades of pink, blue, and lavender starts its show in late spring with larkspur and cornflowers, then keeps the color coming with cleome, ageratum, and zinnias for an abundance of bloom from midsummer through early fall (the midsummer view is shown here). This low-maintenance planting will do well in direct sun and fertile, well-drained soil.

Sowing and planting: Start ageratum seeds indoors 6 to 8 weeks before the last frost. Sow cleome, cornflower, and larkspur seeds outdoors in early spring. Sow zinnia seeds outdoors around the last frost date, and set out dusty miller plants around the same time.



PLANT LIST

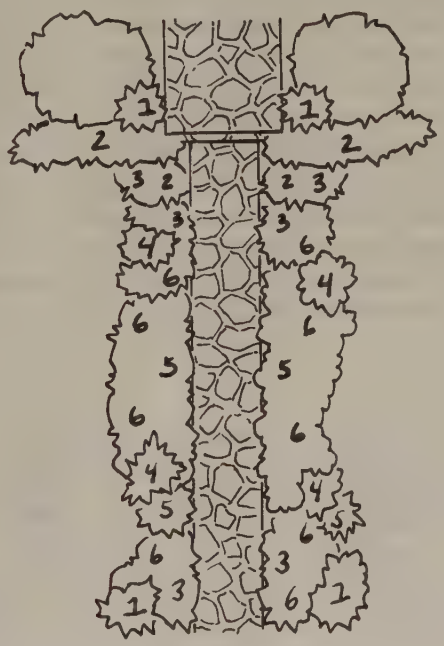
1. *Cleome* (Cleome hassleriana) *(8 plants)*
2. *Larkspur* (Consolida ajacis) *(6 plants)*
3. *Bachelor's buttons* (Centaurea cyanus) *(12 plants)*
4. *'Blue Bouquet' ageratum* (Ageratum houstonianum *'Blue Bonnet')* *(6 plants)*
5. *Zinnia* (Zinnia elegans) *(8 plants)*
6. *Dusty miller* (Senecio cineraria) *(5 plants)*

An Elegant Entrance Border

There's nothing like a flower-filled garden to welcome visitors to your home. Designed by Pam Ruch, this inviting planting (shown in midsummer) combines a touch of formality loosened up by an exuberant mix of colors and heights on either side of

Continued →

the walk. The drought-resistant zinnias add a blast of bright color for months on end, while the Brazilian vervain adds a lively second layer of purple haze. The cool green 'Envy' zinnias provide a pleasant break for the eye. (If your 'Envy' zinnias start looking forlorn by mid- to late summer, Pam suggests pulling them out and letting the remaining plants fill the space—which they'll happily do!) The flowering tobacco offers an extra bonus of evening fragrance. Give this garden a full-sun site with average, well-drained soil.



PLANT LIST

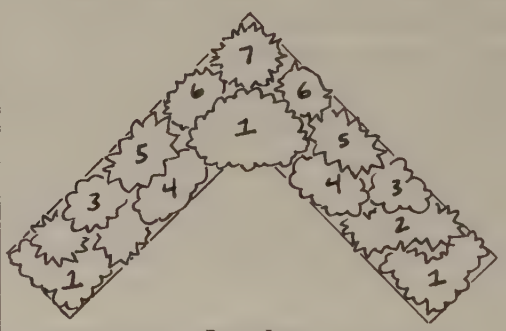
1. *Flowering tobacco* (Nicotiana sylvestris) *(8 plants)*
2. *'Victoria' mealy-cup sage* (Salvia farinacea *'Victoria')* *(72 plants)*
3. *'Profusion Orange' hybrid zinnia* (Zinnia elegans x angustifolia *'Profusion Orange')* *(about 70 plants)*
4. *'Envy' zinnia* (Z. elegans *'Envy')* *(12 plants)*
5. *'Star White' narrow-leaved zinnia* (Z. angustifolia *'Star White')* *(about 70 plants)*
6. *Brazilian vervain* (Verbena bonariensis) *(about 30 plants)*

Sowing and planting: Sow Brazilian vervain seeds outdoors in early spring. Start zinnia seeds indoors 4 to 6 weeks before the last frost date or sow outdoors around the last frost date. Sow flowering tobacco seed outdoors in late spring or indoors at the same time as the zinnias for earlier bloom. Set out mealy-cup sage plants after the last frost date.

A Regal Red Garden

This dramatic collection of rich red flowers and foliage is sure to attract plenty of attention in midsummer, whether you tuck it into an otherwise boring corner or give it a prominent spot near a sidewalk or patio. 'Lady in Red' Texas sage is even a great draw for hummingbirds. To set off the red flowers, this garden includes a variety of other complementary companions, including the chartreuse flowers of 'Lime Green' flowering tobacco, the bright green, red-veined leaves of 'Rhubarb' chard, and the dark purple foliage of 'Purple Ruffles' basil and purple fountain grass. For a more vivid effect, you might replace the purple basil with ferny, bright green parsley. Designed by Nancy Ondra, this garden works well in evenly moist but well-drained soil in either full sun or light shade.

Sowing and planting: Start snapdragon plants indoors 8 to 10 weeks before the last frost date and flowering tobacco seed indoors 6 to 8 weeks before the last frost date. Sow chard seed outdoors in early spring or indoors 6 to 8 weeks before the last frost date. Set out basil, fountain grass, impatiens, and Texas sage plants after all danger of frost has passed.



PLANT LIST

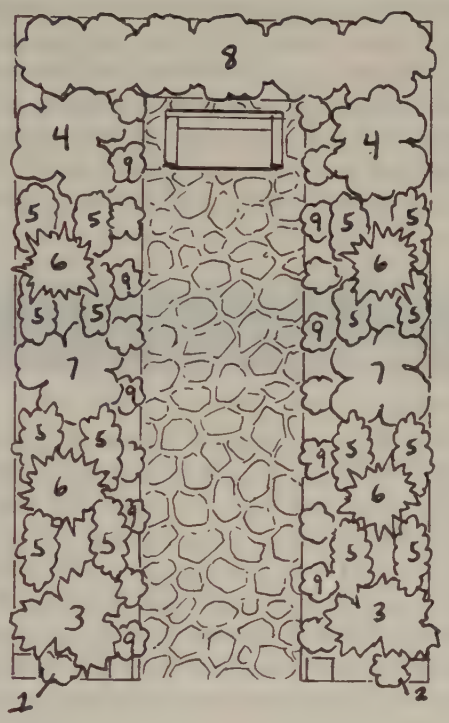
1. *'Accent Red' impatiens* (Impatiens wallerana *'Accent Red')* *(12 plants)*
2. *'Purple Ruffles' basil* (Ocimum basilicum *'Purple Ruffles')* *(12 plants)*
3. *'Rhubarb' Swiss chard* (Beta vulgaris cicia *'Rhubarb')* *(2 plants)*
4. *'Black Prince' snapdragon* (Antirrhinium majus *'Black Prince')* *(12 plants)*
5. *'Lime Green' flowering tobacco* (Nicotiana *'Lime Green')* *(6 plants)*
6. *'Lady in Red' Texas sage* (Salvia coccinea *'Lady in Red')* *(6 plants)*
7. *Purple fountain grass* (Pennisetum setaceum *'Purpureum')* *(1 plant)*

A Garden with Classical Appeal

Designer Stephanie Cohen created a layout that rivals any formal perennial garden for elegance, yet it's composed entirely of easy-care annuals. Shown in midsummer, the mixture of strong spikes, billowing mounds, and cheerful climbers blooms from early summer to midfall. Full sun and average, well-drained soil are ideal for this garden.

Sowing and planting: Start snapdragon plants indoors 8 to 10 weeks before the last frost date. Sow sweet alyssum seeds outdoors in early to mid-spring. Start ageratum and hyacinth bean seeds indoors 6 to 8 weeks before the last frost date. Start

zinnia seeds indoors 4 to 6 weeks before the last frost date or sow outdoors around the last frost date. Set out fountain grass, mealy-cup sage, and marguerite daisy plants, and sow morning glory seeds outdoors after the last frost date.



Plant List

1. *'Pearly Gates' morning glory* (Ipomoea tricolor *'Pearly Gates')* *(1 plant)*
2. *Hyacinth bean* (Lablab purpurea) *(1 plant)*
3. *'Rocket White' snapdragon* (Antirrhinum majus *'Rocket White')* *(6 plants)*
4. *'Splendor Pink' zinnia* (Zinnia *'Splendor Pink')* *(6 plants)*
5. *'Victoria' mealy-cup sage* (Salvia farinacea *'Victoria')* *(16 plants)*
6. *Purple fountain grass* (Pennisetum setaceum *'Purpureum')* *(4 plants)*
7. *'Comet Pink' and 'Comet White' maguerites* (Argyranthemum *hybrids 'Comet Pink' and 'Comet White')* *(10 plants)*
8. *'Blue Horizon' ageratum* (Ageratum houstonianum *'Blue Horizon')* *(7 plants)*
9. *'Carpet of Snow' sweet alyssum* (Lobularia maritime *'Carpet of Snow')* *(20 plants)*

Caring for Annuals

Barbara W. Ellis

Annuals are bountiful beauties loved by gardeners for their long blooming season, easy culture, and many uses. Annuals are distinguished from other flowers such as perennials and biennials because they will germinate, flower, set seed, and die, all within one growing season. Unlike most perennials, which generally bloom for only two or three weeks, many annuals flower week after week from spring until they are cut down by frost. Ageratums, fibrous-rooted begonias, marigolds, impatiens, and petunias all provide long blooming seasons.

There are many ways to use annuals in the garden. Many expert perennial gardeners fill summertime color gaps in perennial plantings with generous splashes of annuals. Annuals also can make a fine cover over a springtime bulb garden, for they are generally shallow-rooted and will hide the bulb foliage as it fades. Other gardeners prefer to use annuals alone in colorful masses. For small terraces, porches, or patios, containers and hanging baskets filled with annuals provide garden greenery and color.

Each year the newest geranium, petunia, and impatiens cultivars vie for the number one position in the bedding plant industry. Seed packets of these popular plants are available in stores and from mail-order catalogs across the country. Many of the most common and reliable annuals are also offered as bedding plants. Bedding plants are an easy and inexpensive way to add instant color to the garden. All you need to do to create an "instant" garden is take your garden plan to the garden center and select your plants.

Many gardeners like to raise their annuals from seed. Growing plants from seed is the most thrifty way to produce annuals. It's also great fun, and it provides an opportunity to try many new or unusual cultivars not otherwise available, since seed catalogs offer many more selections than the average bedding plant display.

Some annuals, like marigolds and zinnias, are so easy to start from seed they can be planted directly in the garden. Others, including geraniums and impatiens, need to be sown indoors well before the last frost.

Planting Annuals

If you've grown annuals from seed, be sure to harden the plants off before moving them to the garden. This is also a good idea for greenhouse-grown bedding plants, which haven't been exposed to the rigors of life in the outdoors. You can move them to a cold frame a week or so before they're scheduled to go into the garden; build a simple hoop shelter out of wire and polyethylene; or move them to a sheltered spot outdoors for longer and longer periods each day.

Most gardeners transplant seedlings or bedding plants just after the last average date of frost in their area. If you put them out earlier, be prepared to cover your tender plants with burlap, newspaper, or some other protective layer if frost threatens. Listen to the weather reports during those changeable spring days. Very tender annuals such as impatiens won't really begin to grow until soil temperatures warm.

Routine Care

Once in the garden, annuals need minimal maintenance. One of the best ways to reduce the amount of work they require is to

Continued ➔

find annuals that are adapted to the conditions that generally prevail in your garden. Plants that are naturally inclined to grow in dry, sandy soil, for example, will be healthier and require less care than those that aren't. There are annuals suited to every climate and every type of garden. There are several ways to identify the best ones for your garden: Talk to other gardeners, visit gardens and note which plants are thriving, call your local cooperative extension service, and look for lists in pamphlets, magazines, or other publications that recommend plants for similar conditions. Try growing some new annuals each year and keep notes about their performance.

In a well-prepared bed with enriched soil, most annuals seldom need any additional fertilizer. However, some, like petunias, respond well when cut back in midsummer and given a boost of a balanced fertilizer. Mulch helps keep moisture in the soil, and it also cuts down on weeding.

Most annuals will need to be pinched at least once early in the season to encourage branching and compact growth. To pinch a plant, use your fingernails or a small pair of shears to pinch the bud, or the bud and youngest set of leaves, off the tip of each stem. Annuals that become tall and leggy can be cut back to just above a leaf node. It's best to use shears for this purpose to make sure you make a clean cut.

Deadheading, which means removing spent flowers as they fade, prevents the plants from going to seed. This keeps the garden more attractive and encourages the annuals to produce more flowers. It also is a way to keep annuals that will reseed prolifically in check. Only let a plant set seed if you want to save the seed.

In weeks when there is less than an inch of rain, you'll probably need to water the garden. In parts of the Southeast, Southwest, and California, where there is no rain for months at a time, traditional gardens need to be on a regular watering schedule. Using drip irrigation may be a feasible way to reduce water use.

Today, many gardeners are selecting plants able to survive with a limited supply of water. Drought-resistant annuals, such as African daisy (*Gerbera jamesonii*), sunflowers (*Helianthus* spp.), and moss rose (*Portulaca* spp.), are very useful for adding color to a garden that uses modest amounts of water.

Ending the Season

After enjoying the season of color and beauty annuals provide, there is one final job for the gardener—putting the garden to bed for winter.

Before frost threatens, consider rooting cuttings or digging and potting annuals that are actually perennials and can be brought indoors for the winter. These include wax begonias, impatiens, and verbena. You can enjoy the color they'll provide indoors and also use them to propagate new plants for next spring. You can select annuals to overwinter that have unusual flower color or other attractive features and perpetuate these characteristics for next season. Roots of four-o'clocks can be dug, dried for a few hours, and stored indoors in a cool, frost-free place through the winter.

When frost kills the impatiens, petunias, and marigolds to the ground, it's time to remove the debris from the garden. Pick up or rake off all of the spent plants and toss the remains on the compost heap where they will decompose and be returned to the garden another year in the form of rich brown compost. Leaving the garden clean during the winter is more attractive, and it minimizes insect and disease problems during the next gardening season. If you've grown French marigolds for nematode control, now is the time to till the plants into the soil.

Favorite Annuals

Larry Hodgson

They're tall or short; they're upright, rounded, or creeping; they're great in borders or in containers; they grow under a wide range of conditions; and they come in an incredible range of flower forms and colors. They're multipurpose annuals: plants that offer a bit of everything to every garden-planting scheme. You could easily design a complete annual garden around just these 13 versatile plants! Oh, but did I mention they also mingle well with bulbs, perennials, and shrubs? You simply can't go wrong when you use multipurpose annuals throughout your landscape.

Traditional Yet Ever-Changing

If you're looking for something totally new, a plant of a genus never before seen on the shelves of your local nursery, look elsewhere in this book! This section is made up strictly of plants that have been popular for generations. Snapdragon, pansy, geranium, petunia, marigold: They're all names you've heard before, even if you've never lifted a hoe in your life. That's not to say that multipurpose annuals don't occasionally yield new characteristics: new flower forms or colors or never-before-seen growth habits. It's their tried-and-true performance, however, that you'll learn to love; just stick them in the ground and watch 'em grow. They'll bloom and bloom and bloom, making your garden look good right through the summer.

Tailor-Made to Suit Our Tastes

There are many annuals whose entire range consists of one or two cultivars. When you head to the garden center or market to buy one of these, you have little choice: just pink or white perhaps, or maybe tall or taller. Compare this sort of meager selection to nursery displays of any of the plants featured in this section. Even corner stores offer dozens of varieties of each in an equally wide range of colors and forms. And if you really want choice, go beyond local stores and delve into one of the larger

seed catalogs: There are literally pages and pages of petunias, pansies, marigolds, and China asters, for example.

No matter what your tastes in plants are, each of the multipurpose annuals probably offers at least a few varieties that you'll just love. Of course, this wide range of plants wasn't always available. When these multipurpose annuals were first introduced a few centuries back, there was usually only one species . . . and it wasn't always that impressive. For example, would you believe that the original petunia, now available in such a wide range of cultivars, was a scrawny, creeping plant with tiny white flowers? None of the multipurpose annuals we grow today were any different: The original plants offered little variety and certainly didn't seem to offer much potential.

And then the hybridizers got ahold of them! Under their guiding hand, the wild species morphed into the varied plants we know and love today. Tall, ungainly plants were brought down to size, climbers and creepers became dense and compact mounders, and simple little flowers became large blooms with extra petals that bloomed in a vastly wider range of colors. The end result with each multipurpose annual has been a profusion of cultivars of each plant.

Small Is Beautiful . . .

One of the most remarkable and obvious changes in multipurpose annuals is that they have come down in size over the years. Most of the dense, low-growing annuals we're so used to today were once tall, rangy plants suitable only for the back of the border or scraggly spreaders that needed to be mingled with others to create a worthwhile effect. Hybridization has led to plants with shorter and shorter internodes (the spaces between the stem leaves), resulting in dense, compact plants suitable for edging and bedding.

In fact, the entire concept of a bedding plant (and all multipurpose annuals make superb bedding plants) implies dense, short growth with abundant bloom that creates a carpet of blossoms. The shortening of annual plants over time is so universal that most gardeners would scarcely recognize the gangly ancestors of their common garden annuals. And the trend still continues, with each year bringing ever-shorter cultivars. If it never ends, I can only surmise that future generations of annuals will bloom underground!

. . . But Only in Plant Size

If short plants are generally seen as desirable, small flowers most certainly are not. So another major trend has been toward the development of larger and larger flowers, or at least denser clusters of flowers. Here, too, there seems to be no limit. Many modern annuals have blooms so large that they are beaten to a pulp by the slightest rain (Grandiflora petunias, for example), but gardeners will forgive even that—as long as the plant quickly replaces its damaged blooms with new blooms.

Other trends are easy to see just by looking at what the average nursery offers. Double flowers, for example, are clearly highly prized (although that trend does seem to be abating these days). And increases in color range are a must. Is it any wonder dahlias and pansies are so popular? They are now offered in about every color of the artist's palette—and then some!

Although the trend is toward dense, short-growing annuals, don't totally rule out the more old-fashioned, taller strains of yore. Tall snapdragons, for example, can add great impact to the mid or back border—and make great cut flowers. And the old-fashioned, climbing nasturtiums look just as great on a trellis as their dwarf brethren do at the front of the border.

Annuals for Everyone

And there you have a portrait of the average multipurpose annual: dense and compact, with large, often double, flowers in a wide range of colors and forms. These versatile annuals are the wallpaper of the flower garden. There is so much choice, you can't help but find exactly what you want!

Antirrhinum

Snapdragon

Snapdragons are instantly recognizable by their terminal spikes of unique flowers. The tubular blooms with a pouting lower lip seem closed to all traffic until you lightly pinch the sides; then they quickly open to reveal a gaping maw, as if they were dragons ready to snap off your finger! Of course, the flowers are perfectly harmless, but they have fascinated generations of young and young-at-heart gardeners for decades.

PLANT PROFILE

Antirrhinum: an-tir-RYE-num

Bloom Color: Pink, purple, red, orange, yellow, white; bicolor

Bloom Time: Summer; fall through spring in mild climates

Height: 6 to 36 inches (15 to 90 cm)

Spread: 6 to 12 inches (15 to 30 cm)

Garden Uses: Container planting, cut-flower garden, edging, mass planting, mixed border, rock garden

Attracts: Bees, hummingbirds

Light Preference: Full sun or partial shade

Soil Preference: Humus-rich, moist but well-drained, neutral to very acid soil

Best Way to Propagate: Sow seed indoors in late winter or outdoors in early spring

Hardiness: Tender perennial grown as a half-hardy annual

Growing Tips

Snapdragons are easy-to-grow annuals with a long blooming season, particularly in cool summer areas. On the down side,

Continued →

they tend to peter out quickly in hot summer climates. If you live where summer temperatures soar, get your snapdragons into the ground early to take full advantage of their spring bloom; and plant them in partial shade, where it is naturally cooler.

You could sow snapdragons outdoors in early spring, as soon as the ground is workable, but then you'll miss half their blooming season. Instead, start them indoors 8 to 10 weeks before your last frost date. Sprinkle seed over the surface of the growing mix—don't cover it; mist lightly and expose the tray to light to stimulate germination. Look for the first seedlings in 10 to 21 days. Snapdragons germinate readily under cool conditions, down to 50°F (10°C), but they do fine under lights at warm temperatures as well. When the seedlings have four to six leaves, pinch the stem tips lightly to encourage bushy growth. Water carefully, preferably from below; young seedlings are subject to rot if overwatered. Plant outdoors 2 to 3 weeks before your last frost date; snapdragons can take even relatively heavy frosts without complaint.

Snapdragons' excellent cold resistance makes them a great choice for winter bloom in mild-winter areas. Just sow them outdoors in August or September in an out-of-the way spot, then transfer them to your flowerbed when nights start to turn cool.

If you're buying plants, look for healthy, dense, leafy growth. Snapdragons that are planted when already in bloom tend to fade out after their first flowering, so for the best long-term results, remove all of the flower spikes at planting time. In the garden, deadhead regularly, cutting out flower spikes when the last few flowers are opening in order to stimulate rebloom.

Although they are offered as annuals, snapdragons are actually tender perennials and occasionally survive winter even in my cold climate. When they do, though, they tend to start blooming late in the season only to suffer in summer's heat. You're best off planting new ones each spring and then yanking them out when their flowering season ends.

Good Neighbors

Snapdragons are valuable as a vertical accent in the mixed plantings of annuals and perennials. In groupings of three to six, taller cultivars can offset postbloom mounds of lady's-mantle (*Alchemilla mollis*) or perennial geraniums (*Geranium* spp.), bringing color to an otherwise green season. The range of available colors gives you all kinds of combination options, but I think the most useful of all is the cream shade, which looks great with any other color. Picking up a couple of dozen to use as filler is never a mistake.

Problems and Solutions

Rust can be a problem, especially in rainy climates. Look for resistant cultivars and avoid overhead watering. When rust has been a problem in the past, avoid planting snapdragons in the same spot 2 years in a row. Taller cultivars may need discreet staking.

Top Performer

Antirrhinum majus (common snapdragon): Originally tallish plants bearing spikes of flowers over a bushy cluster of stems, most snapdragons are now low-growing, compact plants with short, dense spikes. The original dragon's-head-like flower form is still common, but there are now many open-flowered snapdragons with trumpet-shaped blooms as well as double-flowered forms. There are dozens of cultivars, ranging in height from tall to knee-high to dwarf; and all make good garden plants, so choose according to your tastes.

Callistephus

China aster

The huge blooms of the China aster are a flower arranger's dream, and they don't look half bad in the garden either! The range of flower forms is remarkable, from single, daisylike blooms to double pompoms to those shaggy spider types that seem to be having a continuously bad-hair day. The color range is just as amazing: They've long been available in every possible shade of white, pink, red, and purple, and now there are even shades of yellow and peach. All have dark green, somewhat triangular, coarsely toothed leaves.

PLANT PROFILE

Callistephus: ka-LISS-tee-fuss or ka-liss-TEE-fuss

Bloom Color: Near blue, lavender, pink, purple, violet, peach, red, rose, yellow, white

Bloom Time: Midsummer into fall; early summer for day-neutral cultivars

Height: 6 to 36 inches (15 to 90 cm)

Spread: 12 to 18 inches (30 to 45 cm)

Garden Uses: Container planting, cut-flower garden, edging, mass planting, mixed border, rock garden

Light Preference: Full sun to partial shade

Soil Preference: Average, well-drained, slightly acid to alkaline soil

Best Way to Propagate: Sow seed indoors in late winter or outdoors after all danger of frost has passed

Hardiness: Half-hardy annual

Growing Tips

Although pretty as a picture, China asters have picked up a bad rap over the years as being difficult to grow. While that reputation isn't fully merited, I still wouldn't necessarily recommend the China aster for your first attempt at growing annuals from seed. For your first try, I suggest either buying plants or sowing the seed outdoors when all danger of frost has passed for bloom into late summer and fall.

If you're feeling adventurous, you can grow China asters from seed indoors—if you start them under lights. The problem with growing China asters indoors is that they grow poorly during short days, and because you should start them indoors 6 to 8 weeks before the last frost, the days are always short at sowing time. Giving them 12-hour days from the start, however, produces beautiful, dense, healthy plants. Just barely cover the seed; it germinates readily at room temperature in 10 to 20 days. Water lightly; soggy mix can cause seedlings to rot. Their roots are fragile; so transplant carefully, or sow in peat pots to avoid transplant shock. And prick the seedlings out with the crown at the same depth as before.

In the garden; China asters prefer full sun or only very light shade. Keep their soil moderately moist; and mulch to keep the roots cool. Cut-flower types may need staking, or you can surround them with sturdier plants to keep them upright. Individual plants bloom for only 3 to 4 weeks, so try successive sowings to prolong flowering until fall, or sow early, midseason, and late cultivars. Don't bother deadheading; China asters won't rebloom—just pull out the plants when they finish blooming.

Good Neighbors

China asters and grasses share an affinity for soil of neutral pH, which makes the two good companions. Try direct-sowing them around medium-height grasses, such as blue oat grass (*Helietotrichon sempervirens*) or northern sea oats (*Chasmanthium latifolium*). Sowing tall China aster cultivars around stiffer plants, such as *Artemisia* 'Powis Castle' or *Sedum* 'Autumn Joy', may help you avoid staking.

Problems and Solutions

Aster wilt, which causes the plants to blacken at the base and keel over, was formerly very common; but most modern China asters are now very resistant to the disease. The same can't be said for aster yellows, an incurable virus carried by insects. As the name suggests, the infected plants turn yellow, and then they die. Although leafhoppers and aphids are the main culprits, don't panic when you see them—your plants will likely have time to bloom before the disease affects them. But do destroy obviously diseased plants on sight. The real secret to controlling both aster yellows and aster wilt is to choose a different planting site for your China asters each year and to avoid replanting in the same spots for at least 4 years.

Top Performer

Callistephus chinensis (China aster): It's the only species available, but it makes up for the lack of choice by offering literally hundreds of cultivars. One important development in China asters has been the introduction of "day-neutral" plants. In the past, it was difficult to get asters to bloom early (other than under lights) because they needed the long days of summer to initiate buds, meaning they weren't in full bloom until mid-July at the earliest. Day-neutrals, on the other hand, will start to flower once they reach their adult size, regardless of day length. You won't always find the words "day neutral" noted on the seed pack, though: Look for "early blooming," "blooms within 90 days," or some other phrase that suggests the pack's contents are especially rapid from seed.

Celosia

Celosia, cockscomb

Celosia is a plant of tropical origin, and it looks every bit the part! The shiny, deep maroon or light green leaves are topped by tiny flowers clustered into plumy feather dusters or twisted brain- or coral-like masses, generally in fiery shades of red, yellow, orange, or shocking pink. Some puritanical gardeners disdain celosia's brilliant coloration and complain it stands out too much from the crowd. If it offends your tastes, try something else—but if you want to add a bit of zing to an otherwise drab landscape, this brazen beauty may be just what the doctor ordered.

PLANT PROFILE

Celosia: sell-OH-zee-uh

Bloom Color: Pink, red, orange, yellow, cream

Bloom Time: Late spring through early fall; fall through winter in mild climates

Height: 8 to 36 inches (20 to 90 cm)

Spread: 6 to 16 inches (15 to 40 cm)

Garden Uses: Container planting, cut-flower garden, edging, mass planting, mixed border

Light Preference: Full sun to partial shade

Soil Preference: Humus-rich, evenly moist but well-drained soil

Best Way to Propagate: Sow seed indoors in spring or outdoors in early summer

Hardiness: Frost-sensitive perennial grown as a tender annual

Growing Tips

Although you can sow celosia seed outdoors, you should wait until the ground has warmed up thoroughly, 1 or 2 weeks after the last frost date. You'll probably find, however, that you get better results by sowing the seed indoors, just barely covering it, 4 to 8 weeks before the last frost date. The seed sprouts in 5 to 14 days at 70° to 80°F (21° to 27°C). Celosias resent root disturbance, so for best results, start the seed in peat pots. Wait 1 or 2 weeks after your last frost date, until the night temperatures have warmed up a bit, before setting out the seedlings. When you plant them out, keep the rootball at the same depth as it was in the pot.

Continued ➔

Slow and steady is the key to success with celosia. Abrupt changes in conditions, drought, and even just cold water from the hose can stunt its growth. Even buying plants already in bloom is risky; they often stop growing and fail to fill out. When buying celosias, look for sturdy plants not yet in flower. Failing that, remove all existing flower clusters at planting time. Six packs or cell packs are a better choice than flats because there's less root disturbance at planting time.

Good Neighbors

When planted in masses, celosia can be too much of a good thing; used judiciously, however, it can add a rich accent to a perennial bed. The dark foliage of 'New Look', a plumed cultivar with deep red flowers, makes a great foil for postbloom candy tuft (*Iberis sempervirens*) or perennial geraniums (*Geranium* spp.). Try yellow plumes around purple globe amaranth (*Gomphrena globosa*) for an interesting low border. An edging of a tightly crested cultivar can provide a fascinating contrast in front of feathery Oriental fountain grass (*Penniserum orientale*). Wheat celosia (*Celosia spicata*) has a unique look that can be quite interesting in a naturalistic garden among grasses and meadow plants.

Problems and Solutions

The most common problem is stunted growth due to planting shock or abrupt changes in conditions, so careful planting when temperatures have warmed up is essential. Root rot is possible in soggy soil.

Top Performer

Celosia argentea plumosa (plumed celosia, feathered amaranth): This plant comes in dwarf, knee-high, and tall cultivars with green or red leaves and remarkable feathery clusters of flowers. Taller cultivars form a solid, summer-long mass of flowers at the tip of the bushy plant with smaller plumes toward its base. Dwarf cultivars produce numerous shorter clusters, all reaching much the same height. Dwarf cultivars make excellent bedding plants; taller selections are spectacular cut flowers. Height: 8 to 36 inches (20 to 90 cm). Spread: 6 to 16 inches (15 to 40 cm).

More Recommended Celosia

Celosia argentea cristata (cockscomb): Resulting from a curious mutation that comes true from seed, the flowers of the normally spiky celosia become crested like a rooster's comb. Cockscomb celosias occasionally produce normal plumed flowers; just prune these out on sight. Height: 8 to 36 inches (20 to 90 cm). Spread: 6 to 16 inches (15 to 40 cm).

C. spicata (wheat celosia): These plants are thinner, more open, and less flamboyant in both form and color than their showier cousins—and they are easier to fit into mixed plantings. The spiky flower clusters, in pale pink to deep pink, do look rather like wheat, and they take on a bicolor appearance as the lower flowers on the spike turn paler over time. Height: 28 inches (70 cm). Spread: 6 inches (15 cm).

Dahlia

Dahlia

There's no lack of choice when it comes to dahlias! There are some 20,000 different cultivars in just about every color but true blue, and they range from 1-foot (30 cm) bedding dahlias to 10-foot (3-m) border giants that fill nearly a whole flowerbed by themselves. There are so many flower forms that the American Dahlia Society has designated 16 different classes: everything from spiky cactus dahlias to fully rounded ball dahlias, formal-looking decorative dahlias, and old-fashioned single-flowered dahlias. Even the foliage ranges from dark green to deep purple!

PLANT PROFILE

Dahlia: DAH-lee-uh

Bloom Color: Near black, lavender, pink, purple, violet, red, orange, yellow, white

Bloom Time: Summer through early fall for bedding dahlias; midsummer to early fall for border dahlias

Height: 1 to 10 feet (30 to 300 cm)

Spread: 12 to 18 inches (30 to 45 cm) for bedding dahlias; 18 to 48 inches (45 to 120 cm) for border dahlias

Garden Uses: Container planting, cut-flower garden, edging, annual hedge, mass planting, mixed border

Attracts: Butterflies

Light Preference: Full sun to partial shade

Soil Preference: Average, evenly moist but well-drained soil

Best Way to Propagate: Sow seed indoors in late winter; divide tuberous roots

Hardiness: Frost-sensitive tuberous root grown as a tender annual

Growing Tips

You can start dahlias either from seed or from tuberous roots; nurseries and mail-order sources offer both in early spring. You'd think that those grown from tubers would be faster growing, but oddly enough, seed-grown dahlias usually beat the tubers to the punch. Start the fine seed indoors 6 to 10 weeks before the last frost, barely covering it, and keep it at 65° to 85°F (18° to 30°C) until seedlings emerge in 5 to 21 days. Pinch when the seedlings are about 3 inches (8 cm) tall to promote bushier growth and more abundant bloom. Wait until all danger of frost has passed and the ground has warmed up before setting them out. You can also start the seed directly outdoors, but the seedlings won't bloom until mid- to late summer.

Maintenance is simple: Water when the soil is nearly dry, mulch to keep the weeds in check, and deadhead to encourage rebloom.

I have a basic rule about whether or not to overwinter dahlias: I carefully dig up and store for the winter my favorite tuber-grown cultivars, but I let the seed-grown types freeze. It sounds cruel, but it is actually faster to grow border dahlias from seed each spring than from tubers . . . and just as easy. If you do want to keep your tubers, dig them up after frost has destroyed their foliage; cut off the dead leaves; and store the tubers in peat moss, vermiculite, or perlite in a cool, frost-free spot.

Check them monthly during the winter and spray them with tepid water if they seem to be shriveling. In spring, plant them directly in the garden when all danger of frost has passed, or start them indoors in pots 4 weeks before the last frost.

Good Neighbors

Shorter cultivars mound nicely and present a formal face, making them useful as edging plants, and they look great in containers, too. Combine the taller cultivars, which are excellent for cutting but not the most generous of bloomers, with Brazilian vervain (*Verbena bonariensis*) to add continuous color for those times when the dahlias aren't in flower. The dark foliage of red-leaved selections, such as the seed-grown 'Diablo' strain, makes a handsome accent in perennial borders.

Problems and Solutions

When earwig populations are large, they do considerable damage, entirely emptying out buds before they open. Leave out boards they can hide under, then crush them underfoot. Staking is almost essential with tall dahlias. Otherwise, they are pretty much trouble-free plants.

Top Performer

Dahlia cultivars (dahlia): Almost all dahlias currently grown are complex hybrids and listed either without a species name or as *Dahlia* x *hortensis*. This category includes everything from the tiniest border types to the huge dinner-plate-flowered, back-of-the-border cultivars. Only a handful of these come true enough from seed to be sold in seed packs. Most of the latter are border-type dahlias: short, dense plants with an early-blooming, nonstop-flowering characteristic that makes them outperform even the best of the tuberous cultivars. Seed-grown dahlias do produce small tuberous roots, but they grow so quickly from seed that it is rarely worthwhile trying to maintain them over the winter.

Dianthus

China pink, sweet William

China pinks get top ratings for their incredibly long season of bloom. They're frost hardy, so you can plant them out before the last frost date for extra-early blossoms; under the right conditions, they'll still be in full bloom late the following fall! Their flat-faced, toothed or smooth-edged, 1- to 2-inch (2.5- to 5-cm) blooms are usually bicolored, with contrasting eyes or halos, and are held over mounds of grasslike, gray-green foliage. Some offer a very light clove scent.

PLANT PROFILE

Dianthus: dye-AN-thus

Bloom Color: Pink, wine purple, red, white; bicolor

Bloom Time: Early spring through late fall; fall through winter in mild climates

Height: 6 to 30 inches (15 to 75 cm)

Spread: 8 to 14 inches (20 to 36 cm)

Garden Uses: Container planting, cut-flower garden, edging, groundcover, mass planting, mixed border, rock garden

Attracts: Butterflies

Light Preference: Full sun to partial shade

Soil Preference: Average, well-drained, neutral to alkaline soil

Best Way to Propagate: Sow seed indoors in late winter or outdoors in early spring

Hardiness: Hardy perennial grown as a hardy annual

Growing Tips

China pinks are easy to grow, whether you start them from seed or buy them in six packs or cell packs. They have only two flaws: They hate hot weather (protection from afternoon sun is best where summers are hot) and they like soil on the alkaline side. Although the slightly acid soil of most gardens is acceptable, they prefer a pH of 7.0 or more; so I suggest sprinkling a bit of powdered limestone or wood ashes into the soil at planting time.

Start China pinks indoors 8 to 10 weeks before the last frost or buy plants already in bud. You can also sow them directly in the garden 3 weeks before the last frost for somewhat later bloom; in mild climates, sow in fall for bloom the following spring. Indoors, sow at room temperature, just covering the seed. After germination, in 5 to 21 days, bring the temperatures down to 50° to 60°F (10° to 15°C). Set out these cold-tolerant plants 2 to 3 weeks before the last frost date. During summer, keep them well watered and deadheaded regularly to help maintain constant flowering.

Good Neighbors

Planted in masses, pinks create a low river of intense color that looks super edging a bed or snaking through low-growing shrubs or late-flowering mums. They can also be useful as an underplanting for roses of a complementary color range or as a filler to color the niches of a rock garden.

Continued ➔

Problems and Solutions

When grown as annuals, pinks rarely suffer from insects or diseases, although slugs are sometimes a problem. Rust or wilt sometimes affects established plants; destroy diseased plants and set out new pinks in a different site.

Top Performer

Dianthus barbatus x *chinensis* (hybrid China pink): Almost all modern strains of so-called *D. chinensis* actually belong here. Crossing China pinks with sweet William (*D. barbatus*) has added greater frost resistance, clustered instead of solitary flowers, more fringing (true China pinks tend to have smooth-edged blossoms), and occasionally some perfume. Most modern China pinks are compact plants, which are ideal for edging and containers, although the long-stemmed cultivars seem to be coming back in style. Growing 18 to 30 inches (45 to 75 cm) tall, these taller cultivars make great cut flowers but may require staking. Height: 6 to 30 inches (15 to 75 cm). Spread: 8 to 14 inches (20 to 35 cm).

More Recommended Dianthus

Dianthus barbatus (sweet William): These plants are very similar to China pinks, but they produce clusters of more deeply fringed flowers in pink, red, white, purple, and bicolors—each stem makes a complete bouquet! Sweet Williams were originally highly scented flowers, but modern strains have lost much of their perfume. Originally biennials or short-lived perennials, sweet Williams—through careful selection—now bloom the first year from early-sown seed. Sow annual strains as recommended above; sow the biennial strains outdoors in early summer for bloom the following year. Height: 6 to 24 inches (15 to 60 cm). Spread: 4 to 12 inches (10 to 30 cm).

D. chinensis (China pink): Pure China pinks are now quite rare. Plants sold under the name *D. chinensis* are inevitably hybrids between *D. chinensis* and *D. barbatus*. Height: 6 to 30 inches (15 to 75 cm). Spread: 8 to 14 inches (20 to 35 cm).

Nicotiana

Nicotiana, flowering tobacco

Yep, this delicate summer beauty really is a close relative of the tobacco plant (*Nicotiana tabacum*). Don't try smoking any of the ornamental kinds, though; they're considered toxic! Instead, grow them for their summer-long bloom and often-exquisite perfume. Most nicotianas form a dense cluster of apple green leaves topped with spikes of tubular, five-petaled flowers. Be forewarned, though, that their blooms often close during the day, opening fully only in the evening, at night, and on cloudy days. If you want daytime bloom, look for cultivars labeled "open all day long."

PLANT PROFILE

Nicotiana: ni-koh-shee-AH-nuh

Bloom Color: Green, pink, salmon, red, white

Bloom Time: Late spring through early fall

Height: Varies by species; see individual listings

Spread: Varies by species; see individual listings

Garden Uses: Container planting, cut-flower garden, edging, annual hedge, mass planting, meadow garden, mixed border

Attracts: Sphinx moths, hummingbirds

Light Preference: Full sun to partial shade

Soil Preference: Evenly moist, well-drained soil

Best Way to Propagate: Sow seed indoors in late winter, outdoors in late spring

Hardiness: Frost-sensitive perennial grown as a half-hardy annual

Growing Tips

Nicotianas are adaptable, easy-to-care-for annuals that thrive in most climates and under most conditions, even alkaline soil and partial shade. They're pretty much problem-free plants with lots of visual impact in the garden.

Whether you grow them from seed or buy plants is mostly a question of how much time you have on your hands: Even raw novices will find them a snap to grow from seed. Although *Nicotiana sylvestris* is fast enough to grow from direct-sown seed (in fact, it will often self-sow), it's best to start most other types indoors 6 to 8 weeks before the last frost, at least if you want to have early bloom. Don't cover the fine seed, though: It needs light to germinate. They sprout at 65° to 85°F (18° to 30°C) in 10 to 20 days. For maximum bloom, keep the plants moist throughout the entire growing season (mulch can be a big help).

Good Neighbors

Planted in groups of six or more, the more-compact nicotianas add color and elegance to a perennial garden or a shrub border. Lime green *Nicotiana langsdorffii* looks terrific with any other color but makes an especially handsome contrast with dark foliage; try it with deep purple basil or one of the tall, dark-leafed coleus cultivars that can take a bit of sun. Tuck a plant or two of *N. sylvestris* into the back of a border for wonderful evening scent.

Problems and Solutions

Nicotianas are not particularly subject to pests, but aphids can occasionally be a problem. Knock them off with sprays of water. Reduce the chance of mildew, damping-off, stem rot, and other diseases associated with wet stems and leaves by mulching and watering from below. To help prevent tobacco mosaic virus, keep

nicotianas away from other members of the Solanaceae family, which includes tomatoes, potatoes, and the like.

Top Performer

Nicotiana x *sanderae* (common nicotiana, flowering tobacco): Although often sold as *N. alata* or *N. affinis*, the common nicotiana generally belongs in the hybrid genus *N.* x *sanderae*. True *N. alata* is a tall plant, up to 5 feet (150 cm), with highly scented, yellowish green flowers that open only at night. Crossing with other *Nicotiana* species has resulted in shorter plants in a much wider range of colors. The flowers of most modern hybrids stay open all day long, but many have entirely lost the scent that was half the charm of the species! Height: 8 to 24 inches (20 to 60 cm). Spread: 8 to 10 inches (20 to 25 cm).

More Recommended Nicotiana

Nicotiana langsdorffii (flowering tobacco): This curious plant, with small, bottle-shaped, lime green flowers dangling from upright, branching stems, is actually much more attractive than the description suggests and should be more widely grown. Its flowers remain open all day but are scentless. Height: 3 to 5 feet (90 to 100 cm). Spread: 12 to 14 inches (30 to 35 cm).

N. sylvestris (flowering tobacco): This is perhaps the most highly perfumed of the flowering tobaccos, with tall, candelabra-like stems of white flowers with extremely long tubes that half close on sunny days. Scent is faint or absent during the day but remarkable at night. Height: 3 to 6 feet (90 to 180 cm). Spread: 2 feet (60 cm).

Pelargonium x hortorum

Zonal geranium, bedding geranium

Zonal geraniums are so ubiquitous on winter windowsills and in summer containers and gardens that one could argue they need no introduction. For the benefit of true novices, though, these are the geraniums with thick, somewhat fuzzy stems and rounded, oddly scented leaves, either all green or marked with a dark, horseshoe-shaped band (the "zone" in zonal). Their main claim to fame, though, comes from their stalks of large, rounded clusters of single or double flowers, often in brilliant, eye-catching colors.

PLANT PROFILE

Pelargonium x hortorum: pe-lar-GO-nee-um hor-TO-rum

Bloom Color: Pink, purple, salmon, red, orange; bicolor

Bloom Time: Late spring through early fall; all year indoors and in frost-free climates

Height: 10 to 36 inches (25 to 90 cm)

Spread: 8 to 14 inches (20 to 35 cm)

Garden Uses: Container planting, edging, mass planting, mixed border, rock garden, specimen plant

Light Preference: Full sun to partial shade; partial shade in hot summer climates

Soil Preference: Humus-rich, well-drained soil; tolerates alkaline soil

Best Way to Propagate: Sow seed indoors in winter; take stem cuttings at any season

Hardiness: Frost-sensitive sub-shrub grown as a tender annual

Growing Tips

These easy-care annuals have few special needs: Simply give them full sun or just a bit of shade (partial shade is a must in hot summer climates), water moderately, and you should have no problems. It's when you multiply them that geraniums become more difficult. Beginners would be wise to buy geraniums already started, skipping the seed stage entirely.

If you're adventurous, however, you can start seed indoors in early winter, 14 to 16 weeks before the last frost to get plants that will bloom by summer. That means you'll be starting seed in the dark days of winter and will probably need artificial lights. You may, therefore, prefer to start yours 10 to 12 weeks before the last frost, when days are longer, even if that means your plants won't bloom quite as early in the season.

Seed germinates in 3 to 21 days at 70° to 85°F (21° to 30°C). Barely cover them with mix. Move the seedlings to a cooler spot—60° to 70°F (15° to 21°C)—and pinch them once when they are about 4 inches (10 cm) high to promote bushy growth.

To reproduce favorite plants by cuttings, snip off a few stem sections about 6 inches (15 cm) long and remove the lower leaves. Apply rooting hormone and insert the cut end into damp perlite or sand. Traditionally, gardeners let freshly cut stems "heal over" by setting them in a sunny spot for a week or so before inserting them into the growing mixture, but this actually does more harm than good. This is also one of the rare cases when you shouldn't cover cuttings in clear plastic because geranium cuttings tend to rot without good air circulation.

Good Neighbors

Traditionally used in garish bedding displays and in "you-can-see-it-a-mile-away" pots, geraniums have been somewhat maligned recently by garden connoisseurs who find them too brilliant for more understated modern beds. However, zonal geraniums do come in a number of subdued colors, making them suitable for softer planting schemes. Even the bright reds can be great garden accents: Tuck small numbers of them around dark-leaved neighbors, such as purple-leaved amaranths (*Amaranthus* spp.), or dot them throughout a planting of rambling nasturtiums. In containers, try combining a zonal geranium

Continued →

with blue lobelia and the chartreuse-gray leaves of licorice plant (*Helichrysum petiolare* 'Limelight').

Problems and Solutions

Stem rot (black leg) is common in cuttings. Increased air circulation can reduce the chance of infection. Edema, seen as raised brown patches on the undersides of leaves, is not a disease but a physiological problem resulting from excess watering.

Top Performer

Pelargonium x *hortorum* (zonal geranium): Modern hybrids tend to be dense plants that branch with little pinching: quite a contrast to Grandma's stringy geraniums! They come in a wide range of shades, including bicolors, with single or double blooms. There are dozens of categories, such as rosebuds, cactus-flowered, miniatures, and beautiful fancy-leaved geraniums with colorful foliage that's variegated with white, pink, yellow, or red. Blooms of double geraniums tend to be particularly durable, but you need to pinch them off when they do fade or they become moldy. Single-blossom types are usually self-cleaning.

Petunia

Petunia

Modern petunias are branching, semi-upright to creeping plants with sticky, hairy, spoon-shaped leaves and medium to large, trumpet-shaped, five-lobed blossoms in a wide range of colors and forms. Double, ruffled, striped, netted, picoted: There's practically no limit to their variety, and even flower colors long considered impossible, like yellow, are now common. They all bloom right through summer in most climates; although in hot, humid climates they are best considered for fall planting and winter through spring bloom.

PLANT PROFILE

Petunia: peh-TOON-yuh

Bloom Color: Pink, violet-blue, red, yellow, white

Bloom Time: Late spring through early fall; fall through winter in mild climates

Height: 6 to 24 inches (15 to 60 cm)

Spread: Varies by species; see individual listings

Garden Uses: Container planting, cut-flower garden, edging, groundcover, mass planting, mixed border, rock garden; on slopes, in wet areas

Attracts: Hummingbirds, moths

Light Preference: Full sun to partial shade

Soil Preference: Light, evenly moist, well-drained soil

Best Way to Propagate: Sow seed indoors in late winter or spring; take stem cuttings in late summer

Hardiness: Frost-sensitive perennial grown as a half-hardy annual

Growing Tips

Petunias are among the easiest of all annuals to grow, if you buy them already started. Pinch them before you plant them, and spray occasionally during the summer with organic foliar fertilizer to stimulate continuous growth. Deadheading helps encourage more bloom and keeps the plants tidy. If your petunias get scraggly, prune them back by half, and they'll soon grow back.

Given the wide variety of petunias offered in most nurseries, it is usually not worthwhile to start them yourself from seed, unless you want a cultivar not available locally. Start them indoors 8 to 10 weeks before the last frost (12 to 14 weeks for the slower-growing doubles). Don't cover the seed; it needs light to germinate. Look for seedlings in 7 to 21 days at 70° to 80°F (21° to 27°C). After germination, drop the temperature to about 60°F (15°C). When thinning seedlings, don't methodically eliminate the smaller, weaker-looking ones; they're often the ones with the best color or most interesting forms. Plant out when all danger of frost has passed, giving the seedlings a pinch to stimulate better branching. You can also sow single-flowered petunias directly outdoors, when the soil warms up, for late-season bloom.

Petunias can be highly perfumed, especially at night, so don't hesitate to use them at nose level in flower boxes, on walls, or in hanging baskets.

Good Neighbors

Petunias are extravagant bloomers, which makes them very useful in containers. Combine them with foliage plants, such as lotus vine (*Lotus berthelotti*) or sweet potato vine (*Ipomoea batatas*), for sure success. They can also be useful in the garden as a groundcover beneath the airy clumps of gaura (*Gaura lindheimeri*) or *Artemisia* 'Powis Castle' or surrounding the blades of irises.

Problems and Solutions

Usually petunias are quite pest free, but aphids are occasional problems. Knock them off with a spray of water. Look for weather-resistant cultivars in climates with frequent heavy rains; these cultivars also tend to be less susceptible to gray mold and soft rot, which can otherwise affect both foliage and flowers in humid climates.

Top Performer

Petunia x *hybrida* (petunia): Almost all the petunias sold today are complex hybrids, which are divided into various classes. Grandifloras, with single or double flowers 4 to 5 inches (10 to 12 cm) across, come in both semi-upright and cascading cultivars; the latter are mostly used in containers. Multifloras have smaller flowers—about 2 inches (5 cm) across—but they

tend to grow faster, bloom more freely, and have more weather-resistant petals. Space both types about 1 foot (30 cm) apart so they can grow together and form a carpet. Millifloras are newcomers with tiny 1- to 1½-inch (2.5- to 4-cm) flowers over mounded plants. Space them about 6 inches (15 cm) apart. Groundcover petunias, of which the 'Wave' and 'Surfinia' series are the best known, are low-growing spreaders highly popular for hanging baskets, since they can trail 3 feet (90 cm) or more. Although they are very floriferous, they need constant fertilizing to perform well. Height: 1 to 2 feet (30 to 60 cm). **Spread**: 6 to 36 inches (15 to 90 cm).

More Recommended Petunias

Petunia integrifolia (violet-flowered petunia): One of the rare species of petunias offered, violet-flowered petunia is a low-growing spreader that looks and behaves exactly like a groundcover petunia, of which it is a parent. It bears numerous small violet flowers throughout the growing season. Height: 1 to 2 feet (30 to 60 cm). Spread: 2 to 3 feet (60 to 90 cm).

Tagetes

Marigold

There's no denying that marigolds have sometimes been overused, but think of it this way: Their enormous popularity is a sure sign they are easy to grow. Whether you grow them from seed or buy six packs of plants, you simply can't go wrong! The way I see it, there is always room for such a workhorse, even in the gardens of the most sophisticated plant collectors! There's hardly a need to describe this common annual; the deeply cut, aromatic leaves and yellow to orange flowers are a dead giveaway.

PLANT PROFILE

Tagetes: TAH-jeh-teez

Bloom Color: Varies by species; see individual listings

Bloom Time: Summer through early fall

Height: Varies by species; see individual listings

Spread: Varies by species; see individual listings

Garden Uses: Container planting, cut-flower garden, edging, mass planting, mixed border, rock garden

Light Preference: Full sun to partial shade

Soil Preference: Not excessively rich, well-drained soil

Best Way to Propagate: Sow seed indoors in mid-spring or outdoors in late spring

Hardiness: Half-hardy annual

Growing Tips

Marigolds are a snap from seed, started either indoors 4 to 6 weeks before the last frost date, at 65° to 85°F (18° to 30°C), or directly in the garden, after all danger of frost has passed. Sown ¼ inch (6 mm) deep, they germinate quickly, usually in 4 to 14 days, and are often in bloom in less than 2 months. Of course, they are also widely available in six packs and transplant very well, even when already in bloom. Wash your hands when you've finished planting, though: When handled, marigolds give off a scented oil to which some people are allergic.

Naturally quite drought tolerant, marigolds actually do better in soil that is on the poor side. Pinch young African marigolds at least once or they may produce only one large bloom. Deadheading can help maintain continuous bloom.

Good Neighbors

Enjoy the smaller marigolds as fillers around bold plants, such as yuccas, dark-leaved cannas, or cardoon (*Cynara cardunculus*). The imposing pompoms of African marigold (*Tagetes erecta*) look super as a mass of color around evergreen shrubs. The ferny foliage of signet marigold (*T. tenuifolia*) makes a satisfying companion for more-vibrant flowers, such as zinnias.

Problems and Solutions

Leaf spot, gray mold, powdery mildew, and other leaf diseases can be problematic, especially in humid climates: Look for weather- and disease-resistant strains. Taller African marigold hybrids tend to snap off under the weight of their huge flowers; plant them more deeply than in their original cell packs so the lower part of the stem can root, providing extra support.

Top Performer

Tagetes patula (French marigold): These relatively small, bushy plants bear numerous 1-inch flowers in yellow or orange, often mixed with mahogany red. Blooms can be single, double, or crested and are often bicolored. The foliage has a vaguely unpleasant "greenery" odor. Height: 6 to 18 inches (15 to 45 cm). Spread: 8 to 12 inches (20 to 30 cm).

More Recommended Tagetes

Tagetes erecta (African marigold): This species offers huge yellow, orange, or creamy white flowers from 3 to 5 inches (8 to 13 cm) in diameter. This species is perhaps the stinkiest of all marigolds, but fortunately the odor is emitted only if you touch the leaves or stick your nose into the bloom. Height: 10 inches to over 4 feet (25 to 120 cm). Spread: 12 to 18 inches (30 to 45 cm).

T. erecta x patula (triploid marigold): This sterile plant is an F1 hybrid, a handmade cross between African and French marigolds. It is a perfect mixture of the two and usually displays pompomlike flowers 2 to 3 inches (5 to 8 cm) across. Since they produce no seed, triploids bloom up a storm and need no deadheading. Unfortunately, their germination rate is low and seed is very expensive. Height: 10 to 18 inches (25 to 45 cm). Spread: 12 to 16 inches (30 to 40 cm).

Continued ➔

T. tenuifolia (signet marigold): A delightful but lesser-known plant with extremely fine, lacy foliage that has a pleasant lemon scent. The numerous tiny single yellow or orange flowers don't overwhelm the plant but mingle delicately with the foliage, and they attract beneficial, pest-eating insects. Height: 1 to 2 feet (30 to 60 cm). Spread: 12 to 16 inches (30 to 40 cm).

Tropaeolum

Nasturtium, Canary creeper

Nasturtiums offer both intriguing leaves and complex and colorful flowers, so they look good practically from the time they germinate. Hybridizers have worked long and hard to cut the nasturtium down to size, however, and most modern nasturtiums are "dwarf" or trailing types.

PLANT PROFILE

Tropaeolum: tro-PEE-o-lum

Bloom Color: Varies by species; see individual listings

Bloom Time: Early summer through early fall; fall through spring in mild climates

Height: Varies by species; see individual listings

Spread: Varies by species; see individual listings

Garden Uses: Container planting, cut-flower garden, edging, hanging basket, mass planting, mixed border, vegetable garden; on slopes or covering trellises, fences, and pergolas

Attracts: Hummingbirds

Light Preference: Full sun to partial shade

Soil Preference: Average to poor, well-drained soil

Best Way to Propagate: Sow seed indoors in peat pots in mid-spring or outdoors in late spring

Hardiness: Tender annual or frost-sensitive perennial

Growing Tips

Nasturtiums are fast-growing annuals that seem to thrive on neglect. Sow the large seed directly outside once the ground warms up, covering it with ¼ inch (6 mm) of soil. Or get a head start on the season by starting it indoors in peat pots, in darkness, 2 to 4 weeks before planting out. It usually germinates in 7 to 12 days at 60° to 65°F (15° to 18°C). If you prefer to buy plants in the spring, cell packs are the best choice because there is less risk of transplanting shock.

The secret to great nasturtiums is benign neglect. Plant them in soils that are average to low in fertility, and don't fertilize or overwater them because rich soils can stimulate lush, rapid foliage growth with few flowers. Full sun is usually best, but partial shade is recommended in hot summer areas.

Except in mild climates (Zones 9 to 11), nasturtiums are best treated as annuals. You can, however, overwinter a particularly nice nasturtium by taking stem cuttings in late summer and growing them indoors in a sunny spot.

Good Neighbors

Always a cheerful presence in the garden, nasturtiums can be an easy answer to the problem of unsightly bulb foliage. Even the dwarfs remain distinctly rambling plants, so they are ideal for containers, hanging baskets, borders, and filling in gaps in the landscape. Attractive neighbors include sturdy plants with finely cut foliage, such as artemisias, or plants with stiff upright foliage, such as irises and blackberry lilies (*Belamcanda* spp.). Planted near a large shrub or hedge, canary creeper (*Tropaeolum peregrinum*) will wander happily among the branches.

Problems and Solutions

Aphids are a major problem. Blast them off with a strong spray of water. Caterpillars, whiteflies, flea beetles, and slugs are occasional problems.

Top Performer

Tropaeolum majus (nasturtium, common nasturtium): This is the plant most people think of when the word nasturtium is mentioned, although, in fact, the botanical name *Nasturtium* belongs to an entirely different plant—watercress (*N. officinale*). Our nasturtium bears unique, round, shieldlike leaves in deep to light green. Some cultivars, like 'Alaska' (dwarf) and 'Jewel of Africa' (climbing) are heavily marbled with cream. The 2- to 2½-inch (5- to 6.5-cm) flowers form wide-open trumpets and usually have a long spur at the back. The blooms come in a wide range of colors—yellow, orange, cream, red, mahogany, and cherry pink, often splotched with a contrasting color—and are commonly delightfully scented. Double types are generally sterile and must be propagated by cuttings; semidoubles are available from seed. Height: 8 to 15 inches (10 to 38 cm) for dwarfs and trailers; 10 feet (3 m) for climbers. Spread: 12 to 18 inches (30 to 45 cm).

More Recommended Tropaeolum

Tropaeolum peregrinum (Canary creeper, Canary vine): This is a very different plant with different needs. The small, gray-green leaves are divided into fingerlike lobes. The curious flowers, with two large, highly fringed petals over a smaller cluster of three petals, may be canary yellow, but they actually get their name because of the plant's place of discovery. Botanists first saw this Mexican native growing on the Canary Islands. Canary creeper needs a richer, moister soil than its cousin does. Plants started indoors can bloom faster, but they also tend to peter out before the end of summer. Seed started directly in the garden blooms until fall. This superb climbing plant needs a thin support that the leaf stems can wrap themselves around. Height: 8 to 12 feet (2.5 to 4 m). Spread: 18 inches (45 cm).

Verbena

Verbena

Gardeners have more than 250 species of verbenas to choose from, and a good number of those make great garden plants. The genus includes annuals, perennials, and shrubs; and the different plants vary considerably in appearance and in care. In general, though, they are bushy to creeping plants with four-sided stems and tubular flowers with five well-spaced lobes, often notched at their tip. Although the individual flowers are small, they're held in dense clusters that will knock your socks off, both in the garden and in containers.

PLANT PROFILE

Verbena: ver-BEAN-uh

Bloom Color: Lavender, pink, purple, salmon, red, white

Bloom Time: Late spring through early fall; much of the year in mild climates

Height: Varies by species; see individual listings

Spread: Varies by species; see individual listings

Garden Uses: Container planting, cut-flower garden, edging, hanging baskets, groundcover, mass planting, mixed border, rock garden; on slopes

Attracts: Butterflies, hummingbirds

Light Preference: Full sun to partial shade

Soil Preference: Average, well-drained soil

Best Way to Propagate: Sow seed indoors in late winter; take stem cuttings in late summer

Hardiness: Frost-sensitive perennial grown as a half-hardy annual

Growing Tips

Unless you have a home greenhouse or grow under lights, you're better off buying six packs or cell packs of young verbena plants than trying to start your own from seed. If you like a challenge, though, you can save a considerable amount of money by sowing them yourself. Just don't expect high germination: With verbenas, especially the popular hybrid types, 50 percent germination is considered good; 70 percent is excellent!

Start the seed indoors, 8 to 10 weeks before the last frost. Barely cover the seed; then place in the dark until seedlings appear, usually in 14 to 28 days at 50° to 75°F (10° to 24°C). After germination, try to keep the temperatures toward the lower end of that range. Water very carefully, preferably from below to avoid damping-off, and make sure there is good ventilation.

There are fast-growing verbenas, like Brazilian vervain (*Verbena bonariensis*), that you can sow directly outdoors in early spring for late-season bloom. Even these are best started indoors, though. For good germination, place the six packs or cell packs in the fridge for 2 weeks before exposing them to warmth.

Verbenas may be delicate as seedlings, but once in the garden, they are no-brainers. They prefer full sun (some shade in the afternoon is best in hot summer areas) and do well in ordinary garden soil. They are quite drought resistant, although watering in very dry weather is always wise. Avoid wetting the leaves, if possible, to reduce the spread of the fungal disease powdery mildew. If bloom becomes sparse in midsummer, shear the plants back harshly and spray them with organic foliar fertilizer; they'll soon be in full flower again.

To keep favorite plants from year to year, start cuttings in late summer and grow them indoors in bright light all winter or dig up and bring in a few plants.

Good Neighbors

Because of their cascading nature, low-growing verbenas are ideal choices for pots, but they're useful as groundcovers as well. The lacy foliage and purple flowers of 'Imagination' mingle beautifully with bold kales, yuccas, or Siberian irises (Iris sibirica). Combine garden verbena (*Verbena* x *hybrids*), lantana (*Lantana camara*), and tall Brazilian vervain (*V. bonariensis*) in a large pot and you will have a long season of layered, flowering interest.

Problems and Solutions

Powdery mildew and other leaf diseases are a major problem in humid climates: Grow only disease-resistant strains, like the 'Quartz' series. Control whiteflies, spider mites, and scale insects by spraying with insecticidal soap.

Top Performer

Verbena x *hybrida* (garden verbena): This is definitely a mixed bag of plants! Some types are bushy and upright, while others are spreading, mat forming, or even trailing. The green to gray-green leaves can be simple, toothed, or deeply cut; and the fragrant or odorless flowers come in a wide range of bright and pastel colors. Many modern hybrids, like the 'Temari' and 'Tapien' series (both of which come in an astounding range of colors), are available only as vegetatively produced (cutting-grown) plants. The seed-grown strains—most either bushy or only slightly spreading—are particularly popular for garden use; the more expensive cutting-grown types—most either trailers or semi-trailers—are widely used in containers. Take your pick; they're all great plants! Height: 10 to 20 inches (25 to 50 cm). Spread: 12 to 20 inches (30 to 50 cm).

Continued ➔

Viola

Pansy, horned violet, Johnny-jump-up

The rounded, flat-faced flowers of most pansies look just like a chubby-faced baby: How could you not love them? Garden favorites for generations, they are widely available just about everywhere and are often the first annuals to bloom. They likewise make cute little bouquets and are a standard offering in posies. If only they were a bit more heat resistant, they would be just about the perfect annual. Instead, you have to plan carefully to get the most out of them before the dog days of summer knock them flat on their faces!

PLANT PROFILE

Viola: vy-OH-luh

Bloom Color: Blue, lavender, purple, red, orange, bronze, yellow, white

Bloom Time: Early spring through summer; fall through winter in mild climates

Height: Varies by species; see individual listings

Spread: Varies by species; see individual listings

Garden Uses: Container planting, cut-flower garden, edging, groundcover, mass planting, mixed border, rock garden, woodland garden; along paths

Light Preference: Full sun to moderate shade

Soil Preference: Humus-rich, evenly moist but well-drained soil

Best Way to Propagate: Sow seed outdoors in fall or indoors in winter

Hardiness: Hardy perennial or biennial grown as a hardy annual

Growing Tips

The secret to happy pansies is to remember they like things cool. In temperate climates, you'll get best results from young transplants set out in fall (for the earliest spring bloom) or in early spring, as soon as the ground can be worked. Where summers are generally cool—not over 90°F (32°C)—they bloom best in full sun and keep on going until fall. In hotter climates, look for heat-resistant cultivars and plant them in moderate shade. Where winters are mild, plant pansies in fall for bloom right through winter; then pull them up when the heat gets to them.

The easiest way to grow pansies from seed is to treat them like biennials. Sow them outdoors in midsummer, then plant them in their final home in fall, mulching well in cold winter areas. It is possible to sow pansies indoors, although it is a bit of a challenge. Sow the seed indoors 14 to 16 weeks before the last frost date, barely covering it. Place the containers in your refrigerator for 2 weeks, and then expose the seed to room temperatures; it should sprout in about 10 days. After germination, keep the temperature as low as you can; 50° to 65°F (10° to 18°C) is ideal, but room temperature is acceptable. Plant out hardened-off seedlings as soon as the soil is workable.

Outdoors, water pansies as needed and deadhead them to help maintain blooming. Cut straggly plants back severely to stimulate renewed growth.

Good Neighbors

One of the few annuals that can be planted in fall for early-spring bloom, pansies play a unique role in the garden. Let them take the spring shift in an impatiens bed or front-door planter or fill in the ground level around tall daffodils. Tuck them around plants that thrive in part shade, such as ferns or purple-leaved heucheras (*Heuchera* hybrids), and they'll bloom well into summer.

Problems and Solutions

Pansies are somewhat susceptible to leaf diseases: Choose disease-resistant strains, and rotate plantings if you notice repeated damage. Handpick slugs and snails if they become a problem.

Top Performer

Viola x *wittrocklana* (pansy): These large-flowered plants with overlapping petals are offered in an almost infinite range of colors, including a violet so deep it appears black. Most are bicolored with facelike markings, but some are all one color. Pansies are usually borderline hardy in Zone 4. Height: 6 to 9 inches (15 to 23 cm). Spread: 9 to 12 inches (23 to 30 cm).

More Recommended Viola

Viola cornuta (horned violet, viola): Horned violet is one of the parents of the pansy and is very similar to it, but with smaller flowers. The species is a long-lived plant with violet to lavender flowers, but most plants now sold under this name have been crossed with the garden pansy. They come in a similar range of colors and tend to act as short-lived perennials or annuals. Height: 8 inches (20 cm). Spread: 6 to 12 inches (15 to 30 cm).

Zinnia

Zinnia

Bright, long-lasting, daisylike flowers are the trademark of the zinnia, a New World native that has taken the plant world by storm. Modern zinnias come in a wide range of sizes and shapes, from upright, cut-flower types to multistemmed, multiflowered border zinnias. The flowers can be single or double, big or small, and the color range is just about complete: Only true blue

is lacking. If that weren't enough, they are particularly easy to grow!

PLANT PROFILE

Zinnia: ZIN-ee-uh

Bloom Color: Varies by species; see individual listings

Bloom Time: Summer through early fall

Height: 4 to 48 inches (10 to 120 cm)

Spread: 10 to 24 inches (25 to 60 cm)

Garden Uses: Container planting, cut-flower garden, edging, mass planting, meadow garden, mixed border

Attracts: Butterflies

Light Preference: Full sun

Soil Preference: Humus-rich, well-drained soil

Best Way to Propagate: Sow seed outdoors in late spring or indoors in mid-spring

Hardiness: Half-hardy annual

Growing Tips

No doubt about it, the easiest way to grow zinnias is to sow them directly outside as soon as the ground warms up. They grow quickly, reaching blooming size in just 6 weeks. Just loosen up the soil, toss in the seed, cover lightly, and water; it'll do the rest. Nurseries often offer cell packs, but zinnias generally don't transplant well once they've reached flowering size. If you do buy plants, try pruning them back by one-third at planting time to help them make a successful transition.

You can also start zinnias indoors at 60° to 85°F (15° to 27°C). They're up like a shot (in only 4 to 7 days) and need only a 4- to 6-week head start on the season. Sow them in peat pots or cell packs to reduce transplant shock.

Full sun is a must, and good air circulation is important for preventing powdery mildew. For bushy plants with lots of bloom, pinch young zinnias when they have developed their third set of leaves. Don't put zinnias outside too early because cool air stunts their growth; wait until all danger of frost has passed and the weather warms up. Keep deadheading through summer to stimulate continuous bloom.

Good Neighbors

Combine mixed-color zinnias with tall ageratum (*Ageratum houstonianum*) for an exuberant display. Chartreuse green 'Envy' looks great with just about any other color: Tuck it among perennials in a mixed border. For an eye-catching planting that will bloom freely even through summer drought, pair mildew-resistant, narrow-leaved zinnias (*Zinnia angustifolia*) or the hybrid 'Profusion' series with mealycup sage (*Salvia farinacea* 'Victoria').

Problems and Solutions

Powdery mildew is a major problem in humid climates. Mildew-resistant cultivars are really the only viable option under those conditions. Excessively moist soil can lead to root or stem rot. Where Japanese beetles are a problem, hand-pick and drop them into a container of soapy water.

Top Performer

Zinnia elegans (common zinnia): The most widely grown zinnia, this species has an upright habit, with opposite, bright green, broadly lance-shaped leaves and a wide range of flower colors, sizes, and forms. It is also the species the most susceptible to powdery mildew, so it's best in dry climates and well-ventilated spots in the garden. Height: 4 to 48 inches (10 to 120 cm). Spread: 10 to 24 inches (25 to 60 cm).

More Recommended Zinnias

Zinnia angustifolia, formerly *Z. linearis* (narrow-leaved zinnia): This species is a more modest plant, with smaller, simple flowers in orange to white with a yellow heart and narrower, pointed leaves. Its main claim to fame is that it seems entirely mildew resistant. The easy-to-grow 'Star' and 'Crystal' series belong here. Height: 8 to 24 inches (20 to 60 cm). Spread: 8 to 12 inches (20 to 30 cm).

Z. angustifoia x *elegans* (hybrid zinnia): This cross between the common and narrow-leaved zinnia produces plants much like the latter (and just as disease resistant) but in a wider color range, including orange, pink, red, and white. The highly popular 'Profusion' series falls here. Height: 8 to 24 inches (20 to 60 cm). Spread: 8 to 12 inches (20 to 30 cm).

Z. haageana, formerly *Z. mexicana* (Mexican zinnia): The species name is in doubt, but it's a handy place to place two old-fashioned but still popular narrow-leaved doubles, 'Old Mexico', 16 inches (40 cm) tall, and 'Persian Carpet', 12 inches (30 cm) tall. Both have multicolored blooms: orange or red flowers that are tipped in either white or yellow. Height: 12 to 18 inches (30 to 45 cm). Spread: 8 to 12 inches (20 to 30 cm).

Know Thine Enemies

Larry Hodgson

Annuals tend to be far less susceptible to pests and diseases than other plants, mostly because they don't live long. If you grow different annuals in each spot each year, the pests and diseases won't be able to build up to problem level. Ornamental annuals tend to have plentiful natural defenses against pests. That doesn't mean you will never have any problems, but the chances are reduced.

ROSES

Choosing and Using Roses

With more than 30,000 rose species and cultivars available, choosing the perfect rose isn't easy! The key is answering the question, "What do I want roses to do for my landscape?" Perhaps you want to dress up a split-rail fence, enhance a perennial garden, or add a colorful accent to a shrub border. There's a rose for almost every landscape purpose, and this section will help you decide which varieties are best suited for the project you have in mind.

All Roses Aren't Alike

Before you leap into choosing roses, it's a good idea to learn about the different classes available—what they look like and how they grow and behave. Some roses are small shrubs, while others can grow taller than you. Still other types are long and vining, while some form low groundcovers. The three major categories of roses are species roses, old roses, and modern roses. Read on to learn about these roses and how they might work in your landscape.

USING SPECIES ROSES

Species roses are tough and disease-resistant—excellent for a natural area in your yard or a shrub border. They provide a wide variety of choices of size, form, and hardiness. They bloom once, usually in early summer, and form seed-bearing rose hips in the fall.

Species roses are the original roses. About 200 different species roses exist. In general, species roses bear single, five-petaled flowers, and they self-pollinate. (So if you plant seeds from species roses, the offspring should be identical to the parent plant.)

USING OLD ROSES

Old roses are usually very fragrant, have a pleasing plant shape, and are tough, long-lasting shrubs. Common types of old roses include alba, Bourbon, damask, China, and gallica.

The drawback to planting old roses is that many bloom only once a year, usually in early summer. Although they look and smell beautiful, their blooms don't last long.

USING MODERN ROSES

Unlike species roses and some old roses, modern roses bloom all summer, so you get nonstop color and landscape impact.

But summer-long beauty comes with a price. Many modern roses require more maintenance than old roses or species roses because they aren't as cold-hardy or disease-resistant.

Hybrid Teas

For most people, a rose means a hybrid tea rose. These roses bear long, narrow, high-center buds, one per stem. The canes are often bare at the base, which makes hybrid teas best suited to mixed borders, herb gardens, and perennial beds where lower-growing plants can hide their gawky legs. Hybrid teas grow 3 to 5 feet high.

- Flower continually throughout the growing season
- Are available in all rose colors
- The flower form is usually semidouble or double.
- Hardiness, disease resistance, and fragrance vary greatly from cultivar to cultivar.
- Hardy only to Zone 8, so winter protection is a must
- Need rich soil, plenty of fertilizer, and ample water
- Hard pruning is required to encourage new growth and abundant flowering.

Polyanthas

Polyanthas are bushy, 2-foot-tall plants with finely textured leaves. They're sturdy, trouble-free plants, so they're good choices for massing, edgings, and hedges.

- Produce clusters of small (1-inch) single, semidouble, or double flowers all season
- Generally hardy to Zone 5
- Bloom in shades of pink, white, red, orange, or yellow
- Need little pruning, except to remove dead or diseased wood or to shape the plants
- The Latin word *polyantha* means "many-flowered."

Hybrid Tea Rose

- Plant low-growing polyanthas around the base of taller floribundas and grandifloras for multitudes of blooms.
- Deadhead up to a month before frost for constant color.
- Good choice for small gardens

Floribundas

A result of cross-breeding polyanthas with hybrid tea roses, floribundas are bushy plants that grow 2 to 4 feet tall. They're excellent for low hedges and mass plantings as well as specimens in flower borders.

- Bear many flowers per stem throughout the growing season
- Flowers are larger than polyantha blooms and about half the size of hybrid tea roses.
- Flowers can be single, semidouble, or double and come in the entire color range for roses.
- Generally hardy to Zone 6
- Need pruning to maintain their shape; to remove weak, dead, or old wood; and to remove faded flowers
- Many of the floribundas are disease-resistant—check varieties before choosing.
- Need rich, well-drained soil

Grandifloras

A result of crossing hybrid tea roses with floribundas, grandifloras combine the classic hybrid tea rose flower form with the floriferous bloom habit of floribundas. Grandifloras generally grow 4 to 6 feet—and sometimes even taller. Because they're so tall, grandifloras work best at the back of flowerbeds or shrub borders.

- The high-centered flowers are borne singly or in clusters on long stems.
- Generally hardy to Zone 6
- Bloom continuously all season
- Flowers are generally semidouble or double and come in all rose colors; fragrance depends on the cultivar.
- A good choice for cut arrangements
- Most grandifloras are disease-resistant.
- Deadhead up to a month before frost for lots of repeat bloom.
- Cut back healthy canes by one-half to one-third for vigorous flower production.

Miniatures

Every aspect of miniature roses is reduced in size, including the stems, leaves, and flowers. The flowers can be single, semidouble, or double. Miniature roses can also be raised as houseplants, although you need a great deal of light to get them to bloom indoors.

- Bloom about one month earlier than shrub roses
- Hardy to Zone 5
- Need pruning to remove dead wood, to thin, or to improve shape
- Generally from 10 to 18 inches tall, miniatures come in a variety of forms—trailing, cascading, and climbing.
- Ideal for container plantings, hanging baskets, rock gardens, and as edging in mixed borders
- For long-blooming color in a small area, plant a group of miniatures spaced about 18 inches apart.

Narrowing Your Choices

Once you've decided whether to plant a species rose, old rose, or some type of modern rose, you've taken the first step. However, you still need to decide on a particular species or cultivar. You can narrow your selection by focusing on the flowers. Do you have favorites? Is a rose only a rose to you if it's a double red? Or do you want a particular color to go with other flowers or features? For instance, a yellow, white, or peach rose might look better in front of an orange brick wall than a red or pink rose.

COLOR AND FORM

- Species and old roses tend more toward shades of pink, white, and mauve.
- Species and old rose flowers range from flat single or semi double to many-petaled doubles that are open-cupped, globular, or quartered.
- Newer hybrids include many more reds, oranges, yellows, pinks, whites, and bicolors.
- Modern rose flowers have high centers with long inner petals forming a prominent central cone that rises from a flatter cup of outer petals.

FRAGRANCE

Fragrance is another important aspect of roses, whether you're enjoying them indoors or outside in the garden. Although it's generally true that the older types of roses seem more fragrant than newer roses, many newer cultivars have a delightful fragrance, and there are old roses without a trace of fragrance. Fortunately, fragrance seems to be back on the rose breeder's agenda, so we can look forward to more new roses that "smell like a rose."

If you'll be using your roses for potpourri or other scented crafts, alba, Bourbon, damask, moss, musk, and rugosa roses all make good choices.

Continued ➔

Choosing Roses for Low Maintenance

Beyond their appearance and fragrance, you'll want to keep low maintenance in mind when you choose your roses. Look to the shrub roses first for trouble-free growing, especially the rugosas (species roses), polyanthas, and Meidiland roses. Then consider the hardy, pest-resistant cultivars of the old garden roses, the species roses, and the most pest- and disease-resistant of the modern hybrid teas, floribundas, grandifloras, and miniatures.

Disease-Resistant Roses

The easiest way to cut down on rose maintenance is to start by planting roses that are resistant to pests and diseases. We've divided the disease-resistant roses into groups so you can easily find the type you need for your landscaping purposes. Simply find the heading you're looking for and you'll have your roses at a glance. You don't have to limit your choices to these lists—they're just a starting point for buying disease-resistant roses.

SHRUB AND GROUNDCOVER ROSES

The term shrub rose is a catch-all designation that the American Rose Society has created to include a large variety of hardy, easy-to-grow shrubs. They range in size from groundcovers to 12-foot-tall giants! They're known as low-maintenance landscaping roses and most are attractive both in and out of bloom. Look to this group for the largest number of disease-resistant varieties. Some of the best shrub roses for garden use include David Austin roses, Buck hybrids, Meidiland roses, and the newly introduced Parkland and Explorer series from Canada. Here are just a few of the many reliable varieties of groundcover and shrub roses.

'Carefree Wonder': Clusters of double, deep pink flowers that bloom continuously on shrubs that grow 5 feet tall x 3 feet wide (Zones 4-9)

'John Davis': Large clusters of scented, double, pink flowers on arching canes that reach to 6 feet—best as a trailing shrub or tall climber; very cold hardy (Zones 3-9)

'Knock Out': Scented, deep cherry red flower clusters on a rounded shrub 3 feet tall x 3 feet wide. (Zones 4-9)

'Sarah van Fleet': Sweet, clove-scented pink flowers on upright to arching canes; reaches maximum size of 8 feet x 5 feet wide (Zones 3-9)

'Scarlet Meidiland': Mounding trailing habit; canes grow to 3 feet tall x 6 feet wide; provides good repeat bloom (Zones 4-9)

'Sea Foam': Low-spreading shrub with long-blooming clusters of double, creamy white flowers; vigorous and prostrate, plants grow 3 feet tall x 6 feet wide (Zones 4-9)

MINIATURE ROSES

Although there are many minis to choose from, many are susceptible to diseases. Here are some that are exceptionally disease-resistant. (Note: Most miniature roses are hardy to Zone 5.)

'Baby Diana': An orange bloomer

'Black Jade': Double, dark red, velvety flowers

'Jackie': Climber with fragrant, light yellow blooms

'Magic Carousel': 30-inch shrub with double, white flowers edged with red

'Rainbow's End': Readily available cultivar with yellow blooms edged with red

'Starina': Fragrant, bright red and orange flowers

RUGOSA ROSES AND THEIR HYBRIDS

Both the straight species, *Rosa rugosa*, and its many cultivars are known for their disease resistance. Here are some of the finest varieties and cultivars.

Rosa rugosa var. rubro: Large, single, magenta-purple flowers and large, showy hips (Zones 2-9)

Rugosa hybrid 'Blanc double de Courbet': Fragrant, semidouble, white flowers and showy hips on a 4- to 5-foot shrub (Zones 4-9)

'F.J. Grootendorst': Bears unscented, bright red, fringed flowers that resemble carnations; foliage turns orange-red in autumn (Zones 4-8)

'Frau Dagmar Hastrup': Compact shrub about 3 feet tall x 3 feet wide that produces large, single, silver-pink flowers and tomato-red hips (Zones 4-9)

'Hansa': Reaches 6 to 7 feet in height and has semidouble, purple-red flowers and orange-red hips (Zones 4-9)

POLYANTHA ROSES

The bushy, fine-textured polyanthas have a well-deserved reputation for being trouble-free. Some noteworthy choices follow.

'Cecile Brunner': 3-foot-tall bush with fragrant, pale pink flowers; also available as a climbing cultivar (Zones 5-9)

'China Doll': 2-foot-tall bush with double, pink flowers and bright green, disease-resistant leaves (Zones 5-9)

'La Marne': 5-foot-tall bush with masses of pink-and-white, cupped, and ruffled flowers (Zones 5-9)

'The Fairy': 2-foot-tall bush with abundant sprays of small, double, light pink flowers (Zones 5-9)

RAMBLERS AND CLIMBERS

'America': 8- to 10-foot climber with large, salmon-colored, hybrid-tea-type flowers and a bushy habit (Zones 5-9)

'Alchymist': 8- to 12-foot-tall arching shrub with heavy canes

and large, fragrant, yellow and apricot flowers; doesn't rebloom but is very striking in early summer (Zones 5-9)

'**Climbing Cecile Brunner**': Can climb to 20 feet; fragrant, pale pink flowers (Zones 6-9)

'**Dortmund**': Showy red climber that forms clusters of large, single flowers and orange-red hips if not deadheaded (Zones 5-9)

'**Dublin Bay**': Repeat-blooming, large, double, red flowers (Zones 5-9)

'**New Dawn**': Blooms heavily in early summer with large, fragrant, pearly pink to white flowers; has a second blooming in late summer (Zones 5-9)

HYBRID TEAS AND GRANDIFLORAS

Even disease-resistant hybrid tea and grandiflora roses require a lot of maintenance compared to self-reliant shrub roses or polyanthas. However, disease resistance is a priority with breeders, so every year the organic grower has more choices.

'**Crimson Bouquet**': 4½-foot-tall grandiflora that bears scented, blood red blooms (Zone 4b)

'**Gemini**': Double, creamy pink flowers on a vigorous 5½-foot-tall bush (Zone 5)

'**Keepsake**': 5-foot-tall bush with very fragrant, double, high-centered, multishaded pink flowers, borne singly and in clusters, and glossy leaves on dense, sturdy canes (Zones 5-9)

'**Mrs. Dudley Cross**': Thornless, 3- to 4-foot-high leafy tea rose; creamy yellow, pink-edged flowers (Zones 7-9)

'**Pink Parfait**': 4-foot-tall grandiflora with prolific, double, pink flowers (Zone 6)

'**Pink Peace**': 5-foot-tall bush with very fragrant, very double, high-centered, deep pink flowers and disease-resistant, leathery leaves (Zones 6-9)

'**Queen Elizabeth**': Bears double, clear pink flowers continuously on 5- to 6-foot-tall shrubs (Zone 6-9)

FLORIBUNDA ROSES

When it comes to the best floribundas, here are some of the experts' picks for good disease resistance.

'**Betty Prior**': Continuously bears single carmine pink flowers on 4-foot-tall shrubs (Zones 5-9)

'**Europeana**': One of the best dark red, ever-blooming floribunda roses; bears large clusters of double, deep red flowers on dense, 3-foot-tall shrubs (Zones 6-9)

'**Nearly wild**': Resembles a species rose with its continuously blooming sprays of single, clear pink flowers; upright, rounded shrubs grow to 4 feet tall (Zones 4-9)

'**Sunsprite**': 2- to 4-foot-tall shrub with fragrant, double, golden yellow flowers (Zones 5-9)

SPECIES ROSES

Straight species roses are generally problem-free if grown in conditions that mimic their native habitat. Although not easily found in the market, they can be useful in the landscape.

Chestnut rose (*Rosa roxburghii*): Bears bright pink, 2-inch flowers on a 6-foot plant; has attractive peeling bark and showy hips (Zones 6-9)

Swamp rose (*R. palustris*): A suckering plant that produces fragrant, single, pink blooms in late June to early July (depending on region) and orange-red hips later in the season (Zones 3-7)

Virginia rose (*R. virginiana*): A suckering 3- to 5-foot shrub that produces single, pink flowers in June (depending on region) and red hips, which ripen in late summer (Zones 3-7)

Cold-Hardy Roses

In areas where winters are very cold, many roses won't make it to spring. Fortunately, there are choices even for the Zone 3 gardener. Species roses such as *Rosa glauco* and *R. rugosa* are hardy to Zone 2. Many *R. rugosa* cultivars are also cold-hardy and can survive in Zone 3. The Explorer series and the Parkland series of roses bred in Canada are hardy to -40°F. Some choices from these series follow.

'**Champlain**': 3-foot-tall shrub with prolific, bright red blooms (Zones 3-9)

'**John Cabot**': Prolific climber with fuchsia flowers (Zones 3-9)

'**Morden Centennial**': Well-shaped, 5-foot-tall shrub, covered with fragrant, deep pink blooms in late June and early July (Zones 2-9)

'**Simon Fraser**': 2½-foot shrub with masses of semi-double, pink flowers throughout the summer (Zones 3-9)

Some rose species are also very cold-hardy. *R. rugosa*, *R. seugera*, *R. spinosissima*, and many of their cultivars also survive frigid winters. Here are two good examples.

'**Frau Dagmar Hartopp**': 3-foot shrub with large, single, silver-pink blooms and red hips (Zones 4-9)

'**Wiliam Baffin**': Repeat bloomer; deep pink blooms on arching, 8-foot canes (Zones 2-9)

Heat-Tolerant Roses

Many roses stop blooming and start mildewing during long bouts of humid, moist heat. Here are some roses that can take the heat.

'**Champney's Pink Cluster**': Continuously blooming clusters of small, double, pink flowers on 4-foot shrubs (Zones 6-9)

Cherokee rose (*Rosa laevigata*): Once-blooming, species rose climber with fragrant, large, single, white blooms (Zones 7-9)

Continued →

China roses: Generally hardy to 0°F, these old roses are good choices for Zones 7–10; include 'old Blush', a 6-foot bush with light pink flowers, and 'Archduke Charles', a 3-foot bush with rose red flowers

Lady Banks rose (*R. banksiae* var. *alba-plena*): Hardy to 10°F; 20-foot climber with small, fragrant, double, white or yellow blooms (Zone 8)

'**Queen Elizabeth**': Clear pink blooms on a 6-foot-tall grandiflora (Zones 5–9)

Fragrant Roses

While old roses are known for their wonderful fragrance, many hybrid tea roses are also bred for fragrance. Here are a few relatively disease-resistant choices.

'**Chrysler Imperial**': Deep crimson flowers on a 3½-foot bush; susceptible to mildew and blackspot in cool, wet weather (Zones 4–9)

'**Fragrant cloud**': Repeat-blooming bush with coral-red flowers; vigorous; susceptible to disease (Zones 5–9)

'**Mister Lincoln**': Double, dark red, repeating blooms on erect canes (Zones 5–9)

Moss roses—named for the mossy, resinous growth covering the outside of flower buds—are usually very fragrant. Examples of these old roses follow.

'**Communis**': 4-foot bush with very fragrant, once-blooming, pink flowers (Zone 4)

'**Henri Martin**': 5-foot bush with fragrant, once-blooming, double, crimson flowers fading to deep rose (Zones 4–8)

'**White Bath**': 4-foot bush with very fragrant white flowers (Zones 5–9)

Selecting and Planting Roses

Barbara W. Ellis

Roses have been called the "queen of flowers." Perhaps not surprisingly, they are the oldest cultivated ornamental plant and our national flower. Although many other flowers share the word rose as part of their common names, true roses are members of the genus *Rosa*, which contains over 100 species and literally thousands of cultivars. Their showy flowers, thorny stems, and leathery green leaves are familiar to all gardeners. Blooms come in white, red, pink, orange, yellow, lavender, and all shades in between; some bear bicolored blooms. The flowers can be single or double, large or small, and may be borne singly or in dramatic clusters. In addition, many roses also provide attractive hips that turn red in fall. Rosehips are used in jams, jellies, and teas for their high vitamin C content and tart, cranberrylike flavor.

Making the Right Choice

Probably the most important decision you'll make regarding roses in your landscape is selecting the right plant for the right place. There are so many types of roses available that choosing them requires some knowledge of each group and its distinguishing characteristics. There are roses to blend into a flower or perennial garden, or even a sunny spot in a natural garden. They make fine companions for herbs. Climbing roses are often the most suitable plant for covering a trellis or training as pillar roses on posts or old tree trunks.

The information in this section about some of the major classes of roses will help you make your selection. Rose hybridizers are constantly introducing new cultivars of roses with more attractive, longer-lasting flowers, ornamental hips, and better habit. They are also selecting for plants that exhibit disease- and insect-resistance characteristics. Although you'll find examples of cultivars listed in the sections that follow, ask your cooperative extension agent or local nursery owner for a list of the best roses to consider for your area. Since hardiness varies from class to class and cultivar to cultivar, it's also a good idea to find out which ones will survive best in your area.

HYBRID TEA ROSES

Hybrid tea roses are the most common roses grown today. The first hybrid tea, 'La France', was produced in 1867, the result of complex crosses between Chinese and European roses. Hybrid tea roses gradually gained in popularity because of their long season of bloom and the beauty of their unfurling buds. Hybrid tea roses are 3 to 5 feet tall and are primarily grown for their spectacular, many-petaled blossoms, which are borne singly or in small clusters on long, straight stems. Blooms range from 3½ to 5½ inches wide. Hybrid teas are not reliably hardy in the North and require winter protection if they are to survive in areas where temperatures routinely go below 10°F.

Hybrid teas probably require the most maintenance of any of the roses. Most hybrid teas are highly susceptible to insect and disease problems, and therefore require regular applications of insecticides and fungicides to look their best. Today, the trend is toward cultivars—both old and new—that require less maintenance and have more disease resistance. 'Miss All-American Beauty', 'Mister Lincoln', 'Pink Peace', 'Tiffany', and 'Tropicana' are all examples of hybrid tea roses. (All show resistance to black spot and powdery mildew, the two most prominent diseases of hybrid teas.) New and beautiful hybrid tea cultivars that show superior pest and disease resistance are introduced every year.

FLORIBUNDA AND GRANDIFLORA ROSES

These two classes of roses are closely related to hybrid teas. Floribunda roses, which were created by crossing polyantha roses with hybrid teas, are about 2 to 3 feet tall. The individual flowers range from 2½ to 3½ inches wide but are borne in large, many-flowered clusters. Floribundas are generally quite hardy, and can be easily grown anywhere hybrid teas are grown.

Grandiflora roses are the result of crosses between hybrid teas and floribundas. They are shrubs that can reach 6 to 8 feet in height and are about as hardy as hybrid teas. Grandifloras bear large clusters of hybrid-tea-size blooms. Both floribunda and grandiflora roses are among the most floriferous roses in the garden. 'Europeana', 'First Edition', 'Rose Parade', and 'Razzle Dazzle' are examples of Floribunda roses. 'Queen Elizabeth' and 'Prominent' are both Grandiflora roses. (All of these cultivars exhibit resistance to black spot and powdery mildew.)

CLIMBING AND RAMBLING ROSES

Because of their tremendous versatility and adaptability, climbing and rambling roses are extremely popular. They can be trained to climb over fences, on trellises, against buildings, or up tree trunks. They're not true climbers, though, because they have no natural way to grip or hold onto supports. Instead, they must be tied in place. These roses come in many forms. Some bear clusters of small flowers; others have blooms like those of hybrid teas. Hardiness varies from type to type. Rambling roses tend to have a much more rampant and vigorous growing habit than climbers, and bloom once a season, generally on two-year-old canes. Some climbers, on the other hand, will bloom twice. 'Don Juan' and 'Improved Blaze' are examples of large-flowered climbing roses. 'Chevy Chase' is a rambling rose that is resistant to powdery mildew.

SHRUB ROSES

Shrub roses make up one of the best groups of roses to blend with other plants in a landscape. This is a catch-all class for many of the newer roses, which often are hybrids between old roses and new roses. They tend to be excellent, low-maintenance shrubs that are easy to blend into a variety of landscape settings. Many shrub roses also are highly resistant to insect and disease problems and quite cold hardy. (The shrub roses bred by Griffith Buck, such as 'Carefree Beauty', are particularly good.) 'Bonica' is a popular shrub rose that grows very well with little care. It is approximately 3 to 4 feet tall with medium-pink flowers.

OLD ROSES

Old garden roses comprise a very large group of increasingly popular roses that have been grown since long before modern roses (such as hybrid teas) came into existence. They have been subdivided into many different subgroups, including Gallica, Alba, Centifolia, Moss, Bourbon, Hybrid Perpetual, China, Musk, Noisette, and Species. Although old roses vary a great deal, they possess many unique characteristics. The plants closely resemble shrub roses and range from 2 to 8 feet in height or sometimes more. Blooms may be single or double, solid or striped, and are borne in clusters. Fragrant blooms are another feature of many of the old roses. In addition, many have attractive hips that add fall interest. Hardiness is variable. Rosa 'Mundi', 'Reine des Violettes', and 'Mary Washington' are all examples of old roses.

MINIATURES

These useful roses are excellent as edging plants, in containers, and just about anywhere you want a floriferous, low-growing plant. Often called minis, they range in height from 1 to 2 feet and are easy to grow. Although tiny, they require much the same care as their larger cousins, the hybrid teas.

Planting Pointers

Once you've made your choice, proper site selection and planting are the next steps to getting your roses off to a good start. The following pointers will help you on your way to success.

SITE SELECTION

Roses absolutely require a location that has been carefully planned and prepared. Select a site that gets at least six hours of direct sunlight. Good air circulation is also important, so avoid damp, stagnant spots where there is little breeze. This will help prevent excessive problems with powdery mildew and black spot—the two most serious fungal diseases of roses. Pruning is one way to improve air circulation, but good site selection and a garden design where roses have plenty of room to grow are equally important.

Avoid spots where competition from encroaching tree roots, especially the greedy, shallow roots of trees such as silver maple, will sap the strength of your roses. However, roses are able to compete with smaller, less overpowering plants, such as many types of herbs and perennials, because their roots tend to go deep into the soil.

Soil pH should be somewhere between 6.0 and 6.5 for best growth. If the soil becomes too alkaline, you'll see chlorosis on

Continued →

the leaves because the plants are unable to take up the nutrients they need. Other signs of nutrient deficiencies will also appear.

SOIL PREPARATION

To prepare the soil, either double-dig the bed by hand, going as deep as possible, or use a rotary tiller. You'll need to add plenty of organic matter. Mix in generous quantities of well-rotted manure (cow or chicken are best) and/or well-rotted leaf mold. Spread a layer on top of the bed and then work it into the soil.

Excellent drainage also is a priority. Roses grow best in well-aerated soil that retains moisture but drains well. If you are gardening in heavy clay soil, consider raised beds to improve drainage. Organic matter improves soil structure and improves drainage. Chicken grit, composed of small, sharp pieces of granite, also will help to break up clay soil.

After amending the soil, carefully smooth the bed so that it's slightly higher in the center and carefully graded so that water won't form puddles in the middle of the beds after a heavy rain.

WHEN TO PLANT

Roses can be planted in early spring or in autumn. Generally, dormant, bare-root roses are shipped in autumn, and it's best to plant them as soon as they arrive. (Although bare-root roses are offered for sale in spring, it's best to buy and plant them in fall.) The roots of roses planted at this time of year will begin growing in very early spring, long before you'll be able to spot signs of growth aboveground. If you can't plant in fall (or if you can't plant right away), heeling-in and planting the following spring is the next best alternative. Dig a trench in a convenient area, lay the plants in the trench at about a 45-degree angle, and cover the roots with soil. Be sure that all the roots are adequately covered because new rose plants often dry out if exposed to cold, dry winter winds, but don't mound soil over the entire plant. It's also important to avoid overcrowding. Plants that have been heeled-in need to be moved to their permanent location before mid-spring to avoid root damage.

Container-grown roses can be purchased from garden centers in spring and planted at that time.

PLANTING

As a general rule, roses can be planted just like shrubs and trees. With bare-root plants, it's important to keep the roots from drying out. Unpack the plants as soon as possible and check to see that the packing material is damp. Make sure the roots remain damp until you are able to plant.

To plant bare-root roses, dig a hole large enough to accommodate the plant's roots and make a mound of soil in the center of the hole. Before planting, inspect the plant carefully. Remove broken or split roots or canes. Also remove weak, thin, or badly placed canes, such as those that cross the center of the plant. Most bare-root roses will be properly pruned on arrival, so if you've bought good-quality plants, you may not need to do any pruning at all. When cutting off canes, be sure to cut back to healthy wood and make cuts ¼-inch above a bud eye. Then set the plant in the hole and spread the rose roots evenly in all directions. Be sure to check the depth of the bud union, if you're planting a grafted plant, or crown, if you are planting a plant grown on its own roots. (Usually, all roses except shrub roses and old garden roses are grafted onto an understock.) Where winter temperatures fall below 0°F, the bud union should be planted 1 or 2 inches below the surface of the soil. In the South, the bud union should be planted even with the surface of the soil. Roses grown on their own roots should be planted with the crown at the surface of the soil.

Carefully fill the hole, firming the soil around the plant to eliminate pockets of air around the roots. Water thoroughly when the hole is about two-thirds full, then finish filling. To keep the plant from drying out during the first winter, mound soil up around the base of the plant to protect it. Be sure to uncover the plants in early spring.

When planting container-grown roses, remove the pot and set the plant in place with as little disturbance to the root ball as possible. Many nurseries pot bare-root roses in late winter and then offer them in pots the following spring. Unlike roses that have been grown in containers, the roots of these plants have not yet begun to grow, and it's likely the potting mix will fall from the roots if you remove the plant from its pot. To minimize transplant disturbance, dig a hole the size of the pot, cut the bottom out of the pot, and cut partway up the sides of the pot. Hold the bottom of the pot in place while you set the plant in the hole, then remove the bottom. Cut the rest of the way up the sides and remove the pot. Firm soil around the roots and water thoroughly.

MULCHING

There are several reasons for mulching roses. A layer of mulch will help conserve moisture and prevent weed growth. Mulch also looks attractive, and if applied in autumn, it can help to regulate soil temperature. Mulch can also help prevent fungal spores in the soil from splattering up onto the foliage. Use shredded hardwood bark or bark chips for mulch. Keep in mind that these materials can gradually change soil pH, so be sure to check for pH changes periodically.

WINTER PROTECTION

Protect tender roses in winter by tying up the canes and surrounding them with a burlap-covered collar of chicken wire. Stuff with leaves all around the roses. This helps prevent damage to the canes by moderating temperature changes around the plants.

Pruning Roses

If you're going to grow roses, you'll need to love—or at least like—pruning. Since the best time to prune roses is late winter, many gardeners look forward to pruning as an annual ritual of spring.

Proper pruning is vital for healthy growth—and for gorgeous flowers—so make an annual pruning appointment with your roses in late winter, just as the buds begin to swell. Annual pruning benefits plants by removing dead and diseased canes as well as crossing and weak branches. It keeps the plants well shaped and encourages vigorous growth that will lead to large, abundant flowers. On grafted plants, it's important to regularly remove any suckers that arise from the understock onto which the plant has been grafted. First- and second-year plants will need little pruning, but all other roses will benefit from some annual attention. In addition to late winter pruning, you may also need to prune in summer to keep plants from getting too tall. Remember, too, that deadheading and cutting roses for indoor bouquets is a form of pruning. Here are the supplies you'll need to begin.

- **Sharp pruning shears.** It's a good idea to dip shears in alcohol, bleach, or another disinfectant between pruning cuts to prevent spreading diseases.
- **Loppers.** Although most pruning is done with pruning shears, the larger, older branches may need to be cut with loppers to ensure a clean cut. Be very careful not to rip rose canes when cutting.
- **Wood glue or shellac and a paint brush.** After cutting back canes, paint them with wood glue or shellac in order to prevent cane borers from invading the stems.
- **Gloves.** Heavy leather gloves will help prevent too much damage to your hands and make it easier to remove large canes.
- **Garden rake.** Use this tool to rake out any debris under and around the plants after you've finished pruning. A rake also is useful for keeping the area clean and smoothing out mulch.
- **Vinyl-coated wire fencing.** This may come in handy for taller-growing roses that have problems with flopping over. After pruning, place a cylindrical cone of wire around the rose, up to around 3 feet, to support the rose during the growing season. Wire it together and use hooks of bendable wire to attach the cylinder in place.
- **Large basket or garden cart.** You'll need either or both of these to remove the prunings.

Generally, roses can be placed into one of two categories when it comes to pruning. There are the roses that bloom on old growth (also called old wood) and those that bloom on new growth produced the current season (new wood). Most roses fall into the latter category and are pruned hard in late winter, before the beginning of the growing season.

Roses that bloom on old wood include primarily old garden roses and species roses. These roses should only be pruned lightly in late winter, so that not too many of the flowers are removed. But a late-winter pruning does benefit these plants and results in larger, showier blossoms and fuller, better-shaped plants.

Roses should not be pruned in fall, because pruning at this season removes food reserves that will help the plant survive the winter. Fall pruning also encourages growth at a time the plants should be preparing for winter dormancy. The new stems produced late in the year will not harden properly before winter and will be killed by freezing temperatures.

The general guidelines for pruning vary depending on the type of roses you are growing and where you are growing them. Begin any pruning job by thoroughly studying the plant to decide which canes are to be removed and how the plant can be made more attractive. You should plan on removing old canes that are no longer flowering well, and any diseased or damaged wood. Also remove canes that cross the center of the plant, to improve air circulation, and eliminate any spots where canes rub and damage one another.

Pruning Techniques for Specific Roses

HYBRID TEAS

Ideally, hybrid tea roses should be pruned back to a height of 18 to 24 inches in late winter. Be sure to remove all dead, diseased, and damaged growth. Also remove any crossing branches to increase air circulation at the center of the plant. Gardeners who grow roses for exhibition often cut back more severely in order to get fewer, larger flowers for show, but this is not recommended; it will shorten the life of the plant. Remember, regular deadheading and cutting blooms are also forms of pruning. During the growing season, don't let stray branches grow so long that the plant looks straggly.

Roses that bloom on new wood, such as hybrid teas, are pruned hard in late winter. At that time, cut all dead and diseased canes back to healthy wood, remove weak, thin canes, and eliminate branches that cross the center of the plant to increase air circulation.
You can increase flowering on a hybrid tea rose by deadheading. Cut faded blooms off just below the flowers and ¼ inch above a large bud (left). Unless you're cutting fresh flowers, which will require long stems, don't cut blooms off farther down the stem, because the buds will not be as large and vigorous (right).

Continued ➔

GRANDIFLORAS AND FLORIBUNDAS

Grandiflora and floribundas need only very basic pruning to keep them healthy. In late winter prune back all dead, diseased, and damaged growth. Also remove any crossing branches to increase air circulation at the center of the plant. These roses don't need to be cut back to reduce height. Throughout the growing season, as you remove spent blooms or cut flowers for indoor display, keep in mind that you are also shaping the plant.

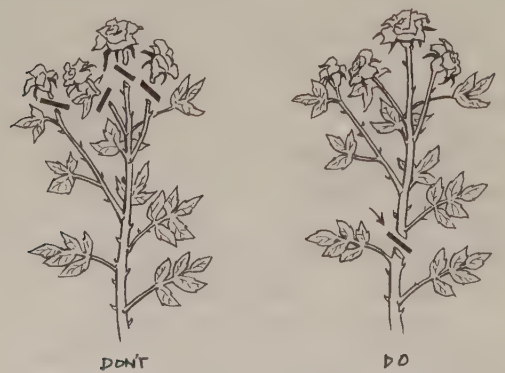
CLIMBING ROSES

When pruning climbing roses, it's best to remove all ties that hold the rose to its support and lay down all canes. Then shape the plant by bringing selected canes back up and tying them in a pleasing, graceful appearance.

For best flowering, always try to have one-, two-, and three-year-old canes on the plants at all times. For example, select at least one or two three-year-old canes for training, one or two two-year-old canes and one or two one-year-old canes. All canes selected to remain on the plant should be healthy and vigorous.

Some of the more rampant climbing roses can become an impossible tangled mess if left unpruned. You can cut these back hard each winter. ('Silver Moon' or 'Dr. Van Fleet' can be treated in this manner.) Since most blooms are borne on new wood, this harsh treatment will not greatly affect flowering. Climbing hybrid teas, on the other hand, are much less vigorous than other climbers and require only a light annual pruning. On these plants, just remove dead, diseased, or damaged growth.

With tall ramblers, it's impractical to pull the whole plant down for pruning. Apply the same principles as for climbing roses—removing diseased and old, woody canes—and prune in place. Nearly all rambling roses bloom only on second-year wood, so be sure you leave young wood to encourage blooming. You can cut the ends of long canes to encourage lateral branches, which will bloom the following year. Many ramblers produce too many canes and become thick and tangled at the base; remove excess canes at the base of the plant. Rambling roses can be pruned in summer after they finish blooming.



When deadheading floribundas, cut to a healthy bud just below the entire flower cluster (right) instead of simply removing the tips of the shoots just below the blooms (left).

OLD, SHRUB, AND SPECIES ROSES

There is such tremendous variation within these groups of roses that you'll need to depend on your own judgment and be sensitive to the growth habits of individual plants when pruning. Don't treat these plants as you would treat other modern roses such as hybrid teas. They don't appreciate hard pruning. Instead, it's best to leave the natural shape of the plants intact, and use pruning simply to enhance their shape and beauty, as well as to keep them under control and healthy. Restrict yourself to a late-winter pruning to remove diseased, damaged, and very old wood. Thin the growth at the center of the plant to increase air circulation, and eliminate crossing branches. You can also cut back any excessively long canes to improve the shape of the plant.

Rose Care: 1-2-3

Vicki Mattern

Many organic gardeners shy away from roses because they think these classic flowers require hours of extra work. But the truth is, you can grow beautiful roses by investing just a few hours per season. Combine careful cultivar selection, proper planting, and a few basic maintenance techniques, and you'll be rewarded with gorgeous flowers and attractive landscape plants.

Proper Planting

If you buy dormant bareroot roses, plant them either in early spring or late fall. You can plant actively growing container roses anytime during the growing season, but the earlier the better.

When you're ready to plant, select a site that receives at least 6 hours of sunlight per day. (In very hot climates, however, roses can benefit from some midday shade.) Be sure the site has good air circulation. Avoid areas close to heat-reflective surfaces, such as concrete walks or south-facing brick walls, which can attract mites. The soil should be loose and crumbly, with excellent drainage. If yours isn't, work in lots of compost or create raised planting beds.

Give rose bushes plenty of room. A good rule of thumb is to plant shrub types (old-fashioned roses, floribundas, polyanthas, and hybrid teas) no closer than 3 feet apart. Plant climbers, ramblers, and large-growing shrub roses (such as many of the David Austin English roses) 6 to 8 feet apart. Space miniature roses about 1 foot apart.

Container roses. Planting container roses is easy. Dig a hole large enough to hold the container, making sure that the top of the soil in the container is just below ground level. Tip the container and tap it to release the soil, or cut the container away from the rootball with a utility knife. Set the rose in the hole, holding onto the top of the rootball rather than grasping the rose by its stem. Fill in around the rootball with soil. Water the rose and add more soil, if necessary.

Bareroot roses. To plant bareroot roses, choose a day when the soil is relatively dry. (If conditions aren't right for planting when the roses arrive, set the plants in a bucket of water until you're ready.) Prune off any damaged or dead roots, as well as dead or damaged canes, cutting back to a healthy bud.

Dig a hole large enough for the roots to spread out naturally, then make a mound of soil inside the planting hole. The mound should be high enough that the bud union is at the proper depth.

Set the rose on the mound, spreading out its roots. Completely cover the roots with soil, tamp gently, and water well. The soil will settle and fill the hole.

Easy Maintenance

After you've got your roses planted, maintaining them organically is a simple matter of mulching, watering, feeding, and pruning. Pay attention to these basics and you should prevent most rose disease and pest problems. If diseases or pests do show up, manage them organically using the methods described on the previous pages.

Mulching. Surround the plants with a mulch to conserve soil moisture and help keep roots cool through summer. Mulching also helps prevent black spot disease by keeping the fungal spores from splashing up onto the plants from the soil. Choose mulches that will decompose and add organic matter to the soil, such as compost, shredded leaves, or shredded bark.

Depending on the material you use, the mulch layer should be 2 or 3 inches thick. (A 1-inch layer of compost, however, is all that's needed to suppress diseases.) As the mulch breaks down over time, work it into the top few inches of the soil, then add fresh mulch to bring the depth back to 2 or 3 inches.

Watering. Rugosa roses are very tolerant of dry conditions, but most other species and cultivars shine with just a bit of extra watering beyond what Mother Nature provides. Once a week, water the plants thoroughly—enough to soak down through their entire root area. Use a soaker hose or other form of drip irrigation, if possible. Overhead watering with a hose or sprinkler can promote the spread of diseases such as black spot, powdery mildew, and rust.

Feeding. Before you apply any fertilizers, it's a good idea to have your soil tested to determine any specific nutrient deficiencies. If your soil appears to be in good shape, put your roses on this simple diet regimen to keep them robust:

- About 2 weeks after spring pruning, apply a balanced organic fertilizer or a dressing of compost. (Don't feed newly planted roses until they've completed their first bloom cycle, though.)
- After roses have finished their first heavy bloom cycle in early summer, give them a second application of fertilizer.
- Feed reblooming roses again, after the second bloom cycle. (Don't use nitrogen fertilizers within 6 weeks of the first fall frost in your area, however. Late feedings encourage tender growth that frost will kill.)
- Always water your roses the day before feeding and again the day after applying fertilizer. This prevents fertilizer burn.

Pruning Basics

Don't be too nervous about pruning your roses incorrectly—they are very forgiving, even if you make a wrong cut or two. Each year, the plants produce strong new shoots, giving you beautiful blossoms and another try at pruning.

The best time to prune most roses is either late winter or early spring, about 4 to 6 weeks before the last killing frost in your area. Summer pruning is really just a matter of removing faded flowers throughout the growing season. Because pruning promotes soft new growth, discontinue it in late summer to avoid subjecting plants to winter damage.

What to Prune

The toughest part about pruning roses is deciding what to cut off and what to leave alone. As a rule of thumb, most vigorous roses can be pruned back to 6 inches tall, while others can be pruned to 10 to 12 inches without harm.

All roses. Remove canes that are dead, diseased, flowering poorly, crossed or rubbing, or growing inward. If suckers emerge from the area that's grafted, just below the ground, don't just cut them off at ground level or they'll resprout. Instead, follow each shoot underground to where it joins the stock, then use a trowel to snap it off.

Hybrid tea roses. Cut off the oldest stems at the base, leaving three to six healthy canes. Prune the remaining canes to shape the plant.

Floribunda roses. Remove the oldest stems at the base, leaving six to eight healthy canes. Prune off the top third of each remaining cane.

Climbers. Prune climbers to train and shape them, cutting back side branches to about 6 inches. Leave more canes than on other roses—about 15 or so—to get a good flush of bloom next year.

Ramblers. Ramblers bloom on first-year wood, so you should prune them more heavily each year. Cut them back to 12 to 18 inches from the ground each year.

Shrub roses. Prune off the top third of new canes and cut side shoots and older growth to 4 to 6 inches.

How to Prune

Pruning roses is a snap if you follow this advice:

- Make cuts ¼ inch above an outward-facing bud—the point where a leaf is or was attached to the stem.
- Cut at a 45-degree angle away from the bud. This promotes open growth in the center of the bush, encouraging air to

Continued ➔

circulate and preventing disease. Angling the cut prevents moisture from gathering on the bud and rotting it.

- Cut back to at least a five-leaflet node. Otherwise, the sprouting stem will be weak and spindly.
- If the inside, or pith, of the cane is discolored, cut the shoot back until the pith is white and healthy.
- If, after pruning, two or three shoots emerge from one bud, pinch off all of them but one.

Landscaping with Roses

Roses are perfect landscape plants because you can use them in so many ways. Think of them as part shrub, part perennial, and part vine. Some varieties offer season-long blooms, and many produce brightly colored hips that add a burst of color to your landscape throughout the fall and winter, too.

Use Roses Anywhere

Roses are great planted with herbs, in a cottage garden, or in a perennial flowerbed. You can also use roses as hedges or train them to climb arbors, trellises, walls, even lampposts. Your imagination is the only limit to creating a beautiful and interesting garden with roses.

A Gallery of Ideas

Once you've summed up all the ways you can use roses in your landscape, it's time to review the possibilities in more detail. The information contained here will help you decide exactly how and where you should use roses on your property and which roses are the best choices for your intended use.

In this section, you'll find ideas for different types of plantings from low-growing ground covers to 20-foot climbers. You'll also find tips to help you train climbers and ramblers, as well as suggestions for what to plant with roses to show them off to their best advantage.

The Rose Garden

The time-honored way to use roses in the landscape is to plant a rose garden—with roses in the spotlight and no supporting players. If your heart is set on a rose garden, by all means plant one, but don't grow the roses all by themselves. A bed with nothing in it but roses will attract pests and diseases, and it will look dull when the roses have finished blooming.

- Underplant your roses with herbs like lavender and catmint (*Nepeto x faassenii*) for a lovely contrast.
- Choose a mixture of repeat-blooming roses, including hybrid teas, floribundas, grandifloras, miniatures, shrubs, rugosas, polyanthas, and repeat-blooming old roses for a garden that will be full of blooms throughout the season.

Perennial and Shrub Borders

Roses are natural partners in the perennial garden, adding height, texture, fragrance, and even season-long bloom. Shrub, old garden, species, and grandiflora roses are all excellent choices for a perennial border.

Plant tall roses in the back of the bed, shorter ones in the middle, and minis in the front, the same way you'd use perennials. In an island bed designed to be seen from all sides, put the tallest plants in the center and work down from there.

In mixed shrub borders, where roses share the billing with other plants, multiseasonal interest isn't critical for each rose—other plants can easily take over when rose bloom is past. In both perennial and shrub borders, you can base your choice of roses on color, plant and flower form, and personal preference.

Roses with Herbs

No type of garden is more romantic or has more historical significance as an herb garden. People have used herbs as medicines, cosmetics, seasonings for foods, and decorations throughout the ages. For many centuries, roses were an integral part of herb gardens, so selecting an old rose or two to complement your herb garden is a wonderful choice. 'Apothecary's Rose' (*Rosa gallica* var. *officinalis*) is probably the rose grown in western gardens the longest. It has magenta, semidouble flowers that bloom in early summer—a perfect partner for lavender- and white-blooming herbs.

Don't be afraid to use culinary herbs as well as more decorative herbs to hide the base of leggy rose canes. Sweet basil, curly parsley, chives, French tarragon, 'Fern leaf' dill, and others are not only pretty to look at but are useful, too.

Roses on Structures

You may want to dress up or hide a fence, arbor, trellis, pergola, wall, building, or other structure with roses. The tall climbers, ramblers, and more aggressive shrub and old roses are ideal for this purpose. Use the shorter climbers for low fences or train them on pillars.

Miniature climbers have a powerful impact for their diminutive size. An ideal place for a miniature climber is on a mailbox or lamppost.

Combine roses with other climbers like clematis for even more beauty and bloom. Underplant with cheerful annuals in complementary colors or with cool foliage plants like hostas to create ground-level interest.

With a little guidance from you, your climbers and ramblers will create a stunning landscaping effect. Use raffia or rubber- or plastic-coated wire for the ties, making a figure-eight between the cane and the support so the tie won't put pressure on the cane.

TRAINING ROSES TO A FENCE

Ramblers are the best type of rose to train to a fence. Train the canes to grow horizontally on the fence for best bloom.

When the main canes are forced to grow horizontally, they will produce more new shoots that will bear the blooms. As canes die or stop flowering well, untie them and cut them off at the base because ramblers bloom only on new wood.

TRAINING ROSES TO A TRELLIS

Train climbing roses to a trellis by starting on the outside of the plant and working across, spacing the canes evenly against the trellis as you tie them to it. The more horizontally you bend and tie the canes, the more flowers you'll have. Train climbers to an arbor in the same way, planting a rose on each side of the arbor.

Roses as Groundcovers

Planting low-growing, sprawling roses is an excellent solution for hard-to-mow slopes, as long as the slope isn't too dry. Although the foliage of groundcover roses isn't as dense as that of traditional groundcovers such as pachysandra, it's thick enough to serve the purpose. *Rosa wichuraiana*, climbing roses like 'New Dawn', and some of the Meidiland landscape rose cultivars such as 'Alba Meidiland' make colorful, effective groundcovers. They're most effective if you install them with a combination of plastic mulch and an organic mulch like bark chips, or with a thick organic mulch like shredded leaves.

Other excellent choices for groundcover roses include the following:

- 'Sea Foam', a repeat-blooming creamy white rose that grows 2 feet tall x 8 feet wide
- 'The Fairy', a repeat-blooming double pink polyantha rose that grows 2 feet tall x 3 feet wide
- Miniature roses, such as 'Snow Carpet', which grows 1 foot tall x 3 feet wide

Rose Hedges and Edgings

Shrub, old garden, and taller grandiflora roses are perfect for creating hedges as a background, screen, or barrier. Although the plants lose their leaves in winter, the thorny branches still serve as a physical barrier and also provide shelter for wildlife. Many of these roses have beautiful hips in fall and winter, so they add color to the winter landscape and attract birds to your yard. You can mix roses of similar size and compatible flower colors, or mix roses with other shrubs for a more informal, colorful hedge.

To create a thick, blooming tall hedge, you simply have to pick the right rose—one that's upright, densely bushy, and disease-resistant so it doesn't need coddling.

If you'd like a low hedge or edging, there are plenty of options. Instead of a sprawling groundcover rose, choose one that's more upright but only reaches a mature height of 1 to 4 feet tall. Most floribundas, polyanthas, and miniature roses grow beautifully as low hedges, which are useful along walks and paths and around terraces and beds. They make a clear boundary but don't block the view.

Roses in Containers

One of the greatest pleasures of container gardening is that it's like having furniture. You can move the containers around to suit your mood or the occasion. The best arrangements of containers are in informally arranged, odd-numbered groups of different-size pots, but it's always fun to experiment with different looks and groupings.

Roses look lovely in containers. The miniature roses and shorter-sprawling cultivars are graceful in hanging baskets. You can also grow roses in containers to place on decks, terraces, porches, and patios and throughout the yard.

Smaller-growing types such as miniature roses are perfect choices for containers, as are the floribundas and polyanthas. Combine roses with annuals like ivy geraniums, annual candy tuft, sweet alyssum, and petunias for two-story color. Or create a more subtle look with herbs like prostrate rosemary or creeping thyme.

Overwintering potted roses in colder climates requires some effort, so be prepared to bring them indoors or provide protection if you live where temperatures dip below 20°F. Standard, or tree, roses are also perfect for container growing. Standard roses have a tough time surviving in winter winds, so it's best to bring them inside during the winter. When you grow a standard rose in a container, it's easy to move it in and out of your house.

Roses as Cut Flowers

There's nothing more elegant than a bouquet of roses, and when you grow your own, you can bring in armfuls of roses from the garden to enjoy without spending a fortune at a flower shop!

Make the Most of Your Roses

In this section, you'll learn how to cut and condition your roses properly so they have the longest vase life possible—nine days or more. You'll also learn how to show off your cut roses to their best advantage. You could just stick a bunch of roses in a jelly jar. But, if you arrange them in that jelly jar, you can let your creative juices produce a display that does justice to your beautiful blossoms.

Luckily, casual, simple arrangements are the style today, rather than the more stiff, formal, rule-bound arrangements of the past. Even so, to create the most satisfying arrangements, you will need to pay attention to a few guidelines regarding size, balance, color, and shape. With a little practice, you'll be able to fashion beautiful arrangements and savor the fruits of your gardening labors. But first, let's take a look at how to cut roses properly.

Continued →

Wild Rose

When and How to Cut Roses

To enjoy your rose arrangements the longest, cut roses from your garden either in the evening or early in the morning. This is when the plants are most filled with water. Gather rosebuds and half-open flowers, but avoid fully open roses because they won't last long. Be sure to use pruning shears, not scissors, to cut roses because scissors don't have enough leverage to cut cleanly through the woody stems.

4 STEPS TO SIMPLY BEAUTIFUL CUT ROSES

1. Cut stems just above a five-leaflet leaf at a 45-degree angle. It's best if the leaf is facing outward because another shoot will grow from this point. Also, consider the shape and size of the bush before cutting any roses so that you don't ruin its form.
2. Once you've cut a rose, strip the foliage from the bottom 3 to 4 inches of its stem. Carry a bucket of water with you and plunge the stems into the bucket as soon as you've cut them.
3. Once you're back indoors, recut each stem underwater at a sharp angle so that the maximum area of the cut end is exposed to water. Cut off the thorns in the area where you have stripped the foliage away, using thornstrippers or a sharp knife.
4. Set the container of roses in a dark, cool, humid place (such as a refrigerator or a basement) for at least several hours, preferably overnight, in order to condition the roses before using them in an arrangement. (Cut other flowers and foliage for your arrangement at the same time as you cut your roses and put them in that same dark, humid place as your roses to condition them, too.)

Choosing Colors

Although you don't need to know a thing about color theory to arrange a beautiful bouquet, you'll have a higher success rate if you know some elementary color combinations.

- Pairings of complementary colors such as orange and blue, yellow and purple, and red and green tend to be bright and vibrant. One example is a simple arrangement of yellow roses with purple catmint (*Nepeta x faassenii*).
- Related colors—such as pinks, magentas, lavenders, and purples—can also make for lovely arrangements. Imagine an arrangement of pink roses, pale pink lilies, and purple lavender.
- A monochromatic arrangement is built basically around one color. For example, a bouquet of all white to creamy white flowers, such as white roses with white larkspur (*Consolida ambigua*) and white coral bells (*Heuchera sanguinea*) accented with herb foliage would be wonderful.
- A polychromatic arrangement includes a mix of many different colors. Go to your garden, gather roses and any other flowers and foliage that catch your eye, and enjoy a bounty of beauty.

Creating Your Arrangement

Styles in flower arranging are very personal, ranging from bouquets that look as though they've just been gathered from the garden to more formally arranged styles. Follow the basic principles of balance, rhythm, and scale to help guide you in making arrangements you'll love.

BALANCE

A balanced arrangement seems secure and stable. Balance your arrangement by putting the heavier-looking flowers toward the center and lower parts of your arrangements.

RHYTHM

Rhythm is how your eyes are led from the focal point (the central point of interest) throughout the arrangement. Get rhythm in your arrangements by repeating shapes and colors and by arranging branches and stems to create a continuous flow of line.

SCALE

Scale is the size relationship of the various elements. An arrangement with good scale means that the proportions of each element are pleasing and in harmony with the others. A basic guideline is that your arrangement should be 1½ times as high or as wide as the container.

CONTAINER CRITERIA

Containers can vary with the style or arrangement and type of roses. A hybrid tea rose with its long, stiff stem will work in a tall vase, while old-fashioned roses with multiple flowers on short stems lend themselves to small, informal, charming containers, such as a pottery bowl. The major point to keep in mind is that the container should complement the flowers, not detract from them. Containers that work best are those with the simplest designs or colors.

Live Rose Arrangements

For the simplest rose arrangements of all, grow miniature roses as houseplants and when they are at their peak bloom, put them in a decorative container and use them as centerpieces or room accents.

For miniatures to grow successfully indoors, they need at least 5 hours of bright sunlight in a south- or west-facing window. Or put them under fluorescent lights for 14 hours daily. Place the lights 3 to 4 inches above the tops of the plants.

Another important factor in indoor rose growing is soil moisture. Keep the soil evenly moist but not soggy. Feed your roses twice a month with a water-soluble organic fertilizer for indoor use. Miniature roses will bloom best at daytime temperatures of 70° to 75°F and nighttime temperatures of 60° to 65°F.

Preserving Roses with Your Microwave

Microwave oven drying with silica gel (a desiccant that resembles white sand) gives the freshest, most colorful preserved flower possible, other than freeze-drying. You can dry lots of flowers with a small amount of silica gel. The disadvantages are that you can only dry one or two flowers at a time and it can be difficult to judge the correct drying time.

1. Preheat silica gel in the microwave for 1 minute on high power.
2. Pour a 1-inch layer of the preheated gel in a small, deep, microwave-safe container or cardboard box. (Do not use the container for food preparation after using the silica gel.)
3. Place a rose with a 1-inch stem into the silica gel.
4. Microwave for 2 minutes on high power, using a turntable or rotating the container one-half turn every 30 seconds. Let the container cool for 20 to 30 seconds.
5. Carefully pour off the silica gel and check the condition of the flower. If it's too "done," cut the cooking time in half for the next rose.
6. Make a replacement stem with floral wire and floral wrapping tape. Insert a wire through the fat part of the flower just below the petals and center the wire. Gently bend the wire down on both sides and overlap the wire to form a single "stem."
7. Place the end of the floral tape against the rose and wrap the wires, twirling the wires and stretching the tape as you go. Tear off the tape at the base of the stem.

Your Seasonal Rose-Care Calendar

Now that you know the basics of good organic rose care, you need to know when to feed, mulch, water, plant, prune, and do all the other things roses need to thrive. Here's a calendar that gives you a glance of what you'll need to do each month throughout the year to keep your roses growing and blooming their best.

Also keep in mind that planting roses in Florida isn't the same as planting them in Maine because of the climatic conditions. That's why before you even start planning for roses, you need to know what hardiness zone you live in.

A plant's ability to withstand a given climate is called its hardiness. The USDA has developed a Plant Hardiness Zone Map that divides North America into ten numbered climatic zones. Zone 1 is the coldest, and Zone 10 is the warmest. Parts of Hawaii are even warmer and fall into Zone 11.

January

All climates:

- Plan your garden for the coming year, decide which roses you want to add, and order them.
- Purchase whatever new garden tools you need.
- Clean, sharpen, and repair tools you have on hand.
- Check to make sure winter protection remains in place.

Zones 8 to 10: Plant both container-grown and bareroot roses and transplant any roses you want moved.

February

All climates: Clean, sharpen, and repair any equipment you didn't get to in January.

Zones 7 to 10: Plant container-grown and bareroot roses, and transplant roses as necessary.

March

Zones 2 to 5:

- Make any adjustments to garden plans.
- Review information on roses you're planning to purchase.
- Order roses.

Zone 6: Remove winter protection from plants. Prune roses to shape, encourage new growth, or remove dead, diseased, or damaged wood.

Zones 7 to 10: Apply a balanced organic fertilizer to the soil around roses, scratching it in lightly.

April

Zones 2 to 7:

- As soon as the soil is dry enough to work, plant bareroot and container-grown roses.

Continued

- Move any roses that would look better or grow better in another part of the garden.
- Prune roses to shape, to encourage new growth, or to remove dead, diseased, or damaged wood.

Zones 7 to 10:

- Remove faded flowers and remove buds on side blooms of hybrid teas for larger, longer-stemmed blooms.
- Plant container-grown roses.
- Apply balanced organic fertilizer to the soil and scratch in around roses.

May

All climates: Check for pest and disease problems and water as necessary. Apply a balanced, organic fertilizer to the soil around roses. Gather roses for bouquets for yourself and friends.

Zones 2 to 4: Plant bareroot roses as weather and soil conditions permit.

June

All climates:

- Remove faded flowers and remove buds on side blooms of cutting roses.
- Continue to check for pest and disease problems and control them as necessary.
- As rose canes extend themselves, tie and peg climbers to their structures.
- Enjoy your roses!

July

All climates:

- Continue to remove faded flowers, monitor for pests and disease problems, and water as necessary.
- Apply a foliar feeding of fish emulsion or liquid seaweed.
- Apply balanced organic fertilizer to the soil and scratch in around roses.

August

All climates:

- Monitor for pests and disease and water as necessary.
- If desired, make a final application of a balanced fertilizer.
- Remove faded flowers and disbud side blooms on hybrid teas for larger, longer-stemmed blooms.

September

Zones 2 to 6: Get new beds ready for spring planting. Stop removing faded flowers.

Zones 6 to 10: Send off orders for fall planting. Plant container-grown roses. Continue to keep garden areas weeded, and water as necessary.

October

All climates: Plan new plantings.

Zones 2 to 4:

- Prune roses.
- Remove leaves from plants and from surrounding soil, and destroy.
- Apply winter mulch.

Zones 7 to 10: Send off orders for fall planting. Stop removing faded flowers.

November

All climates: Send off your rose orders for spring planting.

Zones 5 to 7:

- Prune roses.
- Remove diseased leaves and canes from plants and from surrounding soil, and destroy.
- Apply winter mulch.

Zones 6 to 10: Get new beds ready for spring planting. Stop watering.

December

All climates: Use discarded Christmas tree branches as mulch around roses.

Zones 7 to 10:

- Plant container-grown and bareroot roses as weather and soil permit.
- Transplant roses as desired.
- Continue to check for pests and diseases.

Rose Glossary

Alfalfa meal. One of the most commonly recommended organic fertilizers for roses.

Aphids. Soft-bodied green, red, pink, brown, or black insects about ⅛ inch long that attack roses. Found mostly on new growth, clustered on leaf tips and buds.

Axil. The angle between the cane and the upper surface of the leaf stalk.

Bareroot. A common form of shipping roses, where dormant roses are packed without pot or soil.

Beetles. Chewing insects with hard wings that eat rose leaves and flowers. Some larvae feed on the rose's roots.

Black spot. A fungal infection that forms black circles with yellow margins on leaves.

Blood meal. Also known as dried blood, blood meal is an animal by-product that contains 13 percent nitrogen. Sprinkled on garden beds, blood meal can repel rabbits.

Bonemeal. Finely ground bones (another animal by-product); contains 10 to 12 percent phosphorus, 24 percent calcium, and a small amount of nitrogen.

Bud. A growth bud, or eye, found on a cane; a vegetative growing point located where a leaf joins the stem.

Bud union. The swollen point where the bud is joined with the rootstock.

Cane. A main stem, or basal shoot, of a rose, usually arising at or very near the bud union.

Clay soil. Soil that is made up of very fine particles that hold nutrients well but are poorly drained and difficult to work.

Climber. A rose that grows very tall and can be trained to grow on a trellis, an arbor, a pergola, or a wall.

Compost. Decomposed and partially decomposed organic matter that is dark in color and crumbly in texture. Used as a soil amendment, compost increases the water-holding capacity of sandy soil, improves drainage of clay soil, and is an excellent nutrient source for microorganisms, which later release nutrients to your plants.

Crown. The point on the rose where the canes sprout from the bud union.

Cultivar. Short for "cultivated variety," a cultivar is any plant that is bred for specific characteristics such as color, fragrance, disease resistance, or other desirable qualities.

Double flower. A rose that has 30 to 39 petals in four or more rows.

Eye (bud eye). A vegetative bud, or growing point, on a stem.

Feeder roots. Thin, fine-textured roots that absorb nutrients and water from the soil; also called hair roots.

Fertilizer. A natural or manufactured material that supplies one or more of the major nutrients—nitrogen (N), phosphorus (P), and potassium (K)—to growing plants.

Floribunda. Bushy roses that are a cross of hybrid tea and polyantha roses. Flowers may be single, semidouble, or double, and plants stand 2 to 4 feet tall.

Grafting. The process of joining a stem or bud of one cultivar onto the rooted stem, called the rootstock, of another cultivar.

Grandiflora. A cross of hybrid teas and floribunda roses that grow 4 to 6 feet tall. Flowers have high centers and are borne singly or in clusters.

Hip. The fruit or seedpod of the rose. Some roses have very showy hips, which add color and beauty to the fall and winter landscape.

Hybrid tea. Narrow, upright bushes that grow 3 to 5 feet high and need extra fertilizer to sustain heavy blooming. Flowers are long, narrow, and high-centered.

Lateral cane (branch). A side branch arising from a main, or basal, cane. Rambler roses, for instance, bloom on the lateral canes.

Leaf/leaflet. A rose leaf is compound and has three or more leaflets that make up the true leaf.

Loam. Textural class of soil that contains a balance of fine clay, medium-size silt, and coarse sand particles. Loam is easily tilled and retains moisture and nutrients effectively.

Main shoot. A basal or strong lateral cane.

Micronutrient. A plant nutrient needed in very small quantities, including copper, chlorine, zinc, iron, manganese, boron, and molybdenum.

Miniature rose. A rose that grows only 6 inches to 2 feet tall and all parts are miniaturized. The flowers can be single, semidouble, or double.

Modern rose. Any rose cultivar that was bred and introduced after 1867, the time when modern hybrid tea roses were first introduced.

Continued →

Mosaic virus. A virus that causes leaves to develop circles of yellow or chartreuse, become streaked or mottled, or develop yellow netting. Plants may be stunted.

Mulch. A layer of an organic or inorganic material, such as shredded leaves, straw, bark, pine needles, lawn clippings, or black plastic, which is spread around plants to conserve soil moisture and discourage weeds. As organic mulches decompose, they help to build the soil.

New wood. A cane of the current year's growth. Some roses bloom only on new wood, while others bloom on the previous year's growth.

Old roses. Roses that were bred before 1867, the time when the modern hybrid tea rose was first introduced.

Old wood. A cane of the previous year's growth or older.

Own-root roses. Roses grown from cuttings, rather than being budded onto a rootstock of another plant.

Polyantha. Bushy, 2-foot plants that have narrow, finely textured leaves. Flowers are small and are borne in clusters.

Powdery mildew. A fungal disease that attacks new growth and flower buds, covering them with a thin, white, powdery substance. Growth becomes deformed.

Rambler. Similar to climbing roses, ramblers can be trained to grow on fences. They are once-blooming roses, and flowers are borne on new growth, so they must be pruned back severely each year to produce flowers the following summer.

Reversion. Suckers from the rootstock choking out or taking over from the growth of the bud graft.

Rootstock. The host plant or root portion (understock) onto which a bud of another type of rose is grafted.

Rust. A fungal disease that appears in spring as small orange spots on undersides of leaves and light yellow spots on the upper sides. Spots may also appear on canes. Most common on the Pacific Coast.

Sandy soil. Soil that contains more than 70 percent sand and less than 15 percent clay, generally easy to work and well drained but with poor nutrient- and water-holding abilities.

Scion. The technical term for the bud grafted onto a rootstock.

Semidouble flower. A flower that has 8 to 20 petals in two or three rows.

Shrub rose. A hardy, easy-to-grow plant that can grow as tall as 12 feet. The flowers can be single, semidouble, or double.

Silt. Refers to a soil particle of moderate size—larger than clay but not as large as sand.

Single flower. A flower with 5 to 7 petals in a single row.

Soil amendment. A material added to the soil to make it more productive by improving its structure, drainage, or aeration.

Soil pH. A number from 1 to 14 that is a measure of the acidity or alkalinity of soil, with 7 indicating neutrality; below 7, acidity; and above 7, alkalinity. The pH of your soil has a great effect on what nutrients are available to your plants.

Soil structure. The physical arrangement of soil particles and interconnected pore spaces. Soil structure can be improved by the addition of organic matter. Walking on or tilling wet soil can destroy the soil aggregates and ruin the soil's structure.

Soil texture. The proportions of sand, silt, and clay in a particular soil.

Species rose. Any rose that occurs naturally in nature. There are over 200 species of roses from which all other types of roses are bred.

Standard. Also called a tree rose, a standard is a rose that is grafted to a stalk (or standard), which in turn is grafted to rootstock, meaning there are two bud unions on a standard rose. These roses can be planted in the ground or used in containers as accent plants.

Stem. A branch of a cane, which emerges from a bud eye and bears leaves and at least one flower.

Sucker. A growing stem that arises from a rootstock below the bud union.

Thorn. The prickle, or sharp spine, found on the stem of roses.

Understock. The base of the plant, providing the root system, onto which the scion or bud of another rose is grafted; also called the rootstock.

VEGETABLES

Introduction to the Vegetable Garden

Jeff Cox

Fresh-picked sweet corn, tomatoes, and snap peas are a taste treat you can get only from your backyard vegetable garden. The quality and flavor of fresh vegetables will reward you from early in the growing season until late fall. And when you garden organically, you know that your harvest is free of potentially harmful chemical residues.

Although the plants grown in vegetable gardens are a diverse group from many different plant families, they share broad general cultural requirements. Most will thrive in well-drained soil with a pH of 6.5 to 7.0. Some will tolerate frost; others will tolerate some shade. You should have little trouble growing vegetables successfully if you pick an appropriate site, prepare the soil well, and keep your growing crops weeded and watered.

This chapter will serve as your guide to planning, preparing, and tending your vegetable plot through the seasons.

Vegetable gardens are ideal sites for putting organic soil improvement and pest management techniques into practice. Since you're working the soil each year, you'll have lots of opportunities to add organic matter and soil amendments that help keep the soil naturally balanced.

As you make your yearly plan for planting and caring for your garden, you can incorporate techniques such as crop rotation, soil enrichment, and other cultural pest prevention methods. And there's a broad range of organically acceptable pest control methods and products for vegetable crops.

Planning Your Garden

Planning your garden can be as much fun as planting it. When you plan a garden, you'll balance all your hopes and wishes for the crops you'd like to harvest against your local growing conditions, as well as the space you have available to plant. Planning involves choosing a site (unless you already have an

Continued ➔

established garden), deciding on a garden style, selecting crops and cultivars, and mapping your garden.

SITE SELECTION

Somewhere in your yard, there is a good place for a vegetable garden. The ideal site has these characteristics:

Full or almost full sun: In warm climates, some vegetables can get by on six hours of direct sunshine each day, while a full day of sun is needed in cool climates. The best sites for vegetable gardens usually are on the south or west side of a house, where sunshine is most abundant. If part of the site you select is too shady for planting, put your compost pile there.

Good drainage: A slight slope is good for vegetable gardens. The soil will get well soaked by rain or irrigation water, and excess will run off. Avoid low places where water accumulates.

Limited competition from nearby trees: Tree roots take up huge amounts of water. Leave as much space as possible between large trees and your vegetable garden.

Easy access to water: If you can't get a hose or irrigation line to a prospective garden site, don't plant vegetables there. No matter what your local climate is, you'll most likely have to provide supplemental water at some point in the growing season, or your harvest will suffer.

Accessibility: Organic gardens need large amounts of mulch, plus periodic infusions of other bulky materials such as well-rotted manure or rock fertilizers. If you have a large garden, you should be able to drive a truck up to its edge for easy unloading. In narrow city lots, the garden access path should be wide enough for a cart or wheelbarrow.

Once you find a site that has these characteristics, double-check for hidden problems. For example, don't locate your garden over septic-tank field lines, buried utility cables, or water lines.

GARDEN LAYOUT

Once you've decided on a site, think about the type of vegetable garden you want. Possible layouts range from traditional row plantings to intensive raised beds and container gardens.

Row Planting: A row garden, in which vegetables are planted in parallel lines, is easy to organize and plant. However, it's not as space-efficient as more intensive methods, such as raised beds. You may spend more time weeding unless you mulch heavily and early between rows. Also, you'll get less yield per area than you would from an intensively planted garden. Row planting is quick and efficient for large plantings of crops such as beans or corn.

You can enhance the appearance and productivity of a row garden by making a raised bed along the front edge and planting it with herbs and flowers.

Beds: Productivity, efficient use of space, less weeding, and shading the soil are all benefits of intensively planted beds. Beds are raised planting areas, generally with carefully enriched soil, so they can be planted intensively. While they require more initial time to prepare, they save time on weeding or mulching later in the season. Because they're more space-efficient, you'll also get higher yields per area than from a traditional row garden.

Beds for vegetables should be no more than 4 feet wide so you can easily reach the center of the bed to plant, weed, and harvest.

Spot Gardens: If your yard is small, with no suitable space for a separate vegetable garden, look for sunny spots where you can fit small plantings of your favorite crops. Plant a small bed of salad greens and herbs near your kitchen door for easy access when preparing meals. Tuck vegetables into flower beds. You can dress up crops that aren't ornamental, such as tomatoes, by underplanting them with annuals such as nasturtiums and marigolds.

Containers: You may not be able to grow all your favorite vegetables in containers, but many dwarf cultivars of vegetables grow well in pots or planters. Garden catalogs include dwarf tomato, cucumber, pepper, and even squash cultivars suitable for container growing. Vegetables that are naturally small, such as loose-head lettuce, scallions, and many herbs, such as basil, also grow nicely in containers.

CROP CHOICES

Generally, vegetables can be divided into cool-weather, warm-weather, and hot-weather crops.

Consider the length of your growing season (the period of time between the last frost in spring and the first one in fall), seasonal rainfall patterns, and other environmental factors when choosing vegetables. There are many new fast-maturing and heat- or cold-tolerant cultivars that make it easier for northern gardeners to grow hot-weather crops such as melons and for Southern gardeners to be able to enjoy cool-loving crops such as spinach.

Have some fun when you choose plants for your vegetable garden as well. Make some of your selections for beauty as well as flavor. Beans with purple or variegated pods are easy to spot for picking and lovely to behold, for example. Look through catalogs and try some of the heirloom or other unusual cultivars they offer.

GARDEN MAPPING

As you fill out seed order forms, it's wise to map planned locations for your crops. Otherwise, you may end up with far too little or too much seed. Depending on the size of your garden, you may need to make a formal plan drawn to scale.

Consider these points as you figure out your planting needs and fill in your map:

- Are you growing just enough of a crop for fresh eating, or will you be preserving some of your harvest? For some crops, it takes surprisingly little seed to produce enough to feed a family. You can refer to seed catalogs or check individual vegetable entries for information on how much to plant.

- Are you planning to rotate crops? Changing the position of plants in different crop families from year to year can help reduce any pest problems.
- Are you going to plant crops in spring and again later in the season for a fall harvest? Order seed for both plantings at the same time.

Preparing the Soil

Since most vegetables are fast-growing annuals, they need garden soil that provides a wide range of plant nutrients and loose soil that plant roots can penetrate easily. In an organic vegetable garden, soil with high organic-matter content and biological activity is paramount in importance. Every year when you harvest vegetables, you're carting off part of the reservoir of nutrients that was in your vegetable garden soil. To keep the soil in balance, you need to replace those nutrients. Look for every opportunity to incorporate different forms of organic matter into your soil.

ASSESSING YOUR SOIL

If you're starting a new vegetable garden or switching from conventional to organic methods (or if you've just been disappointed with past yields or crop quality), start by testing your soil. Soil acidity or alkalinity, which is measured as soil pH, can affect plant performance. Most vegetables prefer soil with a pH of 6.5 to 7.0. Overall soil fertility also will influence yield, especially for heavy-feeding crops such as broccoli and tomatoes. A soil test will reveal soil pH as well as any nutrient imbalances.

CREATING NEW GARDENS

If you're just starting out, you'll probably be tilling under sod, or possibly bare ground, to start your garden. Using a rotary tiller may be the only practical way to work up the soil in a large garden. But whether you're working with a machine or digging by hand, use care. Don't work the soil when it's too wet or too dry; that would have detrimental effects on soil structure and quality.

If you're ambitious, a great way to start a vegetable garden is by double digging the soil. This process thoroughly loosens the soil so that it will retain more water and air, have better drainage, and be easier for roots to penetrate.

Depending on the results of your soil tests, you may need to work in lime to correct pH, or rock fertilizers to correct deficiencies, as you dig your garden. In any case, it's always wise to incorporate organic matter as you work.

ENRICHING THE SOIL

If you're an experienced gardener with an established garden site, you can take steps to replenish soil nutrients and organic matter as soon as you harvest and clear out your garden in the fall. Sow seed of a green manure crop in your garden, or cover the soil with a thick layer of organic mulch. Both green manures and mulches protect the soil from erosion and improve organic matter content. In the spring, you'll be ready to push back or incorporate the mulch or green manure and start planting.

If you don't plant a green manure crop, spread compost or well-rotted manure over your garden in spring and work it into the soil. You can add as much as a 6-inch layer of organic material, if you're fortunate enough to have that much on hand. The best time to do this is a few weeks before planting, if your soil is dry enough to be worked. You can cultivate with a rotary tiller or by hand, using a turning fork and rake. Never cultivate extremely wet soil, or you will be compacting it instead of aerating it. Be conservative when you work the soil. While some cultivation is necessary to prepare seedbeds and to open up the soil for root growth, excess cultivation is harmful. It introduces large amounts of oxygen into the soil, which can speed the breakdown of soil organic matter. And if soil is too wet or too dry, cultivating it can ruin soil structure.

Other opportunities for improving your soil will crop up at planting time, when you add compost or other growth boosters in planting rows or holes, and during the growing season, as you mulch your developing plants.

Planting Your Crops

Planting season can be the busiest time of year for the vegetable gardener. Some careful planning is in order. To help you remember what you have planted and how well cultivars perform in your garden, keep written records. Fill in planting dates on your garden map as the season progresses. Later, make notes of harvest dates. If you would like to keep more detailed records, try keeping a garden journal, or set up a vegetable garden data file on index cards. With good records, you can discover many details about the unique climate in your garden, such as when soil warms up in spring, when problem insects emerge, and when space becomes available for replanting.

GETTING SET TO PLANT

Once the soil is prepared, lay out your garden paths. Then rake loose soil from the pathways into the raised rows or beds. As soon as possible, mulch the pathways with leaves, straw, or another biodegradable mulch. Lay mulch thickly to keep down weeds. If you live in a region that has frequent, heavy rain, place boards down the pathways so you'll have a dry place to walk.

You can prepare planting beds and rows as much as several weeks before planting. However, if you plan to leave more than three weeks between preparation and planting, mulch the soil so it won't crust over or compact.

Plant Arrangement: There are practically no limits to the ways you can arrange plants in a vegetable garden. In a traditional row garden, you'll probably plant crops such as tomatoes and summer squash in single rows of single species. If you have raised rows or raised beds, you can interplant—mix different

Continued →

types of crops in one area—and use a variety of spacing patterns to maximize the number of plants in a given area.

Planting Combinations: Frequently you can practice succession cropping—growing two vegetable crops in the same space in the same growing season. You'll plant one early crop, harvest it, and then plant a warm- or hot-season crop afterward. To avoid depleting the soil, make sure one crop is a nitrogen-fixing legume, and the other a light feeder. All vegetables used for succession cropping should mature quickly. For example, in a cool climate, plant garden peas in spring, and follow them with cucumber or summer squash. Or after harvesting your early crop of spinach, plant bush beans. In warm climates, try lettuce followed by field peas, or plant pole beans and then a late crop of turnips after the bean harvest.

SEEDS AND TRANSPLANTS

Some vegetable crops grow best when seeded directly in place. Other crops benefit from being coddled indoors during the seedling stage and then grow robustly after transplanting.

Direct-Seeding: You can plant many kinds of vegetable seeds directly into prepared soil. But even when you follow seed-spacing directions given on the seed packet, direct-seeded crops often germinate too well or not well enough. When germination is excellent, thin plants ruthlessly because crowded vegetable plants will not mature properly. When direct-seeding any vegetable, set some seeds aside so you can go back in two weeks and replant vacant spaces in the row or bed.

Soil temperature and moisture play important roles in germination of vegetable seeds. Very few vegetable seeds will sprout in cold soil. High soil temperatures also inhibit germination. Also, be sure to plant seeds at the recommended planting depth, and firm the soil with your fingers or a hand tool after planting to ensure good contact of seed and soil.

Starting Seeds Indoors: To get a head start on the growing season or escape poor outdoor germination conditions, many gardeners start seeds indoors. Tomatoes, peppers, eggplant, cabbage, broccoli, cauliflower, brussels sprouts, onions, and celery are almost always handled this way. Cold-climate gardeners might add lettuce and members of the squash family to this list.

Keep in mind that most vegetable seedlings need sun to grow well. A sunny windowsill is adequate for vegetable seedlings, but natural sun plus supplemental artificial light is best. Also remember that vegetables started indoors receive very little exposure to stress factors present outdoors, such as wind, fluctuating temperatures, and intense sunlight. One week before you plan to transplant, begin hardening off vegetable plants by exposing them to these natural elements. Move them to a protected place outdoors, or put them in a cold frame.

Some Like It Hot

Because vegetables differ so much in their preferred growing temperatures, planting the vegetable garden isn't a one-day job. Be prepared to spend several days over the course of early spring to early summer planting vegetable seeds and plants. You'll plant cool-weather crops a few weeks before the last spring frost. Set out warm-weather crops just after the last spring frost. Hot-weather crops cannot tolerate frost or cold soil. Unless you can protect them with a portable cold frame or row covers, plant them at least three weeks after the last spring frost. In warm climates, plant cool-weather crops again in early fall so that they grow during the fall and winter. Here is a guide to the temperature preferences of 30 common garden vegetables:

Cool	Warm	Hot
Beets	Cantaloupes	Eggplant
Broccoli	Carrots	Field peas
Cabbage	Chard	Lima beans
Cauliflower	Corn	Okra
Celery	Cucumbers	Peanuts
Garden peas	Peppers	Shell beans
Lettuce	Potatoes	Sweet potatoes
Onions	Pumpkins	
Radishes	Snap beans	Watermelons
Spinach	Squash	
Turnips	Tomatoes	

If temperatures are erratic or windy weather is expected, use cloches to protect tender seedlings from injury for two to three weeks after transplanting. Remove cloches when the plants begin to grow vigorously—a sign that soil temperature has reached a favorable range and roots have become established.

In late summer, sun and heat can sap moisture from the new transplants of your fall crops faster than the roots can replenish it. Protect seedlings and transplants with shade covers instead of cloches. You can cover plants with cardboard boxes or flowerpots on sunny days for one week after transplanting, or you can cover them with a tent made of muslin or some other light-colored cloth.

Care during the Season

After the rush of planting, there's a lull while most of your crops are growing, flowering, and setting fruit. But regular plant care is important if you want to reap a good harvest later in the season. Get in the habit of taking regular garden walks in order to thin crops, pull weeds, and check for signs of insect and disease problems.

WEEDING

Start weed control early and keep at it throughout the season. Remove all weeds within 1 foot of your plants, or they will compete with the vegetables for water and nutrients. If you use a hoe or hand cultivator, be careful not to injure crop roots.

Some vegetables benefit from extra soil hilled up around the base of the plant. When hoeing around young corn, potatoes, tomatoes, and squash, scatter loose soil from between rows over the root zones of the plants. Once the garden soil has warmed (in late spring or early summer), mulch around your plants to suppress weeds and cut down on moisture loss. If you have areas where weeds have been a problem in the past, use a double mulch of newspapers covered with organic material such as leaves, straw, grass clippings, or shredded bark.

Another solution to weed problems is to cover beds with a sheet of black plastic. The plastic can help warm up cold soil, and it is a very effective barrier to weeds. If you do use black plastic, buy the thickest sheets you can find, and use them over and over again. Don't leave the plastic in place in the garden any longer than necessary, since exposure to sunlight will quickly degrade it. As soon as you remove the crop, rinse off and store plastic sheeting in a cool place.

WATERING

In the vegetable garden, some supplemental water is invariably needed, especially from midsummer to early fall. Most vegetables need ½ to 1 inch of water each week, and nature rarely provides water in such regular amounts. Dry weather can strengthen some vegetable plants by forcing them to develop deep roots that can seek out moisture. However, the quality of other crops suffers when plants get too little water. Tomatoes and melons need plenty of water early in the season when they're initiating foliage and fruit. However, as the fruit ripens, its quality often improves if dry conditions prevail. The opposite is true of lettuce, cabbage, and other leafy greens, which need more water as they approach maturity.

When to Water: How can you tell when your crops really need supplemental water? Leaves that droop at midday are a warning sign. If leaves wilt in midday and still look wilted the following morning, the plants are suffering. Provide water before soil becomes this dry.

If you don't water in time and the soil dries out completely, replenish soil moisture gradually, over a period of three days. If you soak dry soil quickly, your drought-stressed crops will suddenly take up large amounts of water. The abrupt change may cause tomatoes, melons, carrots, cabbage, and other vegetables to literally split their sides, ruining your crop.

Watering Methods: Watering by hand, using a spray nozzle on the end of a hose, is practical in a small garden but can be time-consuming in a large one. Sprinklers are easier to use but aren't water efficient. Some of the water from a sprinkler may fall on areas that don't need watering; and on a sunny day, some water evaporates and never reaches your plants' roots. Using sprinklers can saturate foliage, leading to conditions that favor some diseases, especially in humid climates. The one situation in which watering with a sprinkler may be the best option is when you have newly seeded beds, which need to be kept moist gently and evenly.

In terms of both water usage and economy of labor, the best way to water a vegetable garden is to use a drip irrigation system. You can buy several different types, including versatile systems that "weep" water into soil via porous tubing or pipes. These systems are most efficient when you install them between soil and mulch and use them at low pressure. Water seeps slowly into the soil, and there is very little surface evaporation.

Many gardeners make their own lines by punching holes into short lengths of garden hose or plastic pipe. You can also drip water to your vegetables by punching small holes in the bottoms of plastic milk jugs, filling the jugs with water, and placing them over the roots of thirsty plants.

Irrigation pipes do not take the place of a handy garden hose—you need both. Buy a two-headed splitter at the hardware store, and screw it onto the faucet you use for the vegetable garden. Keep the irrigation system connected to one side, leaving the other available for hand-watering or other uses.

STAKING

Many vegetables need stakes or trellises to keep them off the ground. Without support, the leaves and fruits of garden peas, tomatoes, pole beans, and some cucumbers and peppers easily become diseased. Also, many of these crops are easier to harvest when they're supported because the fruits are more accessible. You'll find many handy tips for staking and supporting crops in the individual vegetable entries later in this chapter.

FERTILIZING

Keeping your soil naturally balanced with a good organic-matter content will go a long way toward meeting the nutrient needs of your crops. Crops that mature quickly (in less than 50 days) seldom need supplemental fertilizer when growing in a healthy soil, especially if they're mulched. But vegetables that mature slowly (over an extended period) often benefit from a booster feeding in midsummer.

Plan to fertilize tomatoes, peppers, and corn just as they reach their reproductive stage of growth. Sprinkle cottonseed meal or a blended organic fertilizer beneath the plants just before a rain. Or rake back the mulch, spread a ½-inch layer of compost or rotted manure over the soil, and then put the mulch back in place. When growing plants in containers, feed them a liquid fertilizer such as manure tea every two or three weeks throughout the season. You can also use manure tea to feed vegetables grown in the ground.

Foliar fertilizing—spraying liquid fertilizer on plant leaves—is another option for mid-season fertilization. Kelp-based foliar

Continued ➔

fertilizers contain nutrients, enzymes, and acids that tend to enhance vegetables' efforts at reproduction. They're most effective when plants are already getting a good supply of nutrients through their roots. Use foliar fertilizers as a mid-season tonic for tomatoes, pole beans, and other vegetables that produce over a long period.

POLLINATION

You'll harvest leafy greens, carrots, and members of the cabbage family long before they flower. But with most other vegetables, the harvest is a fruit—the end result of pollinated blossoms. A spell of unusually hot weather can cause flowers or pollen grains to develop improperly. Conversely, a long, wet, cloudy spell can stop insects from pollinating. Either condition can leave you with few tomatoes, melons, or peppers, or with ears of corn with sparse, widely spaced kernels. The blossom ends of cucumbers and summer squash become wrinkled and misshapen when pollination is inadequate.

To prevent such problems, place like vegetables together so the plants can share the pollen they produce. Two exceptions here are hot and sweet peppers, and super-sweet and regular hybrid corn: Separate these by at least 25 feet to limit the amount of cross-pollination that takes place, or your harvest may not be true to type.

Tomatoes, corn, and beans are pollinated primarily by wind, though honeybees and other insects provide a little help transporting pollen about the plants. The presence of pollinating insects is crucial for squash, cucumbers, and melons. Plant flowers near these crops to lure bees in the right direction. You'll find more suggestions for helping with pollination in the individual vegetable entries later in this chapter.

PEST AND DISEASE MANAGEMENT

Pests and diseases of vegetable crops include insects, fungi, bacteria, and viruses, as well as larger animals such as raccoons and deer. Fortunately for organic gardeners, there are ever-increasing numbers of vegetable cultivars that are genetically resistant to insects and diseases. If you know that a pest or disease has been a problem in your garden, seek out and plant a resistant cultivar whenever possible.

Prevention can go a long way toward solving insect and disease problems in the vegetable garden. An important part of your continuing care for your garden is to practice the principles of organic pest management. It's important to realize that a weed-free or insect-free environment is not a natural one. If your garden is a diverse miniature world, with vigorous plants nourished by a well-balanced soil and an active population of native beneficial insects and microorganisms, you'll likely experience few serious pest problems.

Animal Pests Rabbits, woodchucks, deer, and other animals can wreak havoc in a vegetable garden. A sturdy fence is often the best solution.

Diseases Vegetable crop diseases are less threatening in home gardens than they are in farm fields, where crops are grown in monoculture. When many different plants are present, diseases that require specific host plants have a hard time gaining a firm foothold. Plus, a healthy, naturally balanced soil contains many beneficial microorganisms capable of controlling those that are likely to cause trouble.

Two of the best techniques for combating disease problems in the vegetable garden are rotating crops and solarizing the soil. Rotate crops by planting them in different places in the garden from one year to the next. When you plant the same vegetable continually in the same spot, disease organisms that feed on that plant flourish. When crops change from year to year, the disease organisms don't have a host plant and will not build up large populations. "Rotating Vegetable Families" presents many helpful suggestions for planning crop rotation in your garden.

Where diseases, weeds, soil-dwelling insects, or root knot nematodes seriously interfere with plant health, you can often get good control by subjecting the soil to extreme temperatures. Leave the soil openly exposed for a few weeks in the middle of winter. In the hottest part of summer, solarization can kill most weed seeds, insects, and disease organisms present in the top 4 inches of soil.

Harvest and Storage

As a general rule, harvest your vegetables early and often. Many common vegetables, such as broccoli, garden peas, lettuce, and corn, are harvested when they are at a specific and short-lived state of immaturity. Also be prompt when harvesting crops that mature fully on the plant, such as tomatoes, peppers, melons, and shell beans. Vegetable plants tend to decline after they have produced viable seeds. Prompt harvesting prolongs the productive lifespan of many vegetables.

Use "Days to Maturity" listed on seed packets as a general guide to estimate when vegetables will be ready to pick. Bear in mind that climatic factors such as temperature and day length can radically alter how long it takes for vegetables to mature. Vegetables planted in spring, when days are becoming progressively longer and warmer, may mature faster than expected. Those grown in the waning days of autumn may mature two to three weeks behind schedule.

In summer, harvest vegetables mid-morning, after the dew has dried but before the heat of midday. Wait for a mild, cloudy day to dig your potatoes, carrots, and other root crops so they won't be exposed to the sun. To make sure your homegrown vegetables are as nutritious as they can be, harvest and eat them on the same day whenever possible.

Refrigerate vegetables that have a high water content as soon as you pick them. These include leafy greens, all members of the cabbage family, cucumbers, celery, beets, carrots, snap beans, and corn. An exception is tomatoes—they ripen best at room temperature.

Rotating Vegetable Families

Susceptibility to pests and diseases runs in plant families. Leave at least two, and preferably three or more, years between the times you plant members of the same crop family in an area of your garden. When planning your rotations, keep in mind that some crops are heavy feeders, taking up large amounts of nutrients as they grow, while others are light feeders. Balance plantings of heavy feeders with soil-restoring legumes or green manure crops. Here are the seven family groups most often planted in vegetable gardens, plus ideas for rotating them.

Family Name	Common Crops	Rotation Relations
Cruciferae	Broccoli, brussels sprouts, cabbage, cauliflower, kale, radishes, turnips	High level of soil maintenance required for good root health. Heavy feeders. Precede with legumes; follow with open cultivation and compost.
Cucurbitaceae	Cucumbers, melons, squash, pumpkins, watermelons	For improved weed and insect control, precede with winter rye or wheat. Follow with legumes.
Gramineae	Wheat, oats, rye, corn	Plant before tomato- or squash-family crops to control weeds and to improve soil's ability to handle water.
Leguminosae	Beans, peas, clovers, vetches	Beneficial to soil and have few pest problems. Rotate alternately with all other garden crops whenever possible.
Liliaceae	Onions, garlic	Rotate with legumes, but avoid planting in soil that contains undecomposed organic matter.
Solanaceae	Eggplant, peppers, potatoes, tomatoes	Heavy feeders with many fungal enemies. Precede with cereal grain or grass; follow with legumes.
Umbelliferae	Carrots, parsley, dill, fennel, coriander	Moderate feeders. Precede with any other plant family, but condition soil with compost before planting. Follow with legumes or heavy mulch.

Some vegetables, notably potatoes, bulb onions, winter squash, peanuts, and sweet potatoes, require a curing period to enhance their keeping qualities. See the individual entries on these vegetables later in this chapter for information on the best curing and storage conditions.

Bumper crops of all vegetables may be canned, dried, or frozen for future use. Use only your best vegetables for long-term storage, and choose a storage method appropriate for your climate. For example, you can pull cherry tomato plants and hang them upside down until the fruits dry in arid climates, but not in humid climates. In cold climates, you can mulch carrots heavily to prevent them from freezing and dig them during the winter. In warm climates, carrots left in the ground will be subject to prolonged insect damage.

Off-Season

After you harvest a crop in your vegetable garden, either turn under or pull up the remaining plant debris. Many garden pests overwinter in the skeletons of vegetable plants. If you suspect that plant remains harbor insect pests or disease organisms, put them in sealed containers for disposal with your trash, or compost them in a hot (at least 160°F) compost pile.

As garden space becomes vacant in late summer and fall, cultivate empty spaces and allow birds to gather grubs and other larvae hidden in the soil. If several weeks will pass before the first hard freeze is expected, consider planting a green manure crop such as crimson clover, rye, or annual ryegrass.

Another rite of fall is collecting leaves, which can be used as a winter mulch over garden soil or as the basis for a large winter compost heap. As you collect the leaves, shred and wet them thoroughly to promote leaching and rapid decomposition. You can also till shredded leaves directly into your garden soil.

The Vegetable Garden

Barbara W. Ellis

Designing a Companion-Planted Garden

Most of us have heard that marigolds help keep insects out of the vegetable garden or that nothing will grow near a black walnut tree. But while some of these claims seem to hold true, others do not. Just where do these horticultural maxims come from? Is there any truth to the notion that growing certain plants together can help or hinder their growth?

Vegetable Harvest and Storage

Your refrigerator is one of your best storage options. If you have two available, set one at a cold temperature (32° to 40°F) and the other at a cool temperature (45° to 50°F). In a refrigerator set for normal operation, the temperature in the center storage section is usually between 38° and 42°F. The temperature just below the freezing unit is lower—often 30° to 35°F. The bottom of the cabinet is somewhat warmer than the center. Check temperatures in different parts of your refrigerator.

Your basement is another possible storage place. Temperatures in most heated or air-conditioned basements will usually be 65°F or higher in summer and 60°F or lower in winter. Create partitions to vary the temperature and humidity. You can use outdoor air, dirt floors, or wet sacks to vary the temperature and humidity needs. Unheated basements, if well ventilated, can provide good storage conditions for some vegetables.

This listing gives you the facts on when and how to harvest your vegetables for maximum flavor and how to store them properly to maintain freshness and taste:

COLD, MOIST

(32° to 40°F, 90 to 95% relative humidity)

Asparagus: Harvest by snapping 10- to 12-inch spears off at ground level. Store in plastic bags in refrigerator for up to one week. Freeze or can any surplus.

Beans, lima: Harvest when pods have filled. For tender limas, harvest when a bit immature; for "meaty" limas, harvest when mature. Store shelled limas in perforated plastic bags in the refrigerator for about one week. Surplus limas can be canned or frozen.

Beets: Begin harvest when beet is 1 inch in diameter. Tender tops make excellent greens. Main harvest is when beets are 2 to 3 inches across. Harvest spring-planted beets before hot weather; fall beets, before the first light freeze. For storage, wash roots, trim tops to ½ inch, place in perforated plastic bags, and store in the refrigerator or cold, moist cellar for two to four months.

Broccoli: Harvest terminal head while florets are still tight and of good green color. Smaller side heads will develop. Store in perforated plastic bags for up to one week in the refrigerator. Freeze any surplus.

Cabbage: Harvest when heads are solid. Store cabbage in the refrigerator, cold cellar, or outdoor pit for up to two months.

Carrots: Harvest spring crops before hot weather; fall ones, before the first light freeze. For storage, wash roots, trim tops to ½ inch, and place in perforated plastic bags. Store in the refrigerator or cold, moist cellar for two to four months.

Cauliflower: Tie outer leaves above the head when curd diameter reaches 1 to 2 inches (except purple types). Heads will be ready for harvest in about two weeks. Cauliflower may be stored in perforated plastic bags in the refrigerator for up to two weeks. Freeze any surplus.

COOL, MOIST

(45° to 50°F, 80 to 90% relative humidity)

Beans, snap: Pods will be most tender when seeds inside are one-fourth normal size. They become fibrous as the beans mature. Store up to one week in perforated plastic bags in the warm part of refrigerator. Can or freeze surplus.

Cucumbers: Harvest cucumbers when they are about 1½ to 2½ inches in diameter and 5 to 8 inches long. Pickling cucumbers will be more blocky and not as long as slicers. Store slicing cucumbers up to one week in plastic bags in the warm part of the refrigerator. Cool pickling cucumbers quickly in ice water; keep up to two days in a plastic bag in the refrigerator.

Eggplant: Harvest when fruits are nearly full grown but color is still bright. Keep in warm part of the refrigerator for about one week.

Peppers, sweet: Harvest when fruits are firm and full-sized. For red fruits, leave fruits on the plant until ripe. Store in the warm part of refrigerator in plastic bags for two to three weeks.

Squash, summer: Harvest when fruits are young and tender. Skin should be easily penetrated with the thumbnail. Store for up to one week in perforated plastic bags in the refrigerator. Surplus can be frozen.

COOL, DRY

(45° to 55°F, 50 to 60% relative humidity)

Onions, dry: Harvest when the tops have fallen over and the necks have shriveled. Remove tops, place in shallow boxes or mesh bags, and cure in an open garage or barn for three to four weeks. Store in mesh bags in a cool place. Keep ventilated during humid, muggy weather.

Peppers, hot: Pull plants late in the season and hang to dry in the sun or a warm place. Store in a dry, cool place, such as a basement.

WARM, DRY

(55° to 60°F, 60 to 70% relative humidity)

Pumpkins; Squash, winter: Harvest when skin is hard and the colors darken. Harvest before frost. Cut the fruits from the vine with a portion of stem attached. Store spread out on shelves so air can circulate.

WARM, MOIST

(55° to 60°F, 80 to 85% relative humidity)

Tomatoes: Ripe tomatoes will keep for a week at 55° to 60°F. Harvest green, mature tomatoes before frost, and keep at 55° to 70°F; for faster ripening, keep at 65° to 70°F. Mature green fruits should approach normal size and have a whitish green skin color. Keep them three to five weeks by wrapping each tomato in newspaper. Inspect for ripeness each week.

COMPANION PLANTING AS A TRADITION

For centuries, gardeners and farmers have cultivated different crops together in the same space to maximize available resources. American Indians, for example, used a corn-bean-squash interplanting scheme that balanced the requirements of each crop for light, water, and nutrients. The practice of companion planting, growing two or more crops simultaneously in a given area to achieve a specific benefit, is still common among subsistence farmers and organic gardeners in many parts of the world today. On large-scale, mechanized farms, however, single-crop cultivation has been the norm for several decades.

In recent years, as the limitations and ill effects of pesticides, chemical fertilizers, and other modern practices have become more apparent, scientists have begun looking more seriously at companion planting and other "old-fashioned" methods once considered inefficient. Small-scale farmers and backyard gardeners who have kept the interplanting tradition alive now serve as a valuable source of information on the complex interactions of crops with each other and with the surrounding environment.

Yet even those who practice companion planting do not know why some interplanting methods seem to work while others don't. Only careful research, combined with the experience and intuition of practitioners, will reveal which plant combinations are most beneficial and why. In the meantime, gardeners are in a unique position to take advantage of what is already known and to try out new combinations in their own plots at home.

Benefits of Companion Planting

Not all crops respond to companion planting in the same way. In fact, some do worse when combined with other crops than if they are grown by themselves. In many cases, however, the positive effects of interplanting are striking.

Some crops, for example, show increased yields when combined with other plants. Studies suggest that different crops planted together may take better advantage of sunlight than those grown separately. Think of cool season crops such as lettuce or spinach. The intense light (and heat) of midsummer sun may damage their leaves. Planting in the filtered shade of a row of tomatoes can allow these plants to receive enough light for good growth, while preventing heat injury.

Scientists have also theorized that interplanted crops make better use of soil nutrients and water than do crops cultivated apart from others. Corn interplanted with soybeans may stimulate the beans, a legume, to fix more nitrogen in the soil. Whatever the reason, you can reap a greater harvest from many of your vegetables if you are willing to spend the extra time to learn about and practice companion planting.

By interplanting certain crops, you can also improve the quality of your soil. Many plants supply nutrients to the soil that are beneficial to crops nearby. In addition, some plants with thick roots work the soil, improving tilth and drainage.

Companion planting is particularly useful in keeping pest and disease problems under control. If you grow only one crop at a time, you are likely to attract only a small variety of insects or diseases, but these may be great in number and can wreak considerable havoc in your garden. On the other hand, if you plant two or more crops together, you may have a large variety of pests, but there will be few of each in number. In the first instance, you are creating a less stable environment where one disease or insect population can easily take over all the rest; in the latter case, the diversity of plants allows for a more stable environment in which the various pests keep each other in check.

You can also include certain plants in your interplanting scheme that will repel insects and thus prevent pest damage to other crops in the vicinity. Companion plants can even be used to attract beneficial insects to the garden.

DESIGNING A COMPANION GARDEN

Selecting the right arrangements or combinations of plants for the companion garden can be tricky. You must aim for a balance between the benefits of mixing crops and the possible competition between those crops for space, sunlight, nutrients, and water. Lettuce interplanted with kidney beans may benefit from shading by the bean plants; this advantage will have little

Continued →

value if the beans compete too strongly with the lettuce for available water and nutrients, however.

Companion planting of reputedly repellent or attractant plants also requires careful investigation. Research has shown that some plants traditionally relied upon to repel pests may have other, harmful effects on companion crops or may actually attract some harmful insects. Some species of marigolds have been shown to repel harmful nematodes but may cause stunting of some vegetable crops. Tansy is an herb which may repel some insects but has been shown in some studies to attract other pests.

Every garden is different, too; what works in one may not work in another. Soil, available light, and many other factors will affect the outcome of any given planting. Even your own goals as a gardener probably differ from those of your neighbor. For example, what you consider a "high yield" may be a "moderate harvest" to others.

Nevertheless, certain companion planting arrangements that have worked for many gardeners are worth trying. Even if you do not see spectacularly increased yields or reduced pest damage, you will have gained a better awareness of how plants interact with one another and their environment. Gradually, as you gain more experience with your own particular growing conditions, you may want to experiment with new companion planting schemes.

Fencing the Garden

How many times have you carefully planted a vegetable garden, only to have the fruits of your efforts devoured by the wildlife sharing your property? While plant lovers are typically wildlife aficionados as well, the different objects of our admiration are often incompatible, especially when it comes to hungry animals and edible plants. The only solution—barring exterminating the animals, an unacceptable and generally impossible option for most of us—is to provide barriers to keep flora and fauna apart.

There are many types of fencing from which to choose. What you end up erecting will depend on the culprits doing the damage and the amount of time and money you want to spend on the project. Whatever design you select, remember that you should put up fencing before the animals have begun rummaging in your garden; if they have already munched on your lettuce, they are likely to try to return for another meal.

CHICKEN WIRE FENCES

One of the best ways to ward off midsized animals, including groundhogs and rabbits, is to erect a 3-foot-high chicken wire fence around your garden. By digging a trench and lining it with wire mesh before you set the posts, you will keep most if not all, of the burrowing types from entering your plot. Try spacing the posts far enough apart so that the fence is a bit floppy; animals are less likely to scale a floppy fence this size than a tight one.

Chicken wire fences are also suitable for keeping deer out of your garden. However, since this type of fencing must be 8 to 12 feet tall to be effective, it can be both expensive and difficult to erect as well as to maintain. A high chicken wire fence is often topped with strands of barbed wire to extend its height, but this tends to be aesthetically unappealing.

DOUBLE FENCES FOR DEER

One relatively simple and inexpensive solution to the deer problem is to erect two 3-foot-high fences made of three strings each and spaced 3 feet apart. Apparently, deer are reluctant to jump over a low fence if another fence is visible just on the other side.

If you decide to use this design, be sure to select string that is easily seen by the animals. You may want to add height to the fences in wintertime.

Another low-profile barrier that is surprisingly effective in keeping deer away is the double mesh fence. For this design, try stringing 4-foot-high, 12½-gauge mesh fencing between metal stakes spaced 5 feet apart. Allow 5 feet between the outer and inner fences. Keep the area between the two fences bare if you want to watch for other, smaller intruders such as rabbits.

ELECTRIC FENCING

Electric fences are often the last resort for gardeners, yet many people swear by their effectiveness, especially in areas where wildlife has done extensive damage. The main thing to remember is that this kind of fencing must be treated with respect. If there are children in the area, be sure to spend time explaining to them exactly why the fence is dangerous and where they are permitted to play. (Of course, if the children are very young, you may want to consider another kind of fencing.) A properly designed electric fence will surprise anyone or anything that touches it, not hurt them. In fact, the barrier is more psychological than real. It gives a strong buzzing feeling that makes animals back off when they've touched it once or twice, and they'll avoid it afterwards, often even if the current is turned off. Since you have to be in contact with the ground to receive a shock, birds can safely sit on the wire.

A single strand of electric wire strung at a distance of 1 foot outside your garden's chicken wire fence will give additional protection against small animals climbing over or burrowing under the wire fence. If deer are the main nuisance in your area, try stringing the electric wire 3 feet off the ground at a distance of 3 feet from your chicken wire fence. This fence works on the same principle as the double mesh fence and will be most effective if the chicken wire fence is at least 4 feet high.

Plants and debris that collect against the wire can drain the fence's power, so you will need to keep the area around it clean. You should also check the fence's charge periodically with a voltage tester.

Making a Scarecrow

Scarecrows have been scaring birds away—or in some cases, amusing them—for as long as man has cultivated crops. Some say these whimsical stuffed figures were first used by tribes in central or northern Europe; others claim that pre-Columbian Indians were ahead of the Europeans. Whatever its origin, the scarecrow is a common fixture in gardens and farms across the world today.

Why Build a Scarecrow?

Scarecrows are fun; no one will argue with that. With just a little straw, wood, and some old clothes, it's amazing what creative designs some gardeners come up with. Not only are they an outlet for our creativity, they're also an excellent way to involve children in the garden. Young would-be gardeners who balk at the idea of "helping" in the family vegetable plot are easily enticed by a scarecrow-making project.

Yet scarecrows serve a serious purpose, too. Each year, birds destroy millions of dollars' worth of crops including wheat, corn, sunflowers, and various kinds of fruit. Individual farmers have experienced losses of up to 75 percent or more due to the voracious appetite of birds. For the backyard gardener, too, birds pose a threat to tender young plants. Crows, blackbirds, blue jays, and many other winged creatures have been known to swoop down and snatch seedlings from the ground or to peck holes in newly ripened fruit. Thanks to scarecrows, farmers and gardeners have at least a fighting chance to save their crops from being destroyed by birds.

How Scarecrows Work

It is a common joke that scarecrows attract more birds than they frighten. Indeed, it is not unusual to see a scarecrow with at least one or two birds perched on its shoulders at any given time. If properly designed and utilized, however, these human effigies can be fairly effective in protecting your vegetable garden.

The idea behind scarecrows is simple: Put up a figure that resembles a human being (one of the birds' predators), and the birds will stay away. But there's a catch: Sooner or later, birds wise up and realize that your creative masterpiece will not harm them; in fact, it takes some birds less than a week to figure things out. So you must try to be as ingenious as possible in the short time you have to scare them away. For example, by hanging aluminum pie plates or other shiny objects from your scarecrow's arms, you may be able to buy yourself and your plants a few days' time. Noisemakers, including pie plates banging together in the breeze, can also help to ward birds off a little longer.

The timing of your scarecrow's debut is important, too. You may want to bring your straw man out as soon as your seeds begin to germinate. Or if the birds in your area seem to go more for the ripe tomatoes or cantaloupes than for the seedlings, try putting it up in your garden just as the fruit begins to mature. The key is to use the novelty of your scarecrow's presence for all it's worth.

How to Make a Scarecrow

To build a scarecrow from scratch, you need only a few materials and a willingness to use your imagination.

1. Select two 2 x 4 stakes measuring about 4 to 5 feet long to serve as the legs. Sharpen the ends so that they can be driven into the ground easily.
2. Find an old pair of pants and put them on over the stakes.
3. Put the stakes into the ground at an angle so that they join at the top.
4. For the backbone, take a 2 x 4 measuring about 3 feet long and nail it to the top of the legs.
5. To make the arms, take a 2 x 4 measuring about 4 feet long and nail it perpendicular to the backbone, above the legs.
6. Stuff the pants with straw, then slip a shirt on over the shoulders and fill it with straw.
7. Fill an old pillowcase with straw to make the head, and tie the pillowcase opening closed around the top of the backbone.
8. For the hands, stuff some gloves with straw, then fasten them on the ends of the arms.
9. Draw a face and add any embellishments you like, such as hair, a hat, or a pipe.

Companion Planting Options

Here are some companion plantings you may want to try, with information on the type of interaction between the crops and whether the pairing has been confirmed by research studies or is simply part of companion planting tradition or folklore.

Sample Combinations	Relationship	Folklore or Fact?	Tips/Comments
For Interplanting in Neighboring Rows			
Tomatoes with cabbage	Tomatoes repel diamondback moths and flea beetles. Impoved flavor and growth.	Shown in research studies. Folklore	Tomatoes will shade transplants for fall crop from summer heat and sun.
Corn with snap beans or soybeans	Beans enhance growth of corn, possibly due to capability to fix nitrogen.	Research backs this claim in certain specific planting arrangements.	Alternate double rows of corn with double bean rows to ensure good corn pollination.
Peanuts with corn or squash	Intercropping increases yields of both crops.	Shown in research studies.	Leave plenty of space at planting for heavy vegetative growth of peanuts.
Peas with spinach, lettuce, or Chinese cabbage	Peas provide shading and wind protection for young transplants.	Traditional practice	Vining peas must be started early and trained on fence or trellis to provide good protection.
Asparagus with tomatoes, parsley, or basil	Companions help control asparagus beetles.	Folklore.	Allow 5 ft. between rows when interplanting tomatoes to avoid crowding.
For Interplanting within a Row			
Radish, onions, or beets with lettuce, beans, cabbage, or tomatoes	Various beneficial interactions including: Lettuce makes radishes tender; onions help deter weeds and repel some insects.	Mostly folklore.	Fast-growing crops can be grown around slower-growing crops. Harvest before competition between crops has detrimental effect.
Lettuce or spinach with winter squash or cucumbers	Makes better use of space and soil materials.	Traditional practice.	Lettuce and spinach are harvested before vine crops spread over bed.
Cabbage with garlic	Garlic reputedly repels many harmful insects and helps prevent disease.	Folklore; some research shows garlic contains bactericidal and fungicidal substances.	Garlic has a cold requirement for bulbing. Try as a fall planting; allow garlic to overwinter.
Corn with beans, cucumbers, melons, or squash	Makes best use of light and bed space.	Traditional practice; some research shows beans promote corn growth.	Border rows of corn with vine crops; plant beans and corn in alternating hills; 3-4 plants per hill.
Other Arrangements			
Lettuce, cabbage, bush beans, basil, seed onions, tomatoes, beets in 1-ft.-square blocks	Various beneficial interactions, good for seed-starting beds.	Mostly folklore; research shows pest repellent properties for some crops.	Block planting is best for compact, low-growing plants.
Radishes planted in a circle around a hill of bush squash or cucumbers	Radishes repel vine borers and cucumber beetles.	Folklore.	Circle planting is a way to surround crops with repellent plants.
Strips of clover or alfalfa between corn rows	Helps control weeds and conserve moisture.	Traditional practice.	Sod strips may require periodic mowing. Strip plantings of tall crops with tender low-growing plants can reduce wind damage.

Vegetables the Low-Maintenance Way

Barbara W. Ellis, Joan Benjamin, and Deborah L. Martin

If you do just a little planning before you plant and take the right steps to improve your soil, you'll find that vegetable gardening can take a lot less time and labor than you ever dreamed. This section shows you how to design food gardens for easiest care and maximum harvests.

Set Your "Sites" for Success

Before you prepare a new vegetable garden, use your head. Vegetable gardens are easiest to maintain when they have no strikes against them, like deep shade or rocky soil. Here's a checklist of what you need for success. If your site doesn't match up, choose one of the options listed for making it right.

- **At least six hours of full sunlight.** What if you don't have enough sun? Consider growing vegetables in containers on the driveway or deck where the increased warmth will boost

growth. Otherwise, share a sunny site in a friend's yard. Vegetables simply won't be successful in the shade.

- **Good drainage.** If your only sunny site is soggy, building raised beds will pay off big in the long run. They require some work to loosen the soil and heap it up, but once done, you'll have perfect drainage forevermore. Another choice is to build a framed raised bed using lumber or concrete blocks and fill it with good soil.
- **Convenient access to the hose, house, and compost pile.** Think how many steps you'll save if your vegetable garden is close to your house, and your water source and compost supply are near your vegetables. It's nice to have a dry place to store tools near the garden, as well. If there is no outdoor building handy to the garden, a plastic trash can with a lid makes a quick storage bin for the essentials.
- **Limited competition from large trees.** Trees compete with your vegetables for essential water and nutrients, so locate your garden as far as possible from hungry, thirsty tree roots. If you have only a few sunny spots and tree roots are nearby, try planting in containers or framed raised beds to keep your vegetables above the competition.
- **Protection from marauding pets and children.** You can use fences, hedges, and even plantings of large perennials like ornamental grasses to channel children and pets away from vegetables. Or keep plants out of harm's way with raised beds.

Design Convenience into Your Garden

You can plant your garden without planning, but you'll pay for it with added effort when it's time to improve the soil, pick produce, water, or fight weeds. You don't need an elaborate plan to save labor. This garden features a variety of ideas that will make your vegetable gardening easier and more enjoyable.

Save Work by Making Smart Plant Choices

It takes most of us firm resolve (or an avalanche of zucchini) to limit the number and variety of vegetables we plant. But remember, planting decisions frame your workload for the season ahead. Bite the bullet and take these suggestions to heart.

Grow what you enjoy eating. If no one likes broccoli, why bother with it? In other words, grow the crops that are satisfying for you and your family. You may decide to grow arugula or snap peas that you couldn't otherwise afford, for example. Maybe all you really want is fresh sweet corn or tomatoes. If that's the case, don't waste space on crops that end up in the compost pile.

Forget about crops that don't do well in your garden. If you live in the cool Pacific Northwest, heat-loving cantaloupes are a struggle, whereas salad greens and beets will flourish. Likewise, if the frost flattens your 'Big Boy' tomatoes every year in Vermont, maybe it's time to switch to small tomatoes that ripen faster. You'll get big flavor with a cultivar like 'Oregon Spring,' which matures in just 60 days.

Select gourmet vegetables that aren't locally available. Why grow the same tomatoes, lettuce, and snap beans you can buy at the nearest produce stand when you can grow more flavorful choices like 'Royal Burgundy' beans, 'Lolla Rosso' lettuce, or 'Tappy's Best' tomato? Many of the tastiest types aren't grown for market because they lose quality rapidly (like baby lettuce, snow peas, or squash blossoms) or simply aren't cost-effective to grow because people don't know about them. (Ever tried mizuna, fava beans, mâche (corn salad), or "Gilfeather" turnips?) Order some seed catalogs that specialize in gourmet vegetables and choose the plants that pique your palate.

Select cultivars adapted to your growing region. There are vegetable cultivars ideal for every growing region. Instead of buying seed from big seed houses that aim for the average growing climate, patronize regional seed companies. Many focus on continuing old cultivars proven in your area and they also search out and develop new strains.

Grow only as much as you will eat. Do you really need ten tomato plants? Using tomatoes as an example, two plants per person is plenty if fresh salads are the main use. All you need are five to six plants if you want to preserve enough for year-round eating.

Select cultivars that bear throughout the season. You can avoid having to deal with one big harvest—and more produce than your family can eat—if you choose vegetables that bear fruit over a long season. If the crops you like tend to ripen all at once, plant a mixture of early, mid-season, and late-maturing cultivars to spread out the harvest.

For example, try planting a mid-season corn cultivar like 'Honey 'N Pearl' (78 days) at the same time as a later-maturing cultivar like 'Silver Queen' (92 days) to avoid a corn glut. The same technique works great for tomatoes, too.

Grow what you will be home to enjoy. If you vacation the last two weeks of August, plan your crops around your trip. Plant your corn crop so it will peak before or after your trip, for example. Likewise, if you're going to be away or super-busy when peas need to be picked, skip the peas this season.

Be realistic about putting up the harvest. These days, many time-pressed gardeners are opting to "eat what's in season" instead of spending the time it takes to manage and can or freeze large harvests. You can save time and effort if you grow only as much fresh produce as your family can eat—and not enough to fill the freezer. Consider using the extra garden space for spinach, broccoli, collards, and other hardy crops that you can eat fresh well into winter. Fresh vegetables are always tastier and more nutritious than frozen or canned.

Tuck In Your Crops

Before you dig a new garden, look for ready-made planting areas. You just might find a few places where you can tuck in some lettuce or a packet of snap beans with no more effort than clearing a few weeds and adding some compost.

Continued →

You also may find spring vacancies in flower beds. Finding a place for a few "spot" gardens may allow you to grow all the salad greens, radishes, and snap beans your family can use without turning up new ground.

Make a Planting Plan That Saves Time

Before you turn a shovelful of soil in a new garden bed, take time to consider what features will make that bed easy to manage. You'll be living with your design for at least one season, so you'll certainly save enough time, energy, and aggravation to make the planning well worthwhile. Besides, you can do your planning in early spring or late fall when there aren't as many garden priorities.

Consider garden size. Keeping your garden small is the simplest way to keep it low maintenance. If you're a new gardener and don't know how much is too much, begin with an area no larger than 100 square feet. If you've been gardening a while, take a hard look at how much time you want to spend in your garden and which crops will give you the most return.

Picture your space before you dig. Rectangles and squares are the easiest bed shapes for most of us to work with. Preview your garden layout by using a garden hose to represent the perimeter of the garden. Then lay out some newspaper weighted with rocks to mark where the actual beds will be dug. What's left will be the pathways. Then stand back and look at the design and see if it looks workable. Imagine what you're going to plant where. Get out the wheelbarrow and any other garden equipment you use and see if you can reach each bed easily. Consider any hidden hazards, like the septic tank, electrical lines, or the kids' soccer field. Before you put the newspaper away, use stakes to mark the beds. It doesn't hurt to commit your plan to paper, too, before you lose any bright ideas about what you're going to plant where.

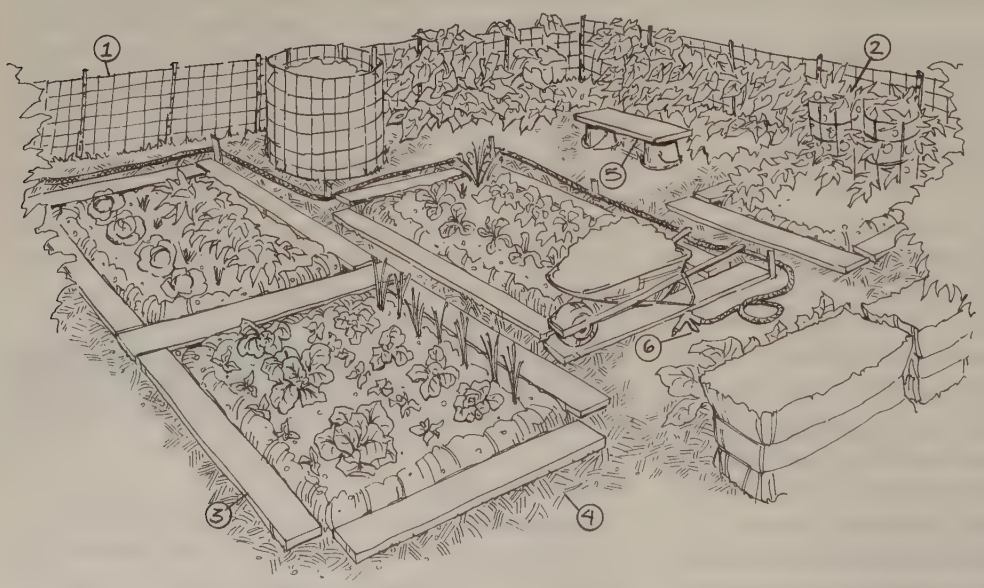
Take a look at garden length. Once you've prepared the soil in your beds, you'll have to walk around them to get from one side of the garden to the other. (Walking on the soil will compact it, destroying all your hard-earned soil improvement.) Beds 5 to 15 feet long work well in small gardens. You can increase the length up to 30 feet in larger gardens. If you're planning framed raised beds, plank "bridges" from one edge to the other make it easy to cross from side to side in a long garden.

Keep plants within reach. You should be able to reach the middle of planting areas without trampling the beds—4 feet is a comfortable stretch for most gardeners. If you've never planted in beds before, make some sample patches before you plant; experiment with 3 feet, 3½ feet, and 4 feet and see what feels best to you.

Leave room for you! Pathways between beds need to be at least 1½ feet wide to allow for foot traffic. They should be at least 3 feet wide if you intend to take a wheelbarrow into the garden with you. In a large garden, plan for a central crossroads at least 4 feet wide to accommodate the garden cart and to allow some leeway for hauling mulch, compost, and other supplies.

Should You Grow Row by Row?

Once you've selected the best site for your vegetable garden and the crops you want to grow, you'll need to decide whether to plant in rows or beds.



1. *Train vines to save space. One way to keep vines like cucumbers from wandering is to train them up a fence. Fruits hang down for easy picking.*
2. *Stake tomato cages. Insert a stake inside each tomato cage to hold it in place and keep it from toppling over under heavy fruit load.*
3. *Use wooden planks for easy access. Wooden planks in the pathways make it easier to maneuver wheelbarrows and other equipment around raised beds.*
4. *Mulch to pathways to control weeds. Use bark mulch to keep pathways clear of weeds all year long.*
5. *Plan to rest. Make sure you take frequent breaks to keep your back in working order. A bench made out of two buckets and a wooden plank makes an inexpensive seat.*
6. *Keep your hoses controlled. Buy hose guides, or make ones like the bamboo guides shown here, to keep unruly hoses from hurting plants.*

GARDENING IN ROWS

Gardens planted in narrow, parallel rows or strips with paths in between are easy to plan. The soil is usually turned over each spring to clear space for new crops; it's a simple matter if you have a tiller. Row gardens are well suited to large crops like corn, pole beans, tomatoes, and potatoes.

Multiple Plantings Mean Manageable Harvests

By planting crops over several weeks (a technique known as succession planting) rather than all at once, you'll get a steady supply of produce instead of a one-time onslaught. How much you pick at any one time depends, of course, on how much you plant each time. The idea is to get as much as you need for a week or two, plus a little extra if you plan to store any vegetables long-term. That way, you'll never be overwhelmed. Succession planting works best with crops that ripen all at once like lettuce and other salad greens, bush beans, and corn.

To plan on a continuous but not overwhelming harvest, spread out planting times throughout the season. For example, three beds of lettuce, each planted two weeks apart, will be ready for harvest about two weeks apart as well.

On the downside, row gardens require lots of space, and you have to spend time maintaining lots of walkways where you don't grow food. Row gardens generally have less drought resistance, and the large expanses of unplanted soil are an open invitation to weeds. Frequent cultivation also depletes soil organic matter, which increases the need for compost and fertilizer. Mechanical tillers also cause petroleum pollution.

GARDENING IN BEDS

Crops grown in beds are set out in wide areas or blocks not separated by rows. Paths between beds allow easy access to vegetables but minimize wasted space. That means you can grow more vegetables in a smaller area than with row gardens. Beds can be tilled each season—but once you're satisfied with the location and layout, it's easier and more economical to maintain them without tilling. Because plants are spaced close together and you're not maintaining wide walkways, bed gardens need less weeding and less watering. Beds are most suitable for smaller vegetables like greens, root crops, and cole crops.

On the downside, it takes more work to prepare beds the first season. They also may be harder to design at first if you're used to planting in rows, and they aren't well suited to mechanical cultivation.

PICK YOUR STYLE

In large gardens, a combination approach works well. Plant the big crops in rows and the smaller stuff, like salad greens, cole crops, and root crops, in beds. For small gardens, beds are the obvious choice since they maximize space. Not only will you harvest more food than if you planted in rows, but grouping vegetables in blocks conserves water and reduces weeding since the leaves shade the soil between plants.

Soil Preparation without Tears

Believe it or not, sweating and straining are optional activities when it comes to making new garden beds. Try the techniques that follow for easy ways to make gardens that produce trouble-free harvests year after year.

You'll find a range of options—from beds you never dig to ones that take some effort initially but are quite easy to maintain ever after. Choose the method that fits your site and lifestyle best.

NO-DIG GARDEN BEDS

Yes, you can grow great vegetables without ever turning over the soil! Here's how.

1. Mow the area with the mower blade set as low as it will go.
2. Spread a six-page-thick layer of newspaper over the spot and water it well.
3. Cover the newspaper with at least 2 inches of compost or good soil mix. Add some balanced organic fertilizer at the rate listed on the package.
4. Rake the bed smooth and sprinkle it with water until it is evenly moist. Wait a day or two and then plant, cutting through the newspaper if setting out transplants.

Believe it or not, this method works fine the first season for everything but long-rooted crops like carrots. Plus, there's no need to dig these beds every year. Just add 2 inches of compost on top and plant.

After three years you should be able to grow anything, and you can cut back the compost you add each spring to a maintenance amount of ⅛ to ¼ inch. If you'd rather, add the compost as a side-dressing around plants in the summer.

JUST-A-BIT-OF-DIGGING GARDEN BEDS

This method requires a large supply of compost-making materials and a half hour of shoveling per bed. The advantage is that you'll have terrific soil by the end of one season.

1. **Pile up organic matter.** Start by piling up organic matter as if you were making a compost pile. You're aiming for a pile about 4 feet wide and 2 feet high and as long as you want to make it. The combination of ingredients isn't critical, but an even mix of leafy green stuff and tougher materials like leaves and stalks is ideal. Shredded leaves are a real bonus.

Continued ➔

Sprinkle in a little soil on the pile to start the decomposition process, and moisten the ingredients with water. They should be as wet as a wrung-out sponge.

2. **Dig a path.** Once your pile is in place, dig a path about 2 inches deep and 2 feet wide all around it, pitching the soil over the pile. You want to end up with 2 to 4 inches of soil covering the pile.
3. **Add fertilizer.** Sprinkle on a thin layer (⅛ to ¼ inch is plenty) of finished compost. Or apply a balanced commercial organic fertilizer at the rate listed on the package.
4. **Rake it smooth.** Rake the bed smooth and then sprinkle it with water until it is evenly moist.
5. **Wait.** Sit tight for a week to allow the pile to settle a bit.
6. **Plant.** That's all there is to it!

This method has two special benefits. First, it provides bottom heat early in the season from all the decomposing organic matter, a real boost in cool climates. Second, all that organic matter decomposes into an excellent foundation for your garden bed.

Finding enough organic matter to make a 4 x 2-foot base isn't as overwhelming as it sounds. Just drive around the neighborhood during leaf-raking and lawn-cutting seasons and you can rescue tons of bagged leaves and grass clippings destined for the landfill. You may want to stock up on bed-making materials in the spring and fall, too, when supplies are abundant.

LOTS-OF-DIGGING GARDEN BEDS—BUT JUST THIS ONCE

You've probably heard about the benefits of double digging, a method used to create great soil that has excellent drainage, warms early in the season, and provides perfect conditions for intensive planting. But double digging is a lot of work, isn't it?

Well, yes, but once the soil has been prepared this way, you hardly have to lift a finger again. You'll rarely need to water since double-dug beds are rich in moisture-holding organic matter. Your soil will be fertile without fertilizing, so you'll get bumper crops of vegetables—even if you plant close to make the most of your hard-earned space. Of course, close spacing means fewer weeds, so that's another task you can avoid. Plus, you'll have soil that's ready to plant whenever you're ready—even in soggy seasons.

For vegetable gardeners pressed for space or those with serious drainage problems, double-dug raised beds are ideal.

Tips for Gardening on Tough Sites

When difficult conditions make gardening seem like a lost cause, look for ways to grow around, above, or below the problem. Here are some ideas to get you started.

Grow veggies in the lawn. Is your garden site presently a lawn? If so, consider leaving the grass in place in the pathways and just digging up the growing space you'll need. This minimizes weeds and erosion, and the grass pathways are easy to keep up by mowing. Be sure to make the pathways at least as wide as your lawn mower.

Create instant raised beds. Is poor soil giving you a headache and backache? Cover the growing area with straw bales laid flat and placed end to end. Spread a 2-inch layer of compost on top and then plant. The bales will decompose within a year, creating a wonderful growing base. Good crops to try in "bale beds" include bush beans, peas, greens, okra, and eggplants. Large vining vegetables like squash, melons, and tomatoes also perform well, especially if you make a hole in the bales, pour in a bucket of composted manure and then set in transplants.

Create soil on barren sites. Are you a gardener without any soil? If you live on bedrock, or if the bulldozer that leveled your lot stole your soil, here's a solution. Make an enclosure out of lumber, stone, cinder blocks, or even straw bales. (Or buy a kid's sandbox!) The sides should be at least 8 inches high—1 foot is ideal. Put an inch of gravel or sand in the bottom to ensure good drainage. Then fill the enclosure with a mixture of good soil and compost and plant. If you want to economize on soil, fill the bottom half of the enclosure with a mix of organic matter—shredded leaves, sawdust, rotted manure, and weeds.

Save water with sunken beds. Are you gardening in the desert? Take a hint from ancient Indian tribes and plant your crops in sunken beds that capture and conserve water. To make a sunken bed, dig out a bed 1½ feet deep. Reserve the best soil in a wheelbarrow or on a tarp, and place the rest in the paths. Mix the good soil with some compost, fill the trench with 6 inches of this mix, and you're ready to plant.

Work Your Soil with Roots

Let the roots of robust seedlings cultivate the soil for you before you plant. Here's how.

1. Sow quick-growing seeds like mustard and radish by broadcasting them thickly in early spring. Several weeks later, chop the young plants out with a sharp hoe.
2. Ventilate the soil by rocking the tines of a garden fork back and forth in the soil. Or use a broadfork, which is especially designed for aerating the soil.

Easy Steps for Keeping Your Soil Healthy—and Your Vegetables Happy

Vegetables need fertile soil with lots of organic matter to grow their best and stay problem free. You can keep your soil in tiptop form by mulching and adding compost to the soil every year, but collecting, hauling, and spreading soil amendments takes work. Isn't there an easier way? Absolutely! The tips below will help

you maintain your soil but let you relax the endless hunt for tons of compost and mulch-making materials.

Concentrate your efforts in beds. Instead of turning and amending your entire garden area each spring, limit your soil improvements just to your planting beds. It's a lot more economical and less time-consuming to enrich the areas where you'll actually plant crops and leave the pathways alone.

Don't till every season. As long as your soil isn't compacted, there's no need to till or dig every season. Keep your feet out of your beds, and you'll have won the battle against soil compaction.

Let plants do the tilling. Letting plants do your work is better for you and the soil. And all you need to do to accomplish this is keep something growing at all times. It's as simple as sowing seeds: As soon as one crop is finished, replace it with another. The constant action of roots and a myriad of other living processes will keep the soil loose and friable.

Grow organic matter for your soil. Instead of making tons of compost to keep your soil provided with plenty of organic matter, carry a single seed packet to your garden and grow green manures. You can plant green manure crops throughout the growing season, whenever it's convenient for you, and they'll produce the organic matter your soil needs right where you need it.

Keep Green Manures on Hand

If you'd prefer to follow through on your intentions to plant green manures (instead of having those plants turn into good intentions), make sure you have seeds on hand year-round. Otherwise, the day that you pick to plant your crop may be the day you realize you forgot (again!) to order the seeds. Instead, order seeds like clover, hairy vetch, or soybeans when you place your next seed order. Whenever you have the time—whether it's spring, summer, or fall—you'll be ready to plant a soil-protecting cover over any garden bare spots.

Super-Simple Soil Improvement with Green Manures

Spring planting can be a snap if you grow green manure crops in summer or fall. With the simple system outlined below, all you'll need to do is rake away the winter-killed green manure and sow your seeds. Plus, you'll have a healthy, productive garden—all without digging, hauling compost, or buying fertilizer. Here's a walk through the seasonal tasks for the easiest garden you can imagine.

FIRST SPRING

A few weeks before you're ready to plant your vegetable crops, sow a mixture of seeds like radishes, mustard, or rape—any quick-growing crops that like cool weather—for an early-season green manure crop. Sow the seed thickly. A few days before you're ready to plant your vegetables, chop out these "sacrificial crops," leaving the residues to decompose.

SUMMER

Keep something growing in your garden beds at all times. If you have some empty space and you're not ready to plant a food crop, sow warm-weather green manures like buckwheat, cowpeas, or soybeans to fill the vacancies. Chop these crops down when you need the space, working the debris into the soil or using it as mulch as soon as it dries.

Don't let green manure crops get out of hand—they're easier to manage if kept small. Even if you're not ready to plant a food crop, cut them down before they get more than 8 inches tall or start to go to seed. Just plant another round of green manure to keep the process moving until you need the space.

Wait two or three days to plant vegetables after chopping down a green manure crop. (Decomposing plant material draws nitrogen from the soil, which temporarily robs it from any growing plants.) The chopped material will disappear in a day or two in warm weather; it will take a few days longer in cool weather. If you can't wait, simply rake the green manure onto the pathways. Once it dries, rake it back onto the bed as mulch.

Scrape up any mulch that has decomposed in the pathways and use it to cover vegetable crop seeds when you plant. This humus-rich blanket will keep the top of the soil from drying out and give the young seedlings a wonderful nutrient boost.

EARLY FALL

Remove the remaining summer crops and compost them. Clip the plants off at the soil level, leaving the roots in the ground to rot. In climates with cold winters, sow oats or mustard in the beds by mid-September. (Austrian winter peas are a good choice for the South.) These plants will grow until freezing temperatures hit, and then they die back, forming a mulch blanket.

If you miss planting a fall green manure crop, be sure to cover the bed with shredded leaves. Whatever you do, don't leave the soil uncovered and open to erosion.

SECOND SPRING

About a month before your first spring plantings, push the remains of last year's green manure or any mulch you've used to cover your beds to the side, and plant the spring seed mix again. When it's time to plant early spring crops, chop out the seedlings—use hedge clippers or a string trimmer if a hoe proves difficult. You don't need to remove the roots of green manures—they should be left to rot in the ground. To aerate the bed, use a garden fork to gently lift the soil—no need to turn it over. That's all it takes! You're ready to plant.

Undersow to Grow Your Own Fertilizer

Growing a green manure crop under your main crop is a simple way to grow next year's fertilizer right where you'll need it. You'll avoid all the hassle and expense of buying soil amendments, and when used this way, green manure crops act as a living mulch, which conserves moisture and suppresses weeds.

Continued →

You can undersow corn with hairy vetch but there are many other combinations to try, including tomatoes with oats, corn with soybeans, cabbage with cowpeas, and squash with sweet clover.

1. Plant your main crop and let it become established before broadcasting seed for your green manure crop. Corn, for example, should be about 10 inches tall before you sow.
2. To cover the green manure seed, sprinkle the area with compost or mulch it lightly with straw.
3. Let the green manure crop grow through the season and till or dig it under the following spring. It will protect the soil over the winter.

When You're Planting, It Pays to Watch the Weather

The easiest way to plant seeds and transplants in the garden is to wait until the weather is right. There's nothing wrong with trying for an early start, but you'll probably have to replant seeds that were lost to rot or replace transplants blasted by an Arctic wind. In other words, gambling on an early spring is very rarely a low-maintenance venture!

But when is the weather right? Try taking a cue from the trees and plants growing around you. Lilacs and honeysuckle grow almost everywhere, so they make good examples. When their leaves show their first green, it's safe to plant early crops like lettuce, cabbage, and peas. For warm-weather crops like corn and beans, wait until the honeysuckle or lilac blossoms are fully open.

Mix Seeds and Transplants for Speedy Planting

If spring zooms by before you finish planting, speed up the process by using both transplants and seeds. These tips will help you plant and sow your vegetables efficiently.

Tips for transplants. Use transplants for crops that take a long time to grow, like cabbage, broccoli, and tomatoes. Buy the healthiest starts you can find—this is not the place to pinch pennies on rootbound, overcrowded seedlings. Healthy transplants will get off to a faster start, bear a better crop, and crowd out weeds more effectively than sickly ones. If you don't have time to tend to young seedlings daily, use transplants for the majority of your needs. They're successful for all but long-rooted crops like carrots, radishes, turnips, and beets.

Suggestions for seeds. Buy seeds for plants that you use in quantity and that grow quickly, such as snap beans, spinach, arugula, and lettuce. Also buy seeds of plants that are so easy to handle that there's no need to spend the extra money on transplants. Examples include crops with big seeds like peas, beans, corn, and squash.

Sow Seeds Evenly to Save Time Thinning

There's no doubt about it, sowing seeds carefully is easier on the nerves than weeding extra seedlings out later. After all, what gardener likes to pull up healthy little plants? But sowing evenly is tough—especially with small seeds like carrots. Here are some simple techniques and tools that will make sowing and thinning easier for you.

Try creasing your seed packet down the middle and tapping the seeds out gently along the crease line. If seedlings still pop up in clumps, thin them out with a metal rake when they are about ½ inch high. Drag the rake across the width of the row so that the teeth dig in only about ¼ to ½ inch. The bed will look terrible for a few days, but the remaining seedlings will soon fill in the gaps. This technique works well for beets, carrots, chard, collards, kale, radishes, spinach, turnips, lettuce, and other salad greens.

If you have a large garden, consider investing in a few specialized seeding tools that make the process more efficient. A mechanical seeder makes planting lots of corn a snap and is very simple to use. These seeders have adjustable seed plates for other sizes of seeds and can be used in wide beds as well as in rows.

Crank seeders save a lot of time for crops that are broadcast—green manures, for example. This device looks a bit like a ricer only it spews out seeds instead of applesauce as you crank the handle. Most garden centers and hardware stores carry these tools.

Tactics for Timely Transplanting

Want to set out your transplants without watering them every day for a week? Let Mother Nature do the job. Sit tight until the weather is right and set in your plants when winds are calm and rain is expected. To give your plants an extra boost, soak them in seaweed solution before taking them out of their pots and give them another good drink once they are in the ground. Make a ring of soil around the base of the plant to help capture and retain water around the roots. Once transplants have been rained on, they can make it on their own unless drought sets in.

If you live in an area where rain is scarce and you have no irrigation, prick a small nail hole in the bottoms of several plastic gallon jugs, fill them with water, and space them around your plants. The water will drip out slowly, saving you from watering for at least a week.

TRANSPLANTING TOOLS EASE PLANTING PAINS

Why limit yourself to a trowel or shovel when other new or familiar tools can make planting much easier? Hand-diggers shaped like mini-plows let you open up planting holes in one quick swoop. A long-handled bulb planter works as well for transplants as for bulbs (unless the soil is compacted) since you can dig holes without stooping.

Don't Make Room for Weeds

Where do weeds come from, anyway? The truth is, gardeners plant most of them. Some weed seeds blow in, but the vast majority arrive in compost and mulch. Letting weeds go to seed is another prime source of future weeding headaches. All those

weed seeds lie in the soil, waiting for a chance to come to the surface where there is enough light to germinate.

Every time you turn the soil over, you bring up another crop of weed seeds. Knowing all this, what's the low-maintenance way to keep weeds out of your way? Try these tips.

Keep your beds full of growing plants. If all the space is occupied by green manure crops or vegetable crops, weeds won't have room to sprout. In addition, growing your own organic matter with green manures reduces the likelihood you'll bring weed seeds to your garden with compost.

Keep your soil mulched. If you get caught with nothing growing in your beds, keep them mulched with at least 4 inches of materials like shredded leaves, dried grass clippings, or straw. Keep a supply of these materials handy for emergencies.

Rake out uninvited sprouts. If you till up a new area or dig a new bed and don't have time to plant a green manure crop, wait a few days for the weeds to sprout. (If you can, hang in there until the first rain.) Then use a metal rake to scratch the top ½ inch of the soil, which will disrupt any germinating weeds without bringing up lots more. This tip is especially useful if you want to grow crops like carrots or lettuce, which are tedious to weed.

Cut unwanted seedlings to the quick. If a few weeds pop up early in the season, snip them off at ground level with sharp scissors while they are still small. For weeds like dandelions that have long roots, push the scissors into the soil and cut off the root as far down as you can reach. This will keep you from uprooting young crop seedlings.

Crowd out weeds with leaves. To keep weeds out of beds planted with crops, space your vegetables as closely as possible. Imagine how big your vegetables will be when they mature, and space or thin the plants accordingly. The leaves of growing plants will form a "living mulch," shading out most weed problems.

Skim the soil. To keep ahead of weeds in more open planting areas, like blocks of corn or hills of squash, chop them out while they are still small. Use a sharp hoe or a spade to skim off the weeds at soil level, and you'll avoid the hassle of digging and pulling. The only secret here is to keep the blades of your tools razor sharp. Once crops have reached full size, you can relax your weeding routine, but never let weeds go to seed!

Don't Dig Potatoes—Grow Them in Mulch!

Growing potatoes under mulch couldn't be easier. There's no digging, no tools—just a few bales of straw.

1. Place seed potatoes 1 foot apart on top of the soil and cover them with 1 foot of straw, hay, or shredded leaves. (Be sure each piece of potato has 2 or 3 eyes.)
2. Believe it or not, potato shoots and leaves will eventually poke through the mulch. When they do, add 6 more inches of clean straw mulch around the plants. (Don't cover the leaves.) Peek underneath the mulch periodically to watch the tubers develop and check to make sure they aren't turning green, which is a signal to add more mulch.
3. Begin harvesting new potatoes when the vines flower. Simply lift up the mulch and pick a few baby spuds. Harvest the main crop when the vines begin to die down.

With Beans, Peas, and Other Legumes, It Pays to Inoculate

The first time you plant legumes like peas and beans in your garden, inoculate them with the bacteria they need to fix nitrogen in their roots. Tests show that yields on inoculated crops increased up to 77 percent. To inoculate seeds before planting, moisten them in a flat pan and sprinkle on the black dustlike inoculant powder. Shake the pan to ensure good coverage.

Different legumes need different types of bacteria. The inoculant powder most commonly sold contains a mix suitable for peas, snap beans, and lima beans. If you grow other legumes, like cowpeas or scarlet runner beans, buy the proper inoculant. Once you've planted inoculated crops, you don't need to do it again. The bacteria will remain in the soil.

Which Tomato Type Is Best for You?

The type of tomatoes you plant can mean the difference between a crop that's over in a few short weeks and one that lasts throughout the summer months. That's because tomatoes are either determinate or indeterminate.

Determinate tomatoes set all their flowers and fruit at the same time, then stop growing. Choose them if you have a short growing season—since their fruits ripen all at once, you can squeeze in a complete harvest before frost. Determinate plants stay shorter, so they're easy to grow in cages and a good choice if

Continued →

you hate staking. Canning tomatoes, like 'Heinz' and 'Roma,' are popular determinate cultivars.

Indeterminate tomatoes continue growing and setting flowers throughout the growing season. They usually require staking, although they can be grown fairly well in extra-tall cages. On the plus side, though, they'll spread out the harvest so you aren't overwhelmed with too many tomatoes all at once. Most slicing tomatoes, like 'Beefsteak' and 'Better Boy,' are indeterminate cultivars.

Vegetable Crop Guide

Jeff Cox

Good site selection and proper soil care are the two most important steps you can take to ensure a great vegetable harvest. Knowing how to handle your crops at planting time and how to care for them through the season is icing on the cake. Use the guidelines and tips in this crop-by-crop guide to popular vegetables to ensure a bumper harvest every time.

Asparagus

Asparagus officinalis (Liliaceae)

Site: At least ½ day of sun; protection from strong winds.

Soil: Evenly moist, well-drained, light, sandy loam that is rich in organic matter, pH of 6.5–7.5.

How much to plant: 20–40 plants per person.

Spacing: 1½–2' between plants in rows 3'–4' apart.

Seasons to bearing: Begin harvesting after 2–3 seasons of growth.

Asparagus is hardy in Zones 2 through 9. It thrives in any area with winter ground freezes or a dry season to provide a dormant period each year. Asparagus does best in full sun and deep, well-drained soil. Select a permanent location carefully, since plants will produce for 20 years or more. Dig out all weeds and add plenty of compost to the soil before planting. Asparagus requires high levels of nitrogen, phosphorus, and potassium. Do a soil test, and add amendments as necessary. If your soil is heavy or poorly drained, plant asparagus in raised beds.

Plant one-year-old crowns from a reputable nursery that sells fresh, firm, disease-free roots, or start your plants from seed. Soak seeds or crown in compost tea for five minutes before planting to reduce disease problems.

Most seed-grown asparagus plants eventually out-produce those started from crowns. Growing from seed also allows you to eliminate female plants. A bed of all male plants can produce as much as 30 percent more spears than a mixed bed of male and female plants. Plants grown from seed will flower their first summer. When the tiny flowers appear, observe them with a magnifying glass. Female flowers have well-developed, three-lobed pistils; male blossoms are larger and longer than females. Weed out all female plants. The following spring, transplant the males to the permanent bed.

Harvesting new plantings too soon can stress plants and make them more susceptible to pest problems. Harvest for two weeks the second season, four weeks the third season, and up to eight weeks thereafter.

Mulch with a high-nitrogen compost each spring before spears emerge, and again in fall. Leave winter-killed foliage, along with straw or other light mulch, on the bed to provide winter protection. Remove and destroy the foliage before new growth appears in the spring; it can harbor diseases and pest eggs. Over the years, the crowns will push closer to the soil surface, resulting in smaller and less-tender spears. To remedy this, mound 6 inches of soil over the rows each spring.

Bean

Phaseolus spp. (Leguminosae)

Site: Needs at least ½ day of sun.

Soil: Prefers a light, sandy soil with good drainage; pH of 5.5–6.8.

How much to plant: Bush beans: 10–15 plants per person. Pole beans: 3–5 hills per person.

Spacing: Bush beans: 4"–6" between plants in rows 1½'–3' apart. Pole beans: 6"–9" between plants in rows 3'–4' apart.

Days to maturity: Bush beans: 48–60 days. Pole beans: 62–68 days.

Beans thrive in most soil. Work in plenty of low-nitrogen compost before planting to loosen the soil. For a healthy, trouble-free crop, plant beans after soil has warmed. Optimum soil temperature for germination is 80°F. At soil temperatures below 60°F, most bean cultivars germinate poorly and are more susceptible to pests and root rot. Choose light, well-drained soil for early plantings, if possible, and cover beans with a row cover or clear plastic until they emerge. If you use clear plastic, be sure to remove it as soon as the seeds germinate to avoid "cooking" the seedlings.

Beans do best when soil pH is between 5.5 and 6.8. They don't require high soil fertility. In fact, a high nitrogen level will delay maturity. Spray young plants with seaweed extract to prevent micronutrient deficiencies and to improve overall plant health.

Soak seed in compost tea for 25 minutes before planting to help prevent disease and speed germination. Treat seed with an inoculant labeled for the type of bean you are planting before sowing to promote nitrogen fixation. Be sure to buy fresh inoculant each year, or check the date on the package for viability.

Low-Maintenance Tips for Your Favorite Crops

Do you have a favorite vegetable? Check the tips and techniques below for ways to make growing it easier, faster, and more efficient.

Crop	Tips for Sure-Fire Success	Methods to Maximize Efficiency
Beans, snap	Choose cultivars with dark seeds or purple pods for early plantings; they're less likely to rot. Plant small amounts (3 plants per person) every 12 days for a continuous crop and manageable harvests.	Plant snap beans in spaces vacated by lettuce and spinach to return nitrogen to the soil. Train pole beans up a teepee made of saplings to conserve space (1 teepee serves a family of 4).
Beets	Soak seeds overnight to speed germination. Beets need thinning because each "seed" actually contains several seeds. Clip extras with sharp scissors and add to the salad bowl.	For a double crop, harvest beet leaves throughout the season. Leave two-thirds of the leaves so root harvest won't be disturbed.
Cabbage family crops (broccoli, Brussels sprouts, cabbage, cauliflower, collards, kale)	Use row-covers to prevent damage from cabbage worms. Row covers also minimize the temperature fluctuations that cause poor heading in broccoli and cauliflower.	Plant kale, collards, and Brussels sprouts for nutritious, long-season crops, sowing seeds in the spaces left from early peas or beans. These hardy greens will overwinter in many areas with minimum protection.
Carrots	For better germination, cover seeds with ½ inch of compost. Keep the compost moist until seeds are up and growing.	Sow radish seeds with carrots; radishes keep the soil loose and are ready to harvest before carrots need the space. Planting with onions reduces carrot fly infestations.
Corn	Plant when nighttime air temperatures stay above 40°F. (The soil temperature should be about 50°F.) To deter crows, cover seedbeds with row covers.	Plant a mid-season and a late-season cultivar at the same time so you won't have to remember to plant a later crop. Early cultivars aren't tasty enough to warrant the work.
Cucumbers	Use row covers to thwart cucumber beetles. Remove covers when vines blossom to allow pollination. Plant a second crop as insurance against pests when the first crop blooms.	Trellising pays off in increased cucumber yields.
Eggplant	To combat flea beetles, place white plastic buckets around eggplants. Coat the plastic with sticky Tanglefoot to capture the beetles.	Eggplants love heat—cover them with plastic jugs (remove lids and cut out bottoms) until summer nights are warm.
Lettuce	Plant many types, starting with cold-tolerant strains early in the season. Switch to heat-resistant cultivars as summer draws near.	Sow a 2½- to 3-foot block every 10 days to 2 weeks until the weather gets hot. For longer harvests, keep roots cool with mulch to retard bolting. Row covers allow harvest of many greens well into winter.
Onions	Buy sets or transplants instead of seeds for a quick, reliable harvest. Choose small (½-inch diameter), firm sets since they're less likely to bolt.	Onions are good companions for most crops except peas and beans. Keep a bag of onion sets in the refrigerator and use them to fill in blank spaces all season.
Peas	Soak seeds overnight to speed germination. To avoid trellising, select short cultivars and plant seeds thickly so the vines will support each other.	Interplant with radishes and early greens if space is short; avoid planting near garlic or onions. Pick daily to encourage vines to keep producing.
Peppers	To increase yields, snip off early blossoms on young plants to give them a chance to bulk out before fruiting. Boost with 1 teaspoon Epsom salts to 1 quart of water when plants set fruit.	For easy harvest, uproot hot peppers at the end of the season and hang them to dry in a warm closet. Uprooted sweet peppers will hold for a month in a bucket of water if kept in a cool location.
Spinach	Soak seeds in compost tea for 15 minutes or all night before planting. Plant heat- and bolt-resistant cultivars.	Pick outside leaves only, once they reach 3 to 4 inches long—plants stay productive longer than if you harvest the entire plant at once.
Squash	To prevent squash borer attack, use row covers until female blossoms appear. Start another plant or two in early summer for added protection.	Pumpkins and winter squash take up a lot of space. Let them ramble over compost piles and steep slopes where other crops can't grow.
Potatoes	A month before planting, put seed potatoes in a bright, dry location, like a basement windowsill. The sprouts will grow slowly in the light. Cut them into sections with two or three sprouted eyes and plant. Crops will be ready almost a month earlier.	Why grow plain white potatoes? Specialty spuds are available in a riot of colors and shapes and are just as easy to grow. Try potatoes with yellow, pink, or blue flesh for flavors that store-bought spuds can't match.
Tomatoes	Buy the best transplants you can find. Seedlings should be bushy with sturdy stems. Choose disease-resistant cultivars. Try an assortment of single plants instead of buying a six-pack of one cultivar. Tomatoes almost always produce, but different cultivars produce better in different weather conditions.	Staking isn't necessary, but staked tomatoes have larger fruit, are easier to pick, and are less prone to rot. If you use tomato cages, buy the tallest, sturdiest ones available. To prevent cages from toppling, drive a stake inside each cage to hold it in place.

Crops That Wait for You

Few things are more frustrating than planting a beautiful garden and then not being able to keep up with the harvest. Leave your sugar snap peas on the vine for a few too many days, and you might just as well till them under as a green manure crop.

Fortunately, there are a host of forgiving crops that will more or less wait for you. They include onions, leeks, potatoes, garlic, many herbs, kale, beets, popcorn, sunflowers, hot peppers (for drying), horseradish, pumpkins, winter squash, and carrots. You can measure the harvest period for these crops in weeks or even months.

To keep your harvest from hitting all at once, stagger plantings. Make a new sowing every ten days to two weeks. Mix early, midseason, and late cultivars. Some vegetables, like bok choy and other oriental greens, can be harvested through Thanksgiving.

Never have time to pick all of your fresh snap or shell beans at their prime? Relax. Plant cultivars meant for drying, and enjoy hearty, homegrown bean dishes throughout winter.

You can pick leeks young and small or wait the full 90 to 120 days until they mature. Leeks have excellent freeze tolerance. When protected by mulch, they can be harvested well into winter. In mild-winter areas where hard freezes are few and far between, winter is the best time to grow collards, spinach, turnips, carrots, and onions.

In all climates, be prepared to protect overwintering vegetables from cosmetic damage by covering them with an old blanket during periods of harsh weather. Or you can try growing cold-hardy vegetables such as spinach and kale under plastic tunnels during the winter months.

To avoid spreading diseases, don't touch plants when foliage is wet. Compost plants after harvest. Prevent problems by not planting beans in the same location more often than every three years.

Beet

Beta vulgaris (Chenopodiaceae)

Site: Full sun, but will tolerate partial shade.

Soil: Prefers a light, sandy loam; pH of 6.0–7.5.

How much to plant: 5'–10' of row per person.

Spacing: 4"–6" between plants in rows 12"–20" apart.

Days to maturity: 46–70 days.

Beets grow best in deep, well-drained soil with a pH between 6.0 and 7.5. Beets are cool-season plants and will tolerate temperatures as low as 40°F. However, plants will bolt, or go to flower prematurely, if exposed to two to three or temperatures below 50°F after the first true leaves have formed. Beets grow poorly above 75°F and are best grown as a spring or fall crop. Keep soil moist but not soggy, since rapid and uninterrupted growth produces the best roots. Prevent problems by not planting beets in the same location more often than every three years.

Cabbage

Brassica oleracea Capitata group (Cruciferae)

Site: Full sun.

Soil: Rich, sandy loam; pH of 6.0–6.8.

How much to plant: 5–10 plants per person.

Spacing: 15"–24" between plants in rows 2'–3' apart.

Days to maturity: 62–120 days from transplanting.

Plant cabbages in full sun in a site with fertile, well-drained soil and a pH between 6.0 and 6.8. If you have a choice of sites, spring plantings do best in lighter, sandier soils, while fall plantings do better in soils that contain more clay. Plants grow best at temperatures between 40° and 75°F.

Cabbages are biennial, and transplants exposed to cool temperatures (35° to 45°F) for ten or more days may bolt. High temperatures also cause bolting.

These plants have very shallow roots, so be sure to keep the top few inches of soil from drying out. Fluctuations in soil moisture after the heads have formed may cause them to split. Mulching helps to balance and conserve moisture. Most cabbage diseases need free water to spread, so don't water with overhead sprinklers.

To avoid problems, don't plant cabbages where members of the cabbage family (broccoli, cauliflower, brussels sprouts, or kale) have grown for at least three years. Also, avoid areas with cabbage family weeds, such as wild mustard. Destroy all crop residues, including roots, after you harvest.

If you start your own plants, soak the seed in 122°F water for 25 minutes before planting to eliminate seed-borne diseases. Once your seeds have germinated, grow seedlings at 60°F to keep them short and stocky.

Cabbages are heavy feeders and are susceptible to several nutrient deficiencies, including boron, calcium, phosphorus, and potassium.

Carrot

Daucus carota var. *sativus* (Umbelliferae)

Site: Full sun to light shade.

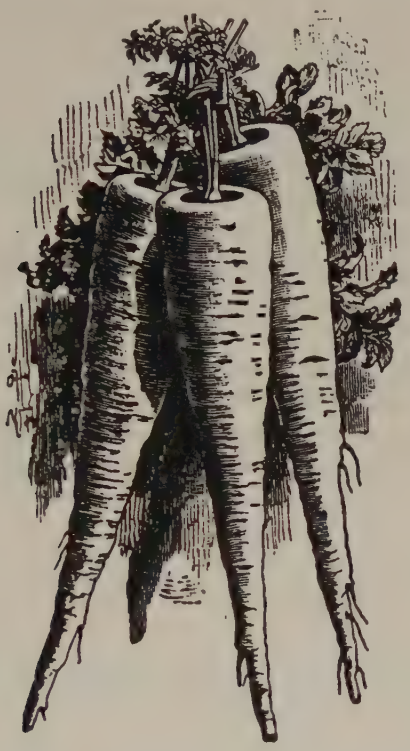
Soil: Deep, loose, moist, and well aerated; pH of 5.5–6.8.

How much to plant: 5'–10' of row, or 30 plants, per person.

Spacing: 3"–4" between plants in rows 16"–30" apart.

Days to maturity: 50–95 days from seed to harvest.

Carrots grow best in deeply worked, loose soils with a pH between 5.5 and 6.8. No other vegetable is as sensitive to poor soil structure. Misshapen carrots result more often from lumpy or compacted soil than from any pest problem. Carrots do well in raised beds. Work in a generous amount of compost or well-rotted manure before planting. Cultivars with short roots will tolerate shallow or poor soil better than long, thin cultivars.



Carrots grow best when temperatures are between 60° and 70°F. They grow poorly above 75°F but will tolerate temperatures as low as 45°F. Most cultivars grow short roots at high temperatures and longer, more pointed roots at lower temperatures.

Abundant water is necessary for good root development. It is especially important to give emerging seedlings an edge against weeds. Keep soil evenly moist but not saturated.

To prevent problems with diseases and insects, do not plant carrots where carrots or parsley has grown for three years.

Carrots require moderate to high levels of potassium and phosphorus, but only a moderate level of nitrogen, so avoid high-nitrogen fertilizers. Carrots are very sensitive to salt injury and do poorly in soils with high sodium levels.

Corn

Zea mays var. *rugosa* (Gramineae)

Site: Full sun; needs wind for pollination.

Soil: Rich, well-drained loam with pH of 5.5–6.8; evenly moist but not wet.

How much to plant: 15–40 plants per person.

Spacing: 8"–12" apart in rows 30"–42" apart.

Days to maturity: 65–90 days from seed to harvest.

Corn does best in a rich, sandy, or well-worked soil with a pH between 5.5 and 6.8. Prepare soil by working in a generous amount of compost. Side-dress plants with alfalfa meal when they are 1 foot high and again when silk first shows at the ends of the ears. Spraying plants with seaweed extract or compost tea periodically also improves your harvest and prevents deficiencies.

Plant corn seed only after the soil is at least 60°F, or 75°F for supersweets. Seed planted in cooler soil is prone to many problems. To help speed soil warming, cover soil with clear plastic at least two weeks before planting. After planting, use row covers for about a month to give seedlings a boost.

Corn needs at least 1 inch of water a week. Keep soil moist but not soggy. Mulch plants to conserve moisture and to cut down on weeds.

Plant corn in blocks rather than long single rows to ensure good pollination. To prevent problems, do not plant corn where it has grown in the past two years. After harvest, cut or mow stalks and let them dry. Then turn them under or collect and compost them. Destroy any diseased or infested material.

Cultivate Some Cole Crops

Cabbage, broccoli, and their less-common cousins such as kale and brussels sprouts all belong to the same family of vegetables—Cruciferae. In fact, they're all different forms of the same species, *Brassica oleracea*. All are grown like cabbage and are cool-weather crops that are good for planting in spring and fall.

Broccoli: Grown for its crisp green heads of flower buds. Prevent problems by planting the following improved cultivars: 'Green Dwarf #36,' 'Emperor,' and 'Mariner' are black rot-tolerant; 'Premium Crop' is resistant to Fusarium wilt; 'Citation,' 'Emperor,' 'Esquire,' 'Green Dwarf #36,' 'Hi-Caliber,' and 'Mariner' are tolerant of downy mildew; and 'De Cicco' is tolerant of flea beetles.

Transplants exposed to cool temperatures (35° to 45°F) for ten days or more may form tiny, useless flower heads prematurely. High temperatures can cause similar tiny head formation. Broccoli grows best at temperatures between 45° and 75°F. Harvest heads when buds are still tight and dark green or dusky violet, except for 'Romanesco,' which should be yellow-green.

Brussels sprouts: One of the hardiest members of the cabbage family, they can tolerate lower pH (5.5 to 6.8) than any of the other brassicas. But they are less tolerant of

Continued →

heat. In warmer climates grow sprouts in soil with a high clay content if you have a choice, and shade the soil around roots. Harvest sprouts when they are 1 inch in diameter or smaller and still tight. Twist them off gently, starting at the base.

Cauliflower: Grown for its dense, white heads of flower buds. Prevent problems by planting the following cultivars: 'Alpha Paloma' and 'White Rock' are tolerant of cabbage root maggots; 'Super Snowball A' tolerates flea beetles better than most cultivars.

Cauliflower is fussier about temperatures than the other brassicas. Plants only tolerate a low of 45°F and grow poorly above 75°F. Transplants exposed to cool temperatures (35° to 45°F) for ten days or more may form tiny, unusable flower heads. High temperatures can cause the same problem. Cauliflower's optimum temperature range is 60° to 65°F.

Kale: Grown for its crinkly, blue-green leaves. It is a very hardy member of the cabbage family, tolerating temperatures below 40°F. Frost improves its taste. It is less tolerant of heat than other members of the cabbage family. In warmer climates, grow kale in soil with high clay content if possible, and shade soil around roots.

Cucumber

Cucumis sativus (Cucurbitaceae)

Site: Full sun, or full morning sun and less than 3 hours of afternoon shade.

Soil: Well-drained sand or clay loam with pH of 6.0–6.8.

How much to plant: For eating fresh: 1 plant per person; for pickling: 5 plants per person.

Spacing: Grow trellised plants 6"–10" apart, or grow in hills spaced 4'–6' apart.

Days to Maturity: 55–70 days from seed, depending on the cultivar.

Cucumber seeds need 60°F soil to germinate, so wait until weather is warm to plant. Make a second planting four to five weeks after the first so you will have fruit all season. Cover plants with floating row covers to protect them from insects and late cold snaps. Remove row covers when plants begin to flower so insects can pollinate the blossoms, or you will not get any fruit.

Cucumbers do best in well-drained, loose-textured soils with lots of organic matter. They will grow in soils with a pH between 5.5 and 6.8, but they prefer a pH above 6.0. Plants need lots of water, but don't let soil become saturated. Prevent disease problems by keeping leaves dry. Mulch cucumbers to help conserve water; black plastic is a good choice for central and northern areas, but in extremely warm areas it can warm the soil too much. Organic mulches are good, too, but may provide shelter for pests like squash bugs. Foil mulches help prevent aphid problems. If rotting fruit is a problem, raise fruits off the ground by placing scraps of wood under them.

Rotate crops so that no member of the cucurbit family (squash, melon, and cucumber) is grown in the same place more often than every four years.

Caution: Cucumber leaves are easily burned by insecticidal soap and copper sprays. Use the most dilute spray recommended and use sparingly. Do not spray plants in direct sun or if temperatures are above 80°F, and don't spray drought-stressed plants.

Eggplant

Solanum melongena var. *esculentum* (Solanaceae)

Site: Full sun.

Soil: Moderately fertile, well-drained loam; pH of 6.0–6.8.

How much to plant: 2–3 plants per person.

Spacing: 20"–24" apart each way.

Days to maturity: 60–100 days from transplanting.

Eggplants do best in full sun and well-drained, fertile soil with lots of organic matter. They prefer a pH between 6.0 and 6.8 but will tolerate a pH as low as 5.5. Eggplants need a high level of nitrogen and moderate levels of phosphorus and potassium. Have the soil tested, and correct any deficiencies. They grow best at temperatures between 70° and 85°F, and poorly above 95° or below 65°F.

Eggplants need lots of water. Keep the soil evenly moist, and never let it dry out. They do well in mulched, raised beds with drip irrigation. Black plastic mulch is a good choice because it warms the soil.

Purchase stocky, insect- and disease-free plants, or start your own from seed indoors. Eggplant seeds germinate best between 80° and 90°F. Once seedlings are up, they grow best at 70°F. Do not plant out before average daily temperatures have reached 65° to 70°F. Protect transplants from wind, and water new transplants well with seaweed extract or compost tea to give them a good start. Spray plants with seaweed extract with 1 teaspoon of Epsom salts added per gallon when the first flowers open to improve fruit set.

Eggplants are susceptible to many of the same problems, pests, and diseases as tomatoes, including flower drop or misshapen fruit due to extreme temperatures, flea beetles, Colorado potato beetles, aphids, hornworms, mites, Verticillium and Fusarium wilts, tobacco mosaic virus, and anthracnose fruit rot.

Lettuce

Latuca sativa (Compositae)

Site: Tolerates partial shade; thrives in light shade in summer; does well in humid spots.

Soil: Loamy soil that is well drained and moderately rich; needs constant moisture; pH of 6.0–6.8.

How much to plant: Plant 15–20 leaf lettuce plants or 7 head lettuce plants per person.

Spacing: Leaf lettuce: 6"–12" between plants in traditional rows 1'–3' apart, or in intensive beds with 6"–9" between plants. Head lettuce: 8"–14" between plants in traditional rows 1'–3' apart.

Days to maturity: Leaf lettuce: 40 days from seed to harvest. Head lettuce: 70 days from seed to harvest, or 20–35 days from transplanting to harvest.

Lettuce grows best in rich, loose soil with a pH between 6.0 and 6.8. It likes full sun, but in hot weather it does better with light shade in the heat of the day. Lettuce needs to grow rapidly and without interruption. Provide plenty of nitrogen in both quicker-release forms, such as blood meal or soybean meal, and slower-release forms, such as compost or alfalfa meal. Spray the plants with compost tea and/or seaweed extract every other week to give them an extra boost. Spraying with compost tea may also help prevent some fungal disease problems.

Lettuce grows best at temperatures between 60° and 65°F. Most lettuce cultivars grow poorly above 75°F but will tolerate temperatures as low as 45°F. Plants exposed to high temperatures will bolt. Prevent bolting by providing plants with partial shade in the heat of the summer, harvesting promptly, and planting bolt-resistant cultivars.

To grow tender, trouble-free lettuce, keep the soil moist but not soggy, and do not allow the soil to dry out. Unlike most vegetables, lettuce responds well to having its foliage sprinkled with water. Plant in raised beds to improve drainage. To help prevent disease problems, do not plant lettuce in soil where it has been grown within the last three years.

Melon

Melon, *Cucumis meto* and Watermelon, *Citrullus lanatus* (Cucurbitaceae)

Site: Full sun.

Soil: Moderately rich, well-drained soil with a pH of 6.0–6.8.

How much to plant: 1–2 plants per person.

Spacing: 8"–12" apart in rows 6'–10' apart or 2 plants per hill, with the hills spaced 2'–3' apart.

Days to maturity: 75–90 days from seed, depending on cultivar.

Melon seeds need 60°F soil to germinate. In northern areas, start plants indoors two to three weeks before the last frost date and transplant outside once weather is warm. Melons need sun and warmth—90°F is ideal. Melons are especially vulnerable to pests and cool temperatures below 50°F can be permanently injured and fail to set fruit. Cover plants with floating row covers or clear plastic tunnels as soon as they are set out. If temperatures exceed 90°F inside the tunnels, vent them with a 6-inch cut in the plastic directly over each plant. Remove covers when melons flower so insects can pollinate the blossoms, or you will not get any fruit. In the fall, temperatures below 50°F cause cold stress and rapid wilting. Cover plants on cool nights.

Melons perform best in well-drained, loose-textured soils with lots of organic matter. They prefer a pH between 6.0 and 6.8 but can tolerate a pH as high as 7.6. Melons are shallow-rooted and may wilt on hot, dry days even when they are not diseased. Keep them well watered, but do not let the soil become saturated. Wet soil can cause stems to rot at soil level. Overwatering or uneven watering can cause fruit to split. Potassium deficiency can also cause split fruit.

Prevent disease problems by keeping the leaves dry. Water carefully or use drip irrigation. Mulch melons to help conserve water: Black plastic is a good choice for central and northern areas, but in extremely warm areas it can warm the soil too much. Organic mulches are good, too, but also provide shelter for pests like squash bugs.

Caution: Melon leaves are easily burned by insecticidal soap and copper sprays. Use the most dilute spray recommended and apply sparingly. Do not spray plants in direct sun or if temperatures are above 80°F, and don't spray drought-stressed plants.

Onion

Allium cepa and other species (*Liliaceae*)

Site: At least ½ day of sun.

Soil: Richly organic, well-drained loam with pH of 6.0–6.5; constantly moist, but not wet.

How much to plant: About 40 plants per person.

Spacing: 1"–4" between plants in rows 1'–2' apart.

Days to maturity: Varies with cultivar and method; 100-160 days from seed to harvest. Green onions: Harvest in 45 days from transplants or sets. Bulb onions: Harvest in 90 days from transplants or sets.

Onions grow best in full sun and deep, fertile, well-drained soil with lots of organic matter. Work in a generous amount of compost before planting. Onions need high levels of nitrogen and potassium and a moderate to high level of phosphorus, so do a soil test and amend soil as needed before planting. Onions grow well in raised beds or ridges, especially if soil is clayey.

Continued →

Onions grow best between 55° and 75°F and will tolerate temperatures as low as 45° and as high as 85°F. They prefer cool temperatures early in their growth and warm temperatures near maturity.

Keep the soil moist since onions have shallow roots, but don't allow soil to become saturated because onions are susceptible to several root rot diseases. Mulching onions with composted leaves or straw is highly recommended to maintain soil organic content, help prevent disease, and keep down weeds. Wait until soil warms to apply mulch.

To help prevent populations of disease organisms from building up in the soil, avoid planting onions where onion-family members have been grown during the previous three years. In general, white onions are more prone to problems than yellow or red ones.

You can grow onions from seeds, transplants, or sets. Discard any disease sets or transplants. Transplants are seedlings started in the current growing season and sold in bunches. Sets are immature bulbs grown the previous year. Soak sets, roots, or seeds in compost tea for 15 minutes before planting to help prevent disease. Dust the roots of sets and plants with bonemeal after soaking and before planting to give them a good start.

Onion bulb formation is controlled by day length, so selecting suitable cultivars for your area is crucial. In the North choose "long-day" cultivars, and in the South choose "short-day" cultivars.

Allow tops to fall over naturally, then pull bulbs and let them air-cure for two weeks. After curing, sort out damaged bulbs and those with thick necks and put aside for immediate use. Store others at temperatures just above 32°F.

Pea

Pisum sativum (Leguminosae)

Site: Full sun; will grow in partial shade.

Soil: Well-drained soil with high organic matter is best; pH of 5.5–6.8.

How much to plant: 40 plants per person.

Spacing: Bush types: 2' between rows. Climbing types: 3' between rows. Both types: 2"–3" between plants.

Days to maturity: 56–75 days from seed to harvest.

Peas grow well in almost any soil but do best in soil with lots of organic matter and a pH between 5.5 and 6.8. A 1-inch layer of compost worked well into the soil before planting will provide sufficient nutrients for a good crop.

Peas are a cool-season, moisture-loving crop. They grow best between 60° and 75°F; they do poorly at temperatures above 75°F but will tolerate temperatures as low as 45°F. Pea foliage can withstand a light frost, but pods and flowers will be damaged unless they are covered.

Most disease problems in peas can be avoided with proper culture. Do not plant in wet soils. Plant in raised beds, and add plenty of compost to loosen the soil. Rapid germination is essential to avoid root rot problems. Choose lighter soils for earliest plantings if you have a choice, and keep soil moist but not wet. Avoid touching plants when they are wet. Dispose of vines after harvest and till soil to reduce future problems. Plant peas where no peas or beans have grown for at least three years.

Soak seed in compost tea for 15 minutes or as long as overnight to help prevent disease and speed germination. To promote nitrogen fixation, treat seed with an inoculant labeled for garden peas before planting. Be sure to buy fresh inoculant each year, or check the date on the package for viability.

Peas are susceptible to certain micronutrient deficiencies. Spray young plants with seaweed extract every two weeks to help prevent deficiencies and boost production.

Pepper

Capsicum annuum var. annuum (Solanaceae)

Site: Full sun.

Soil: Sandy loam, or any good, well-drained soil with a pH of 6.0–6.8.

How much to plant: 3–4 plants per person.

Spacing: Plant on 1½' centers.

Days to maturity: 65–80 days from transplanting.

Peppers require deeply worked, well-drained soil with lots of organic matter. They do best at a pH between 6.0 and 6.8 but tolerate pH as low as 5.5. Peppers require a moderate to high level of nitrogen and moderate levels of phosphorus, potassium, and calcium. Have the soil tested and amend as needed before planting. Peppers grow best between 65° and 80°F. Temperatures above 85°F or below 60°F can cause blossoms to drop without setting fruit.

Peppers tolerate drought, but they do best in soil that is evenly moist but not soggy. Plant in raised beds to improve drainage, if needed. Stake peppers to keep fruit from touching the ground, and use mulch to control weeds and prevent soilborne diseases from splashing up on the fruit.

Do not plant peppers where tomatoes, potatoes, eggplants, or peppers have been planted within the past three to five years. Also, try to plan your planting scheme to separate these crops in the garden. Compost or till under all plant residues at the end of the season, and till the soil to reduce overwintering pests.

Purchase sturdy, insect- and disease-free above 80°F. Once seedlings are up, they grow best at 70°F during the day and 60°F during the night. Wait until soil temperatures reach 65°F before setting out transplants. Spray transplants with an antitranspirant to help reduce disease problems, and water them with seaweed extract or compost tea to give them a good start. To improve fruit set, spray plants when the first flowers open with a mixture of 1 gallon of seaweed extract and 1 teaspoon of Epsom salts.

Potato

Solanum tuberosum (Solanaceae)

Site: Full or nearly full sun, with good air circulation.

Soil: Any good garden soil that drains well; pH of 5.0–6.8.

How much to plant: 5–10 plants per person.

Spacing: Leave 1' between plants in rows 3' apart, or plant in raised beds on 1½' centers.

Days to maturity: 90–120 days, depending on cultivar and climate.

Potatoes require deeply worked, well-drained soil with lots of organic matter and a pH between 5.0 and 6.8. They need moderate to high levels of nitrogen, phosphorus, potassium, calcium, and sulfur. Have the soil tested and amend as needed before planting. Gypsum is a good source of calcium and sulfur for potatoes.

Keep soil moist but not soggy, and do not allow it to dry out. Alternating dry and wet soil can cause cracked or knobby tubers. Once tops begin to yellow near harvest, you can let the soil dry out without damaging tubers.

Do not plant potatoes where tomatoes, potatoes, eggplants, peppers, strawberries, or brambles have been planted within the past four to five years. Also, try to plan your planting scheme to separate these crops in the garden. Don't plant potatoes where sod or small grains were grown the previous year: Wireworms, a common sod pest, also feed on potato tubers. Compost or till under all plant residues at the end of the season. Tilling the soil helps prevent pests from overwintering.

Potatoes are usually grown from seed potatoes (tubers) or "buds" (tiny tissue-cultured tubers), but a few cultivars, such as 'Explorer' and 'Homestead Hybrid,' are grown from true seeds. Prevent problems by planting only certified disease-free tubers. Planting true seeds or buds also helps avoid many tuber-borne diseases.

Be sure to consider the end use of your potato crop when you select cultivars for planting—the texture of a cooked potato depends on its starch content. Higher starch content yields a drier, flakier texture. New potatoes of most cultivars are 90 percent water and only 7 percent starch. At maturity, most bakers contain 15 to 18 percent starch. However, cultivars used for potato chips and french fries contain as much as 22 percent starch.

Pre-condition tubers by storing them between 65° and 70°F for two weeks before planting to encourage rapid growth. Soak pieces in compost tea for several hours before planting to help prevent disease problems. Plant them out when soil is at least 40°F.

Radish

Raphanus sativus (Cruciferae)

Site: Full sun or partial shade

Soil: Any soil; pH of 5.5–6.8.

How much to plant: A few feet of row per person per planting.

Spacing: 2" apart in rows 8"–18" apart.

Days to maturity: Spring types 21–35 days; winter types 55–60 days.

Radishes are annual and biennial vegetables grown for their crisp, peppery roots. Certain cultivars do not have fleshy roots but are grown for their crunchy seed pods. Some Daikon radishes grow 2-foot roots.

Most radishes do best in cool, moist conditions. They need a pH between 5.5 and 6.8 and light, relatively rich soil. Plant radishes as soon as soil can be worked in spring. Make small plantings weekly until early summer for a continuous supply of radishes. Temperatures between 50° and 65°F produce the best radishes; growth above 75°F is poor. Some cultivars of Daikon radishes are designed for summer planting and will flower without forming large roots if planted too early.

The secret to mild, tender radishes is rapid growth. Water heavily the first two weeks after they come up if soil is dry. A light application of compost is usually enough for a good radish crop. Radishes will not tolerate soils high in salt.

Radishes are related to cabbage and suffer from many of the same problems. Since leaves are not harvested, more insect damage can be tolerated than in cabbage plants. See the Cabbage entry on page 400 for descriptions and controls. Prevent problems with Fusarium wilt by planting resistant cultivars such as 'Fancy Red,' 'Fuego,' 'Red Devil B,' 'Red King,' and 'Red Pak.'

Spinach

Spinacia oleracea (Chenopodiaceae)

Site: Sun to partial shade; needs a cool, moist site.

Continued →

Soil: Heavy, fertile loam that is moist but not soggy; pH of 6.0–7.0.

How much to plant: About 30 plants per person.

Spacing: 1'–3' between rows, 2"–6" between plants.

Days to maturity: 37–45 days from seed.

Grow spinach in well-drained soil with lots of organic matter and a pH between 6.0 and 7.0; it won't tolerate pH below 5.0. Spinach seed germinates best at soil temperatures between 45° and 75°F but will germinate as low as 35°F.

Mature spinach can survive temperatures of 20°F if gradually hardened off. However, prolonged exposure of young plants to temperatures below 45°F will cause bolting-production of a flower stalk and plants will produce few, low-quality leaves. Temperatures above 75°F and long days also cause bolting. In warmer climates, plant spinach in filtered shade to extend its season into the warmer months.

Keep soil moist but not soggy. Do not allow it to dry out, or plants may bolt. Spread a thin layer of mulch around plants to conserve moisture, suppress weeds, and keep soil cool.

Soak seed in compost tea for 30 minutes before planting to speed germination and to help suppress soilborne diseases.

Spinach requires moderate levels of potassium and phosphorus and a high level of nitrogen. It is also sensitive to low levels of calcium and boron. Have the soil tested and amend as necessary. Fast-acting sources of nitrogen, such as blood meal and soybean meal, are good fertilizers for spinach.

Squash

Cucurbita spp. (Cucurbitaceae)

Site: Full or almost full sun.

Soil: Any good garden soil that drains well; pH of 6.0–6.8.

How much to plant: 2–4 plants per person.

Spacing: Bushy cultivars: in hills 2'–4' apart. Vining types: in hills 3'–8' apart.

Days to maturity: Summer squash: 45–50 days. Winter squash and pumpkins: 85–110 days. Squash seeds need 60°F soil to germinate, so wait until warm weather to plant. Cover plants with floating row covers to protect them from insects and late cold snaps. Remove row covers when plants begin to flower so insects can pollinate the blossoms, or you will not get any fruit.

Squash perform best in well-drained, loose-textured soils with lots of organic matter. They will grow in soils with a pH between 5.5 and 6.8 but prefer a pH above 6.0. Squash need lots of water, but don't let the soil become saturated. Prevent disease problems by keeping the leaves dry. Mulch squash to help conserve water. Black plastic is a good choice for northern areas, but in extremely warm areas it can warm the soil too much. Organic mulches are good, too, but may provide shelter for pests like squash bugs. Foil mulches help prevent aphid problems. To prevent rot, support fruit on scraps of wood.

Rotate crops in your garden so that no member of the cucurbit family (cucumbers, melons, and squash) is grown in the same place more often than every four years.

Caution: Squash leaves are easily burned by insecticidal soap and copper sprays. Use the most dilute spray recommended and use sparingly. Do not spray plants in direct sun or if temperatures are above 80°F, and don't spray drought-stressed plants.

Sweet Potato

Ipomoea batatas (Convolvulaceae)

Site: Full sun; afternoon shade in warm climates.

Soil: Loose soil with a pH of 5.5–6.5.

How much to plant: 2–4 plants per person.

Spacing: 12" apart in rows 3' apart; 18" apart each way in beds.

Days to maturity: 70–100 days.

Sweet potatoes prefer loose, well-drained soil with a pH between 5.5 and 6.5. They require moderate amounts of nitrogen and boron, a moderate to high level of phosphorus, and a high level of potassium. Have the soil tested and amend as necessary before planting. Sweet potatoes do well in raised beds. Work in lots of organic matter before planting. Avoid topdressing after early summer, or root formation may be interrupted.

Keep soil moist, but not soggy, until the vines begin to spread. After that, water only if vines wilt. When the roots begin to enlarge in late summer, keep the soil moist until harvest. Mulch plants to suppress weeds and conserve moisture. Black plastic mulch will also warm the soil.

Plant sweet potatoes where they have not been grown for at least two years. After harvest, cut vines and let dry, then compost or till under to reduce disease buildup.

Purchase disease-free plants, or start your own from healthy, overwintered roots, Plant out when nights stay above 60°F. Soak plant roots in compost tea for five minutes before planting to help reduce disease problems. Water well with a fish emulsion or fish-meal tea after planting to give the plants a good start.

Dig potatoes gently before the first frost, after foliage starts to yellow. Dry them for two to three hours in the garden. Use any damaged or diseased potatoes as soon as possible. Cure healthy potatoes for ten days in a humid place at 80° to 85°F. Gradually reduce temperature and store them in a humid room at 55° to 60°F.

Tomato

Lycopersicon esculentum (Solanaceae)

Site: Full sun or full morning sun and less than 3 hours of afternoon shade.

Soil: Moderately fertile clay or sandy loam with good drainage and a pH of 6.0–6.8.

How much to plant: Warm climates: 2 plants per person; cool climates: 4 plants per person.

Spacing: Staked tomatoes: 1½'–2' apart. Unstaked, uncaged tomatoes: 3'–4' apart. Caged tomatoes: Space 2'-diameter cages 4' apart.

Days to maturity: 90–140 days from seed; 60–90 days from transplanting, depending on the cultivar.

Tomatoes require full sun and deep soil with a pH between 6.0 and 6.8. Work in plenty of compost before planting to add organic matter. Tomatoes require moderate levels of nitrogen and phosphorus and moderate to high levels of potassium and calcium. Tomatoes grow best between 75° and 90°F. Temperatures over 100°F can kill blossoms, while temperatures below 50°F can cause chilling injury.

Keep soil moist but not soggy, and do not allow it to dry out. Avoid wetting leaves when watering to help prevent diseases. Tomatoes do well in raised beds with drip irrigation and mulch. Black plastic is a good mulch in cool areas because it helps warm the soil as well as suppressing weeds and conserving water. Organic mulch helps keep the soil cooler in very warm areas while adding organic matter. Mulch also helps prevent disease by preventing the fruit from touching the ground or being splashed with soil containing disease-causing organisms.

Choose cultivars that are adapted to local growing conditions. Many of them are resistant to one or more problems. Resistant cultivars are usually denoted in seed catalogs as follows: F = Fusarium-resistant, V = Verticillium-resistant, T = tobacco mosaic virus-resistant, and N = nematode-resistant.

Do not plant tomatoes where tomatoes, potatoes, eggplants, or peppers have been planted within the past three to five years. Also, try to plan your planting scheme to separate these crops in the garden. Compost or till under all plant residues at the end of the season to reduce overwintering pests. After tilling, spread 2 to 4 pounds of blood meal or soybean meal per 100 square feet to encourage breakdown of plant material.

Purchase stocky, insect- and disease-free plants, or start your own from seed indoors. Soak seed in a 10 percent bleach solution (1 part bleach and 9 parts water) for ten minutes and rinse in clean water before planting to reduce seed-borne diseases. Tomato seeds germinate best between 75° and 90°F. Once seedlings are up, they grow best between 60° and 70°F. When plants are set out, add 1 cup each of bonemeal and kelp to each hole. Water the transplants thoroughly with fish emulsion or compost tea to give them a good start. Spray young plants with seaweed extract to help prevent transplant shock and nutrient deficiencies.

The Vegetable Plot

Roger Yepsen

When planning next year's garden, consider yourself as well as the plants. What would make this part of the yard more welcoming to you? Vegetable gardens are high-maintenance endeavors, and you'll do a better job of tilling, planting, weeding, and harvesting if you enjoy entering the place. That may mean being more generous with the paths, so that you can walk freely about the garden, with or without a garden cart in front of you or long-handled tools in your arms. You may find that cushioned paths feel a lot better underfoot than those paved with brick or stone. A mulched garden walk, like a thickly carpeted floor, will be less jarring to your joints—and chances are your joints are already being put to the test by yard chores.

Easy Unusual Vegetables

There's always room for a new crop in most vegetable gardens. If you're looking for new tastes and textures, try some of these uncommon—but easy-to-grow—vegetables.

- **Arugula** (*Eruca vesica ria* subsp. *sativa*). Also known as rocket. A fast-growing annual with flavorful leaves. Sow seed in rich soil in early spring and autumn. Needs cool weather and lots of water. Add young leaves to salads and soup for a distinctive nutty, spicy flavor. Use the flowers as a garnish or in salads.
- **Basella** (*Basella alba* and *B. a.* var. *rubra*). Also known as Malabar or summer spinach. A heat-tolerant, 6-foot perennial vine with thick, dark green leaves that can be harvested all season. Start plants indoors and transplant outdoors in rich soil after frost danger is past. Trellis to maximize garden space. Requires warm weather and plenty of moisture. Harvest sparingly until plants branch. Substitute the greens for spinach.
- **Elephant garlic** (*Allium ampeloprasum*). A mild, garlic-flavored ½- to 1-pound bulb closely related to the leek. Prepare a deep bed with compost or aged manure. Plant cloves 8 inches apart in fall or late summer. Mulch well in the North. Harvest bulbs the following season when tops die back. Dry in shade and store in a cool, dark, dry place. Use cloves in cooked dishes and the greens for seasoning.

Continued →

- **Ground cherry** (*Physalis pruinosa*). Also known as dwarf Cape gooseberry. Low sprawling plants produce sweet, marble-sized, golden yellow fruit encased in a papery husk. Will self-sow. Start seed indoors or sow outdoors in rich soil after last spring frost. Harvest when the tan husks turn paper-thin. Add to vegetable and fruit salads for a sweet, exotic flavor. Makes delectable pies and jams. Freeze or dry to preserve.
- **Hyacinth bean** (*Dolichos lablab*). An attractive vining legume with lavender flowers and deep burgundy pods on purple stems. Start seed indoors or direct-seed outdoors in rich soil after frost danger. Grow as you would pole lima beans or on trellises in the ornamental garden. Use flowers in salads and dips. Use the young pods like string beans or fresh in salads. Cook older beans as you would green shell beans.
- **Sorrel, French** (*Rumex scutatus*). A hardy perennial with succulent, lemony leaves high in vitamin C. Start from seed or purchase plants. Plant in rich, well-drained soil in full sun or partial shade. Remove seed heads to prevent leaves from becoming bitter. Mix leaves with other greens for salads, or add them to soups or cooked dishes.

While you're giving some thought to wider paths, how about setting aside a small area for a bench? That will encourage you to indulge in a pleasure that gardeners all too seldom allow themselves—looking up from their work to enjoy the birds, the sky, or even the prim topography of the garden beds themselves. You might choose a spot that gets a bit of afternoon shade from a nearby tree. Or attach a canvas beach umbrella to a fence post next to the bench. The only trick is to remind yourself to take a break every hour or so. One way to do that is to keep an inexpensive nonelectric kitchen timer under the bench. Give it a twist to 60 minutes before you get to work, and wait for the recess bell.

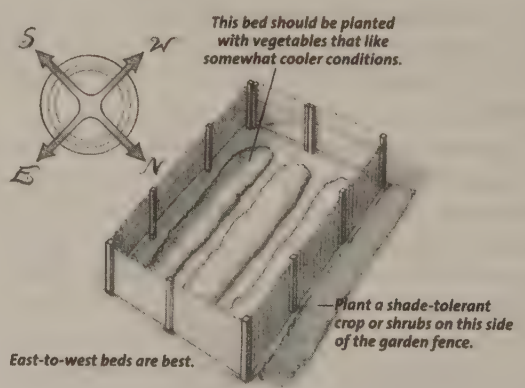
All gardening and no play may not be the best way to approach your hobby. Consider setting aside a corner of the garden, and a few minutes, to enjoy the sights and sounds of your yard.

Plan a Root-Friendly Bed

Carrots, parsnips, beets, potatoes, and turnips thrive in a deep, sandy loam. If you want to be successful with them, it's important to modify heavy soil with sand and lots of organic matter—if you have access to it, 10 pounds of compost for a 10-foot-square bed. Vigorously double-digging a clay-rich soil will also help to aerate and break it up.

All of this is easier written about than done. It may seem like a Herculean task to convert the entire garden to being root-crop friendly, so concentrate on just one bed and dedicate it to deep growers. Either improve the existing soil, or build up a raised bed to establish a better growing medium from scratch. Take care to avoid walking on the bed, or you run the risk of compacting the soil. A footstep exerts between 6 and 10 pounds per square inch—and tiptoeing across the beds won't help.

A broadfork allows you to aerate the soil without bringing up slumbering weed seeds from below.



S
W
E
N
This bed should be planted with vegetables that like somewhat cooler conditions.
Plant a shade-tolerant crop or shrubs on this side of the garden fence.
East-to-west beds are best.

Most yards have different levels of sunlight and shade, at different times of day. Try to position your plants to take best advantage of what the sun has to offer, keeping in mind the shade cast by fences and taller crops.

Gardening by the Compass

Full sunlight is recommended for most plants, as the informative blurbs on seed packets so often remind us. All-day, blazing sunshine will bring out the best in tomatoes and peppers and corn. Vegetables will reap the most solar benefit if growing in east-to-west rows. Alternatively, you can moderate light levels by planting north-to-south and arranging to have taller plants provide shade from the south end of the bed. If you are encircling the garden with a picket fence, it's also possible to use it as a light filter for lettuce and other plants that don't take to hot conditions. Grow them in the row running parallel to the south-facing side. Another such crop can be grown outside the north-facing side if it isn't vulnerable to the animal pests that caused you to put up the fence in the first place.

Gardening in Shady Places

If there are few places in your yard that offer the "full sun" requirement given for many plants, be assured that this condition isn't necessarily meant to be taken literally. After all, only desert dwellers and beachcombers are likely to be entirely free of shadows from hills and trees. Eight to 10 hours of sunlight should be sufficient, even for lumen-loving tomatoes and peppers. And if your garden is blessed with just 5 hours of sun a day, you're in great shape to grow outstanding salad greens, as well as arugula, broccoli raab, chard, collards, kale, parsley, spinach, and an enormous variety of Asian greens. You might also tuck in a few shade-tolerant shrubs for fruit, such as gooseberry, currant, and blueberry.

7 Secrets for a High-Yield Vegetable Garden

Vicki Mattern

Imagine harvesting nearly half a ton of tasty, beautiful, organically grown vegetables from a 15 x 20-foot plot, 100 pounds of tomatoes from just 100 square feet (a 4 x 25-foot bed), or 20 pounds of carrots from just 24 square feet.

Yields like these are easier to achieve than you may think. The secret to superproductive gardening is taking the time now to plan strategies that will work for your garden. Here are seven high-yield strategies gleaned from gardeners who have learned to make the most of their garden space.

1. **Build up your soil.** Expert gardeners agree that building up the soil is the single most important factor in pumping up yields. A deep, organically rich soil encourages the growth of healthy, extensive roots that are able to reach more nutrients and water. The result: extralush, extraproductive growth aboveground.

   The fastest way to get that deep layer of fertile soil is to make raised beds. Raised beds yield up to four times more than the same amount of space planted in rows. That's due not only to their loose, fertile soil but also to efficient spacing—by using less space for paths, you have more room to grow plants.

   Raised beds save you time, too. One researcher tracked the time it took to plant and maintain a 30 x 30-foot garden planted in beds, and found that he needed to spend just 27 hours in the garden from mid-May to mid-October. Yet he was able to harvest 1,900 pounds of fresh vegetables—that's a year's supply of food for three people from about three total days of work!

   How do raised beds save so much time? Plants grow close enough together to shade out competing weeds, so you spend less time weeding. The close spacing also makes watering and harvesting more efficient.

2. **Round out your beds.** The shape of your beds can make a difference, too. Raised beds are more space efficient if the tops are gently rounded to form an arc, rather than flat. A rounded bed that is 5 feet wide across its base, for instance, will give you a 6-foot-wide arc above it—creating a planting surface that's a foot wider than that of a flat bed. That foot might not seem like much, but multiply it by the length of your bed and you'll see that it can make a big difference in total planting area.

   In a 20-foot-long bed, for example, rounding the top increases your total planting area from 100 to 120 square feet. That's a 20 percent gain in planting space in a bed that takes up the same amount of ground space! Lettuce, spinach, and other greens are perfect crops for planting on the edges of a rounded bed.

3. **Space smartly.** To get the maximum yields from each bed, pay attention to how you arrange your plants. Avoid planting in square patterns or rows. Instead, stagger the plants by planting in triangles. By doing so, you can fit 10 to 14 percent more plants in each bed.

   Just be careful not to space your plants too tightly. Some plants won't reach their full size—or yield—when crowded. For instance, when one researcher increased the spacing between romaine lettuces from 8 to 10 inches, the harvest weight per plant doubled. (Remember that weight yield per square foot is more important than the number of plants per square foot.)

Continued →

Overly tight spacing can also stress plants, making them more susceptible to diseases and insect attack.

4. **Grow up!** No matter how small your garden, you can grow more by going vertical. Grow space-hungry vining crops—such as tomatoes, pole beans, peas, squash, melons, cukes, and so on—straight up, supported by trellises, fences, cages, or stakes.

   Growing vegetables vertically also saves time. Harvest and maintenance go faster because you can see exactly where the fruits are. And upward-bound plants are less likely to be hit by fungal diseases, thanks to the improved air circulation around the foliage.

   Try growing vining crops on trellises along one side of raised beds, using sturdy end posts with nylon mesh netting or string in between to provide a climbing surface. Tie the growing vines to the trellis. But don't worry about securing heavy fruits—even squash and melons will develop thicker stems for support.

5. **Mix it up.** Interplanting compatible crops saves space, too. Consider the classic Native American combination, the "three sisters"—corn, beans, and squash. Sturdy cornstalks support the pole beans, while squash grows freely on the ground below, shading out competing weeds. This combination works because the crops are compatible. Other compatible combinations include tomatoes, basil, and onions; leaf lettuce and peas or brassicas; carrots, onions, and radishes; and beets and celery.

6. **Succeed with successions.** Succession (or relay) planting allows you to grow more than one crop in a given space over the course of a growing season. That way, many gardeners are able to harvest three or even four crops from a single area.

   For instance, an early crop of leaf lettuce can be followed with a fast-maturing corn, and the corn followed by more greens or overwintered garlic—all within a single growing season.

   To get the most from your succession plantings:

   - Use transplants. A transplant is already a month or so old when you plant it, and so will mature that much faster than a direct-seeded plant (one grown from seeds sown in the garden).
   - Choose fast-maturing varieties.
   - Replenish the soil with a ¼- to ½-inch layer of compost (about 2 cubic feet per 100 square feet) each time you replant. Work it into the top few inches of soil.

7. **Stretch your season.** Adding a few weeks to each end of the growing season can buy you enough time to grow yet another succession crop—say a planting of leaf lettuce, kale, or turnips—or to harvest more end-of-the-season tomatoes.

   To get those extra weeks of production, you need to keep the air around your plants warm, even when the weather is cold, by using mulches, cloches, row covers, or coldframes.

   Or give heat-loving crops (such as melons, peppers, and eggplants) an extra-early start by using two "blankets"—one to warm the air and one to warm the soil in early spring. About 6 to 8 weeks before the last frost date, preheat cold soil by covering it with either infrared-transmitting (IRT) mulch or black plastic, which will absorb heat. Then, cover the bed with a slitted, clear plastic tunnel. When the soil temperature reaches 65° to 70°F, set out plants and cover the black plastic mulch with straw to keep it from trapping too much heat. Remove the clear plastic tunnel when the air temperature warms and all danger of frost has passed. Install it again at the end of the season, when temperatures cool.

Forecasting a Freeze

Even the best computer model used by professional weather forecasters can't predict just what a cold night might hold for your garden. Learn to look for signs of frost, in the sky and on the ground.

- Look up. A clear sky means there's no cloud cover, which can serve as an insulating blanket to help keep the earth's warmth from escaping to the heavens.
- Wet a finger. If you don't detect a breeze, that favors a frost.
- Feel the lawn. If the grass is relatively dry, not dewy, frost will be more likely.
- Read the thermometers, plural—not just one, but a few placed around the property. The temperature on your back porch may be significantly different from the reading you'd find in the garden.
- If you get a 10:00 p.m. reading of lower than 45°F and the above signs indicate trouble, cover up crops in the ground and bring in potted plants.

Foiling the Frosts of Fall

When the air gets nippy on fall nights, don't give up on your garden without trying a couple of easy ways of protecting the plants. After all, you've already done the hard labor of preparing the soil and pampering the garden.

EVENING DRESS FOR THE GARDEN

As any hibernating animal or insect could tell you, the ground remains warmer than the air as night comes on. You can take advantage of the soil's warmth by placing covers over plants in the evening. Just about anything you have hanging about the house or garage will work: old sheets and blankets, plastic tarps, newspaper, and even overturned cardboard boxes. The results aren't pretty, and you have to remember to remove the covers the following morning. Or, you can buy lightweight floating row covers of spun polyester and bump up the plant's microenvironment from 2° to 5°F. They're easy to lay down, and can be rolled up in a jiffy.

WATERING FOR WARMTH

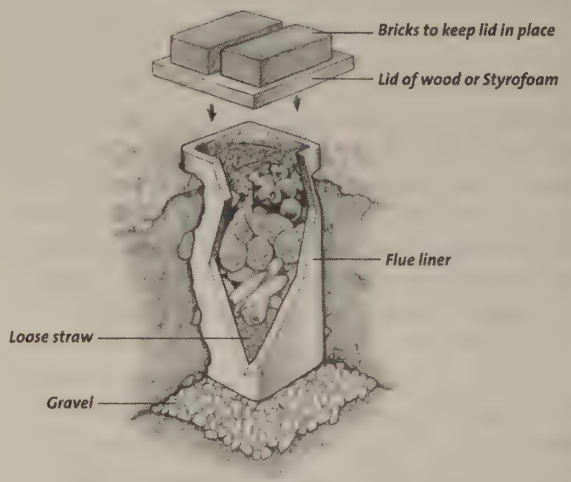
Your neighbors might think it strange to see you out watering the garden on a cool, dark fall evening. If so, reassure them by explaining that crops can be protected from an early frost by putting more moisture in the air around them. Wet soil also is potentially able to hold considerably more heat than when it is dry.

CHEER UP CHILLY PLANTS WITH CHRISTMAS LIGHTS

The Colorado State University Cooperative Extension suggests that as fall turns frosty, you get out the Christmas lights a little early. Suspend a string of lights from the hoops of a hoop house and turn them on at dusk. Not only will the structure take on an unearthly beauty, but plants will benefit from the gentle, evenly dispersed source of heat.

Catch This Winter Flue

It used to be that gardeners routinely stored root crops in their cool basements. But that option is out if you keep this level of the home nice and cozy through the winter. If so, try sinking a section of terra-cotta flue liner in the garden and using that for storage. To ensure good drainage, place a few inches of gravel in the bottom of the hole you dig, followed by a couple of handfuls of loose straw to keep the crops clean. Then put the flue in place and carefully lower vegetables into it—beets, cabbage, carrots, kohlrabi, parsnips, potatoes, rutabagas, and turnips. Add more loose straw to fill the air space. Top off the flue with a lid of wood or Styrofoam insulation, weighted with bricks or a flat stone. When temperatures drop well below freezing, you can replace the bricks or stone with a bale of straw for better insulation.



Root crops take form underground, and after harvest you can preserve their goodness by returning them to the soil. A sunken length of terra-cotta flue liner acts as a mini-root cellar, keeping vegetables at a nearly steady temperature into the winter months.

Perpetual Edibles

Roger Yepsen

Until not all that long ago, you'd expect a good-size American backyard to have at least a few perennial crops: asparagus, rhubarb, and horseradish, as well as all manner of berries and a fruit tree or two. For example, a 1927 book on root crops said about horseradish that "a few clumps are found in nearly every home garden."

Landscaping and gardening fashions change, and traditional perennial vegetables are often overlooked today. But they deserve consideration. Once planted, asparagus, rhubarb, and horseradish can be counted on to perform year after year without demanding much of your time. Choose the site with care, because you're planting for the long term. As with many garden crops, this trio prefers well-drained soil with plenty of organic matter. Rhubarb leaves and the lacy tops of asparagus look attractive throughout much of the growing season, so you might give some thought to placing these plants in a relatively visible site. Horseradish is no beauty, however, and it's apt to wander intrusively, so many gardeners park it in a spare corner of the yard rather than in the garden.

Rhubarb, the Fruity Vegetable

In an era of larger backyards, rhubarb was as common as barbecue grills are today. It's still worthwhile growing, especially to provide a tart counterpoint to strawberries in pies and jams. Plant it once, and you won't have to worry about it for a decade, at which time you may want to restore its vigor by dividing the clump. Older stands of rhubarb become less productive and may send up more flowering stalks, which

Continued ➔

should be cut off as they appear to avoid sapping the plant's energy.

Choose a site that gets full sun. The plants are started from crowns because rhubarb doesn't grow true from seed. Either buy crowns from a nursery or beg a few from a gardening friend. In early spring, plant the crowns with their budding tops just 1 inch below the surface. Top dress with compost each following spring for best performance. And hold off harvesting for at least 2 years, allowing the plants to get established. Begin a normal harvest in the fourth year, cutting stalks that are at least 1 inch in diameter and allowing the rest to grow.

Planting Asparagus without a Backhoe

Well, it's not really necessary to bring in heavy equipment to make an asparagus patch. But you might not know that from reading traditional planting advice for this crop, with directions typically calling for a hip-deep trench. In the venerable *Gardening for Pleasure*, published in 1886, horticultural authority Peter Henderson recommended planting rows totaling 300 to 360 feet to feed an average family. "Pleasure" indeed! Instead, if your soil is reasonably good, you can get away with making a much more modest trench. And in exchange for your labor, you can look forward to 20 to 25 years of harvests.

Gardeners now have their choice of all-male varieties that dramatically outproduce old standards such as 'Mary Washington'; look for 'Jersey Giant,' 'Jersey Knight,' and 'Jersey Pride,' among others. Choose a site with full sun, keeping in mind that the tall ferns will cast shade later in the season; if you are planting alongside the vegetable garden, place the asparagus bed to the west (to filter hot afternoon sun) or to the north.

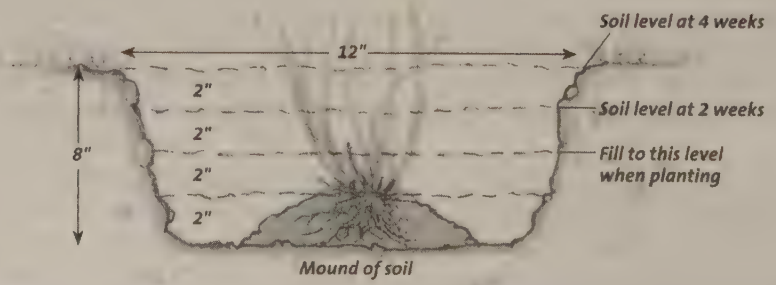
Set out plants in spring, after the chance of frost is past. Typical spacing is 1½ to 2 feet between plants, and 3 to 4 feet between rows. Make the trenches 8 inches deep and 12 inches wide. Perch the crowns atop 2-inch-high mounds of soil, spreading out their roots in every direction. Cover the crowns with 2 inches of soil. Then add another 2 inches in a couple of weeks, and fill the trench to ground level 2 weeks after that. Every year, treat each row to a 1- or 2-inch layer of compost or aged manure and work it into the top foot or so of soil. Come the end of the season, cut down the dried foliage with a mower or scythe and distribute a layer of leaf mulch for protection through the winter.

Putting a Harness on Horseradish

Those little jars of store-bought grated horseradish tend to get lost in the refrigerator, and unfortunately, the characteristic zippy flavor doesn't last for long. You can have your own fresh supply simply by tucking a root or two in an edge of the garden. Somewhat simply, that is. Horseradish loves to roam. Once you establish horseradish, you can't very easily get rid of it.

Planting is usually in March or April. You might want to experiment with a couple of different varieties, available as small roots from mail-order sources (horseradish doesn't grow easily from seed). Or start plants with supermarket roots; they aren't treated to keep them from sprouting as potatoes tend to be. Divide the crown into four pieces, each with some root and some of the leafy top, and allow the cuts to heal for a few days. Set roots or pieces at a 45-degree angle, with the top about 2 inches below the surface. Horseradish is best harvested after a couple of good frosts have improved the flavor. You can keep the roots in the ground through the winter, digging them as needed until just before the tops begin growing again in spring.

To prepare horseradish, wash and peel the roots, then grind them in a food processor with white vinegar and salt to taste. Vinegar helps moderate the root's pungency by slowing the release of key enzymes. For a lovely magentatinted horseradish, toss in a bit of beet. For a creamy condiment to accompany beef, mix in mayonnaise with the prepared horseradish.



Plan a Frostbite Bed

Nothing gladdens a gardener's heart more than crops that sail right through the frosts of fall. Kale, spinach, Swiss chard, beets, carrots, potatoes, turnips, radishes, broccoli, cauliflower, Asian greens, and some lettuces—these may come into their own when the rest of the natural world is settling down for its winter-long snooze. Come spring, you'll find it easier to cultivate and plant for the new season's crops if these over-winterers are growing in their own dedicated part of the garden. So place them with a view to the year ahead.

Growing Better with Age

Here is a rundown of vegetables that go against the rule that fresh is best.

- Some winter squashes will develop their full flavor in the weeks after harvest, including butternut and buttercup.
- Carrots and parsnips may benefit from a light frost.
- Freezing temperatures may bring out the full character of many brassicas: kale, cauliflower, Brussels sprouts, kohlrabi, cabbage, turnips, and rutabagas.
- Garlic right out of the garden will taste like garlic. But if the heads are cured and stored for a time, their full flavor will have a chance to develop.

A Hoop Skirt Keeps Gardens Growing in Good Fashion

While a floating cover will indeed rest lightly on the plants below, you can trap more warm air within a row cover that's elevated by hoops. And just about the easiest hoops to erect are lengths of 9-gauge wire. You can buy coils of it from home and garden centers, as well as mail-order seed and vineyard supply companies. To size hoops for a bed's particular width, experiment with how long a curving piece of wire you'll need, including enough to sink the ends firmly in the soil. Keep the cover in place with anchors made for the purpose or simple V-shaped pieces cut from coat hangers.

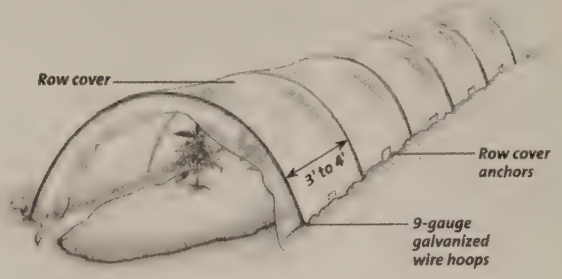
Row covers offer a number of benefits.

- By trapping heat from both the sun and soil, they can protect plants from frost, elevating temperatures by 2° to 7°F.
- They warm the soil and the air in spring, getting plants off to a quicker start, which means faster germination, better root growth, and an earlier-maturing crop (beating the performance of black plastic mulch by 1 to 3 weeks).
- You may get a better yield from a number of crops, especially cukes, squash, and melons.
- The covers serve as a barrier to flying insect pests. Not only will the plants be nibbled less, but you can spare them from diseases commonly spread by bugs. Expect to have good results against such pests as cabbage moths and the cabbage root maggot fly; various flea beetle species on several vegetables; spinach leaf miner; striped cucumber beetle on melons, summer and winter squash, and pumpkins, as well as cukes; European corn borer; Colorado potato beetle on potatoes and eggplant; and potato leafhoppers.

Note that in some circumstances, a row cover can aggravate pest problems, if an insect pest manages to find its way under the cover and then reproduces freely without interference from beneficial insects on the outside. If you see this happening, consider removing the cover temporarily to admit the good bugs. A row cover may also protect pests that have overwintered in the soil below. Again, you may need to pull back the row cover for a time. And consider rotating crops each year so that when pests come out of dormancy, they'll find a barrier between themselves and their target vegetable.

There's another sort of pest to consider when using row covers—mice. If you don't take the trouble to store the fabric at the end of the growing season, you're apt to find that mice have made good use of it for making nests.

- By placing 50-percent shade cloth over the hoops in hot weather, you may be able to grow lettuce right through the dog days of summer; the green cloth can lower temperatures by 3° to 6°F.



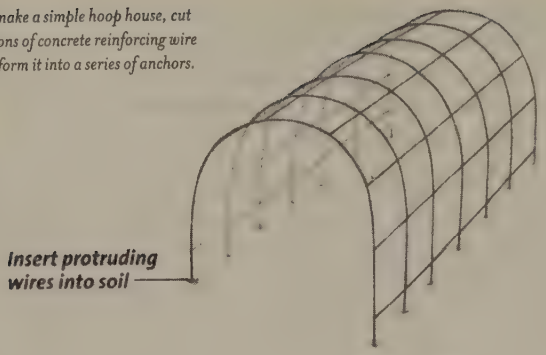
There's nothing much to this plant protecting system—just wires and lightweight spun fabric—but the climate change within the covering is significant.

A Sturdier Hoop House

For a hoop house that gusty weather won't topple, buy a roll of concrete reinforcing screening. It's available through companies that sell concrete supplies. The wire is tough stuff, and you'll need bolt cutters to snip through it. Cut pieces to bend into tunnel-like sections, leaving protruding wires so that you can anchor the sections in the soil. Place the sections side by side, to cover rows of any length. Then drape floating row covers over this hoop house. Tomatoes and peppers will flourish in this environment. Coddle them for up to a month, at which point they'll be outgrowing their house. Then remove the screening and cloth and set them aside for use as a late-season cover-up.

Continued ➔

To make a simple hoop house, cut sections of concrete reinforcing wire and form it into a series of anchors.



Grow Your Own Calcium

Garden vegetables might not look like good sources of calcium—they don't lactate, after all. But a number of crops can deliver a considerable measure of this nutrient. That's a particular plus for people with lactose intolerance. Here's a look at what a 1-cup serving of these cooked vegetables will contain. (To put these numbers in perspective, 1 cup of milk contains 300 milligrams of calcium, and 1 cup of low-fat yogurt contains approximately 400 milligrams.)

Vegetable	Milligrams of Calcium Per 1 Cup (cooked)
Rhubarb	348
Collards	266
Turnip greens	197
Kale	179
Okra	177
Beet greens	164
Pak choi	158
Dandelion	147

A Body-Building Protein Garden

For many people (gardeners included), vegetables still have the reputation of being a "good-for-you" food to be eaten dutifully along with real food—meat and dairy products, which are good sources of protein. In fact, a number of crops can pump you up with substantial amounts of that nutrient. Vegetables should figure importantly in a well-rounded, healthful diet. And as a gardener, you are guaranteed a fresh and unadulterated source.

The big surprise in this chart, unless you are a nutritionist, may be that some leafy greens pack a protein punch. All of this is good news for people who are trying to lower their intake of cholesterol-rich foods. By the way, to put the numbers in perspective, 100 grams of broiled beefsteak would give you about 22 grams of protein.

Vegetable	Grams of Protein Per 100-Gram Serving
Pumpkin seeds	29.0
Peanuts (raw, without skins)	26.3
Adzuki beans (raw)	20.0
Soybeans (dried, cooked)	11.0
Soybeans (green, cooked)	9.8
Lentils (cooked)	9.0
Fava beans (green, raw)	8.5
Peas (green, cooked)	5.4
Kale (cooked, no stems or midribs)	4.5
Brussels sprouts	4.2
Collards (cooked, without stems)	3.6
Spinach (raw)	3.2
Broccoli (cooked)	3.1

Foul Air in the Fridge

The whole idea of storing vegetables and fruits in the fridge is to keep them tasting fresh, but foods in close juxtaposition may taint each other. Peter A. Ferretti, PhD, a Penn State professor of vegetable crops, has identified the most prevalent cases of flavor swapping. He suggests storing apples and potatoes in a cool garage rather than refrigerating them. Keep sensitive items as far as you can from whatever bothers them. Use up older stock first, before it can take on off flavors. And place a box of baking soda in the refrigerator to absorb odors. From time to time, skim off the top layer of powder to expose the fresher product below.

- Carrots affect celery.
- Green peppers affect pineapple.
- Onions affect apples, celery, and potatoes.
- Potatoes affect apples and pears.
- Apples affect cabbage, carrots, onions, and dairy.
- Pears affect cabbage, carrots, celery, onions, and potatoes.

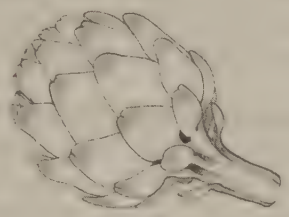
SOME VEGETABLES LIKE IT WARMER

Most vegetables you bring in from the garden will have a longer storage life if kept in the refrigerator just above freezing, or from 34° to 40°F. This slows the enzyme action that results in a loss of flavor and change in texture. By the way, the chilliest section of most refrigerators is at the back of the uppermost shelf. Still, there are important exceptions to the colder-is-better rule. Crops that originated in tropical or subtropical climates don't take to being stored below 50°F, including cucumbers, squash, tomatoes, peppers, eggplant, snap beans, and potatoes. Store them in a cool place rather than the coldest part of the fridge.

Artichokes for Cool Climes

Unless you live in California, chances are you get your globe artichokes at the supermarket rather than from your backyard. But with some care, they can be grown over much of the United States. Even if the crop isn't overwhelmingly generous, there is no disputing the majesty of the plants, which can reach a height of 4 feet and will form big thistlelike blossoms if allowed to.

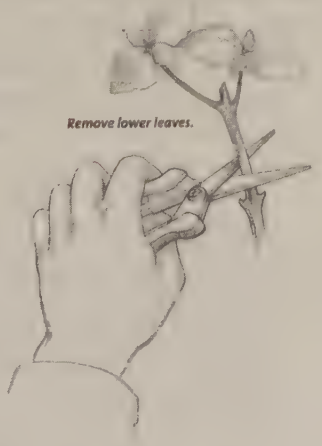
Globe artichokes are cultivated as perennials in warm areas, but they will be done in by winter temperatures below 20°F. If you will be growing artichokes as an annual, 'Imperial Star' is a good variety. Start plants indoors about 8 weeks before your last frost-free date. They will produce better if subjected to a bit of vernalization, or exposure to cool temperatures. Bring the plants out to the garden soon enough that they will spend at least a week in temperatures around 50°F. Although artichokes tend to get off to a slow start once transplanted, they'll need plenty of space before long; allow 30 inches between plants. By July, you can expect to begin harvesting the small buds—small, but more tender than the big commercial ones.



If you have spare room in your vegetable or flower beds, try growing a couple of globe artichokes from seed. They'll be visually outstanding, as well as producing tender, flavorful chokes.

Basil Rescue Mission

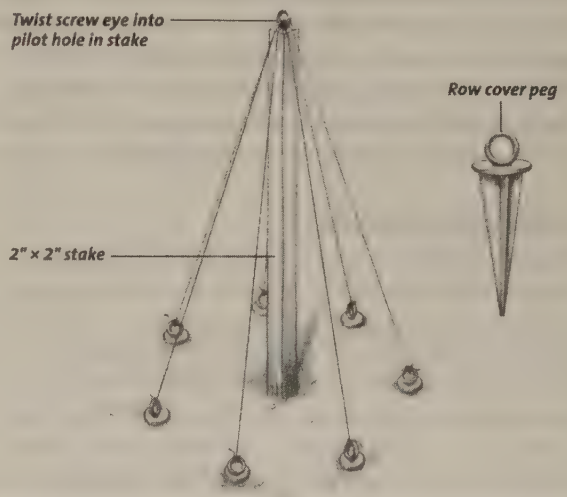
There's no grimmer harbinger of winter's approach than a row of frost-blackened basil. To enjoy this highly aromatic cook's friend through the winter, you might try to dig up a few of the busy plants and wrestle them into pots. But it's easier to take cuttings toward the end of summer. Remove the leaves from the lower end of the cuttings to prevent dehydration. Place the cuttings in a glass of water, then stick them in pots once they've grown roots. The clove-like scent will take you back to summer every time you touch the plants. Next spring, take cuttings from these windowsill basils and repeat the rooting process to have plants you can set out as soon as warm weather returns.



By taking cuttings, you can make clonal copies of your favorite plants, including those about to be done in by freezing weather.

String Climbers Along with a Maypole

Surround this pole with climbing edibles, flowering vines, or a mixture of both. To make it easier to remove the pole at summer's end and return it to the yard in spring, you can bury a length of pipe with a diameter just large enough to accommodate it, so that the top of the pipe is at ground level. Then all you have to do is slip the pole down the pipe, without needing to hammer while balanced on a stepladder.



To make the most of garden real estate, think vertical. This simple pole arrangement will encourage climbers to clamber up the twines radiating down to the ground.

1. While standing on a stepladder held firmly by a helper, pound a 6- or 8-foot-long, 2 x 2 wooden stake into good garden soil. To prevent mashing the stake, you can cut an X in a tennis ball and slip it over the top before hammering.
2. Drill a pilot hole in the top of the stake and twist in a threaded eye.
3. Run lengths of twine from the eye to pegs placed 2 to 3 feet out from the pole's base. You can make pegs by cutting U-shaped hoops from coat hangers, but you'll be less likely to trip over or lose the brightly colored plastic pegs used for row covers.
4. Sow seeds or set out plants next to each peg.

AN EDIBLE ORNAMENTAL BEAN

Scarlet runner beans are a standout in the vegetable garden, producing showy blossoms that act as magnets for hummingbirds and butterflies. The large, shiny beans themselves are every bit as handsome in their own way, and they happen to taste good as well, with a flavor something like chestnuts. Even the flowers are edible, making an attractive addition to salads.

The vines need something to climb on—a maypole, trellis, arbor, or teepee of branches. Or you can snake them horizontally along a picket fence. Some gardeners even send them up tall-growing sweet corn.

Continued ➔

Stubby Carrots for Stubborn Soil

If carrots don't care for the density of your soil, try planting short varieties that won't stick their toes in very deep. 'Parmex' is a chubby ball-type variety that's just 1½ inches long at maturity. 'Kinko' is somewhat more conventional in shape, reaching a modest length of 4 inches by the time they're ready to pull. Short, stout 'Royal Chantenay' carrots will burrow their way down into heavy soil.

If you're stuck with unyielding soil, you can skip it altogether and grow short carrot varieties in pots. While you might be able to get away with as small as a 2-gallon pot, this crop will fare better if treated to a container holding 3 or even 6 gallons of soil. Remember that potted vegetables may need more frequent watering, especially if the pots are of clay and wick moisture.

Try This Artichoke Cousin

Cardoon is an odd-sounding and remarkable-looking relative of the globe artichoke. Preparing it for harvest is an unusual process as well. The stalks of the long, jagged leaves are the edible feature, not the flower buds. To keep the stalks tender, you blanch them once they reach a length of 18 inches or so. Tie the leaves at the top to bundle them, then wrap first with newspaper and then a layer of black plastic, or with burlap. After a month or so, remove this covering and cut the stalks below the crown. Strip off the outer leaves to reveal the blanched center of the plant.

Try sautéing stalks in butter to enjoy them as Italians do. Some cooks suggest simmering cardoons first in water with a bit of vinegar to bring out their best flavor. If you allow some of the plants to mature, they will display lavender flowers that are excellent for fresh or dried arrangements. Don't allow flowers to set seed and be scattered about, or you may have a nuisance on your hands.

Cardoon has a third use, beyond being attractive and tasty. It produces an enzyme that has been used by traditional cheesemakers in Portugal as a coagulant. To try it yourself, pick the flowers, dry them, weigh out about 1 ounce, and steep in a cup of warm water. Use 1 teaspoon per quart of milk to begin with, or more if needed to cause the milk to coagulate.

A CENTERPIECE FOR THE GARDEN

Most vegetable gardens are practical affairs laid out like tiny farm fields, with parallel rows and little thought to visual drama. For something different, try arranging the beds around a central feature. A cluster of three or so tall, commanding plants will do. Cardoon is a likely candidate, spreading its jagged-edged arms over a good area as it tops off at 6 feet or so. Other handsome edibles include globe artichoke and bronze fennel. Or, you can lash together a few 8-foot-long stakes, place them right in the middle of the central bed, and train runner beans up them. Shorter plants can make a bold statement, too, if grown in a super-size urn or pot set on a stump or other base to raise it up enough to stand out.

More Cukes, Better Cukes

Cucumbers aren't a very demanding crop, but they appreciate adequate watering and prompt picking.

DON'T PLUG UP CUCUMBER PRODUCTION

It's important to keep a close eye on the cucumber patch to make sure that you harvest the cukes at their peak. If you spot a yellow one that has gone past its prime, pick it promptly. Otherwise, the vine will tend to stall, putting no more energy into growing more fruits. Another reason to pick sooner rather than later is that plants harvested late in the season tend to yield bitter cukes.

AVOIDING BITTERNESS

Cucumbers react to stress by developing a bitter personality. There can be any of a few causes, including a run of hot days, insufficient moisture, low fertility, or foliar diseases. The off-putting taste is the work of compounds known as cucurbitacins; under difficult growing conditions, they migrate from other plant parts to the fruits. Make sure you water regularly in dry, hot spells. And look into resistant varieties; more than a half-dozen diseases can be dealt with by selecting cucumbers bred for resistance. Cucumber beetles spread pathogens as well as exercising their appetites, and they can be discouraged with a floating row cover. If you find that a particular plant is yielding bitter fruit, pull it, because its cukes won't get any milder; if the leaves show the white coating characteristic of powdery mildew, don't compost the rogued plant.

Corn: Sweet, Sweeter, Sweetest

Buying seed for sweet corn isn't quite as simple as picking up a packet of, say, Deer Tongue lettuce. That's because plant breeders have been fiddling with the genetic makeup of regular old corn, with very sweet results. These newer hybrids are classified as *normal sugary* (SU), *sugary enhanced* (SE), or *super sweet* (Sh2) varieties, as well as synergistic, which sounds frightening but only means that some kernels on each ear are SE and others are Sh2. Here are the characteristics of each group.

- Traditional sweet corn is open pollinated, meaning that you can collect seed for planting the following year—an option you don't have with the hybrids. Gardeners continue to grow old-fashioned varieties for the "corny" taste and substantial, chewy texture.
- The SUs are moderately sweet, compared to those described below. Because their sugars begin to turn into starch soon after picking, they must be eaten within a very short time. Ears have what can be called a traditional corn flavor, harkening back to a time before all these abbreviations appeared.
- Sugary enhanced varieties have a gene that raises the sugar content above that of SUs, with an excellent tenderness and a creamy texture. The ears are slower to convert sugars into starch. Small wonder that SEs are highly popular with home gardeners.

- Super sweet varieties are in fact the sweetest you can grow, and they have a crisp texture with the kernels popping as you bite into an ear. The lack of a traditional corn flavor may be a shortcoming to some people. Plantings should be isolated from other varieties that are tasseling at the same time because super sweets have weak pollen and may turn starchy and tough if pollinated by other types. A distance of at least 500 feet is necessary, because the pollen is carried by the wind.
- Each ear of a synergistic variety will have a mix of sugary enhanced and super sweet kernels to bite into, for a good blend of sweetness and tenderness. The sweetness comes on only as ears reach full maturity; otherwise they will taste watery. You can grow this variety alongside sugary and sugar enhanced rows, but quality will suffer if synergistics exchange pollen with super sweets.

OTHER CORN CODES

When sorting through the many varieties of sweet corn, you also should be familiar with other abbreviations. *Fl* means that the variety is a hybrid and it won't grow true from seed you collect from dried ears. Then there's resistance to common diseases: *NCLB* signifies resistance to northern corn leaf blight; *SCLB*, to southern corn leaf blight; *SM*, to smut; *SW*, to Stewart's Wilt; and *R*, to common rust.

Baby Corn for Stir-Fries

Baby corn is a novel sight in East Asian dishes—and not all that flavorful if it has been languishing in a tin can. Fortunately, it's not that difficult to grow your own. Begin with a variety that yields especially good, tender premature ears, including 'Baby,' 'Bonus,' 'Candystick,' 'Delectable,' and 'Jubilee.' Plant at a tighter spacing, from 2 to 4 inches apart, and keep a close eye on the developing ears to make sure you harvest them before they become too big. Allow no more than a couple of days after the silks first appear. By picking promptly, you also encourage the stalk to produce more ears. Keep the husks on the harvested babies until you're ready to cook them.

Grow Your Own Garlic

Garlic is undergoing a modest rediscovery, as people find out that not all varieties taste alike. Not that there's anything wrong with supermarket garlic. It's cheap. It tastes garlicky, too. But it is only one color in a spectrum of garlics. Have a look at the offerings of seed catalogs for varieties that have become favorites around the world. Some are mild, some assertive. Some keep especially well. Some are a good choice for roasting into a sweet pulp. Some are quite pretty, in rosy or purple hues.

Come next fall, tuck two or three varieties in the garden for the next year's crop, allow them to cure and then rest in storage for a while, and then compare their qualities and culinary talents. Choose from between softneck varieties for good storage and braiding, or hardneck for outstanding flavor.

Chinese Pink. For an early harvest, try this relatively mild-tasting softneck. Stick the cloves in the ground in fall, and you may have fresh-from-the-garden garlic by the following May.

Inchelium Red. Discovered on an Indian reservation in northern Washington State, this softneck garlic has a mild, highly rated flavor. It's particularly suited to baking into a soft pulp.

Polish Softneck. This heirloom has been grown in the United States for a century, remaining popular because of its winter hardiness, large cloves, and sharp taste.

Chesnok Red. Originally from the former Soviet republic of Georgia, Chesnok has a flavor that stands up well when cooked. Try baking this hardneck to make a spread for crackers.

Purple Glazer. Both the bulb and cloves of this lovely hardneck variety are a rich purple embellished with gold or silver. Like Chesnok, it's from the Republic of Georgia and is a good choice for baking.

Spanish Roja. This heirloom is described as having a definitive garlic flavor, which helps to explain why it remains popular year after year.

Getting to Know East Asian Greens

Asian greens come in many shapes and sizes, with tastes ranging from mild and sweet to pungent. These varieties grow quickly with little trouble, and they may keep producing well after hard frosts have sent other vegetables reeling. Many can be harvested either early for salad ingredients and braising mixes, or when full size for steaming and sautéing in a wok. Even the flowers, characteristically a cheerful yellow, make a pretty, edible addition to salads. The only potential problem is the confusing mix of names—English, Japanese, Thai, Chinese, Indian, and more, with a riot of different spellings. You can always go by the photos in catalogs and on seed packets.

Generally, these vegetables are sown directly into the garden from early spring into midsummer, with a second sowing when cool weather returns in early fall.

Pak choi. Also known as bok choy, this is a relatively familiar green, similar in appearance to chard, with a thick white stalk and mild flavor.

Autumn Poem. This is a flowering variety, similar to pak choi but with thick, flavorful stems and attractive flower buds.

Tatsoi. The dark green, spoon-shaped leaves grow in tidy, low-growing rosettes. You can sow this form of pak choi right into fall.

Red Giant and Osaka Purple. Grown for both salads and stir-fries, these mustards have spicy, colorful leaves. They may self-seed and reappear here and there in the garden.

Mizuna. Mizuna is a striking-looking mustard, with deeply toothed leaves and a relatively mild flavor.

Continued →

Komatsuna. Sometimes listed as spinach mustard, it matures quickly, with harvesting possible just 35 days after sowing.

Gai lon. Also called Chinese broccoli, gai lon has thick, flavorful stems. Cut the main stem, and others will branch out.

Hon tsai tai. This one is worth growing for its remarkable color as well as its mildly mustardlike zip. The stems are purple, becoming more vivid in cooler weather; the leaves are dark green; and the flowers bright yellow.

Eggplants in Easter Egg Colors

Try growing slim and modest-size East Asian or Italian varieties. They come in cheerful lavender and cream colors, in solids and stripes. The fruits and the plants themselves are attractive enough to earn a place in flower beds. The taste is agreeable, too: mild, with no hint of the bitterness we associate with the familiar big boys of the produce section. And because they're slim rather than rotund, they cook up quickly in a stir-fry without sopping up a lot of oil.

Go Wild with Kale

Seed companies take pains to provide you with packets that will yield dependable results. Most of the time, that is. Some mail-order firms sell seed for open-pollinated kale that hasn't been stabilized. It's a treat to see the varied forms and colors that spring up out of those apparently identical seeds. Frilly or plain edges, smooth or crinkly, big or small, green or multicolored—it's like looking at a little forest of different trees. Pick them young to add to salads, and you'll better be able to enjoy their distinctive looks than if they're cooked. If you have a favorite couple of kales, allow them to flower and go to seed, and save the seed for the following year. When you label the seed containers, don't be shy about coming up with a fanciful name for your rare variety.

A Lettuce Explosion

There's no explaining taste, in art or in lettuce. Profound changes in the use of lettuce and other salad crops have been taking place in the United States, western Europe, and several other parts of the world. The most surprising change has been the adoption of crisphead lettuce (also known as iceberg) in countries where it was hardly used before. In England, for example, people consumed mostly butterhead lettuce until the late 1970s. At that time, only about 3 percent of the lettuce used was of the iceberg type. Then, the British discovered iceberg lettuce, and it now composes about 80 percent of the lettuce consumed in Britain. Similar changes have occurred in the Scandinavian countries and are beginning in other countries as well.

On the other hand, we in the United States have rediscovered that not all lettuce heads are round, crisp, and hard and once again are eating romaine, butterhead, and leaf lettuces, not to mention endive and escarole (*Cichorium endivia*) and spinach (*Spinacia oleraacea*). In addition, we have discovered 'Little Gem,' a Latin-type lettuce, part romaine and part butterhead, which is small, crisp, and sweet. We have also discovered radicchio, a red Italian chicory (*c. intybus* L.); mizuna, a leafy vegetable from Japan (*Brassica japonica* L.); and rocket (*Eruca sativa* Mill.), formerly found in the wild, but now known in the cultivated form as arugula. Mizuna, arugula, and spinach are often found in a salad mixture called mesclun, which is made up of tiny lettuce leaves of various shapes and colors and other salad greens.

A CHILL PILL FOR BITTER LETTUCE

When lettuce is subjected to hot summer weather or begins to bolt, the leaves are apt to take on a bitter edge. You can sweeten lettuce somewhat by rinsing it and storing it in the refrigerator for a couple of days.

Jump-Start a Salad

The reputation of iceberg lettuce has taken a hit lately because of its famous blandness. But most lettuces are relatively mild-tasting; fortunately, you can perk up a salad by including homegrown greens from the genus *Cichorium*.

- **Chicory.** These full-flavored greens look a lot like the common dandelion and are sometimes referred to as Italian dandelion. Snip them young for salads, or later in the season for braising. If you allow a few to bolt, you'll be rewarded with the familiar sky blue chicory flower seen along roadsides.
- **Belgian endive.** Also known as witloof, this unusual vegetable has a double season. It starts out in the garden, developing a root. Then it is dug up and brought into a cool basement (from 50° to 60°F) for forcing in the winter. The traditional method is to stick them in a bucket of moistened sand, leaving the crowns exposed. A lid is placed over the bucket to exclude light, which would turn the forced leaves green and cause them to be bitter. The *chicons*, as the tight pale heads are known, are ready for harvesting after 3 to 5 weeks. If given a month or two to recover, the roots may produce a second harvest. Newer varieties can be forced without this ritual.
- **Radicchio.** Similar in appearance to a small head of lettuce, the heading radicchios are bright in color and spirited in flavor. Unlike most leafy greens, they can be grilled or roasted.
- **Escarole.** This European salad green has a somewhat bitter flavor. It will taste milder if blanched for a few days or a week before harvest; cover plants with overturned bushel baskets or pots, or simple A-frames of plywood. Or, with a bit of twine, you can tie up the outer leaves to shield those within from the sun. Escarole not only adds oomph and texture to salads, but can be braised with olive oil and a splash of balsamic vinegar.

- **Endive.** Distinct from Belgian endive (see above), this leafy green looks like a frilly lettuce but has a touch of the bitterness characteristic of this group and a more substantial texture. Those with deeply dissected leaves may be listed as frisee in catalogs.

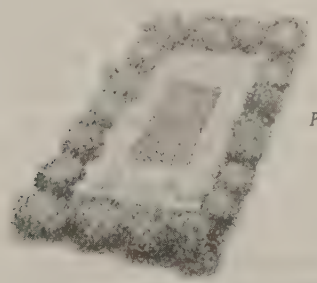
Purples and Golds to Go with Your Greens

To visually spike a salad of greens, toss in edible flower blossoms. Some contribute mainly color, while others add a novel taste. Pick the blossoms just before using them, and either include them in the mix or scatter them over the top of the heap. Soups are famously bland-looking and also will benefit from a garnish of pretty petals. Here is a crayon box of possibilities.

Edible Plant	Color
Borage	Blue
Calendula	Gold
Chives	Purple
Dianthus	Pink
Lavender	Purple
Nasturtium	Yellow, orange
Violet	Purple, yellow, white

Lettuce as an Ornamental

You may be the sort of no-nonsense person who views the garden as a source of good food. Period. But the range of colors and shapes now available in many crops suggests laying out beds with an eye to design. Lettuces, as an example, come in cool and hot colors, and in all sorts of shapes. Instead of sowing separate blocks of this or that variety, try alternating reds and greens, or tall lettuces and round ones. Another approach is to sow a pattern, perhaps a border of 'Red Sails' or 'Outrageous' lettuce surrounding cool green 'Deer Tongue,' which in turn forms a border around a speckled variety such as 'Freckles' or 'Forellenschuss.' For another pattern, divide a bed into equal-size diamonds. To keep the lines sharp between varieties, place boards along the edges of an area as you scatter seed. There's no practical benefit to planting this way—except that you may have the incentive to take more pleasure (and more care) in weeding and watering to maintain that bit of artful design.



Plant concentric rectangles with lettuces of contrasting colors.

For crisp lines between each area, place boards along the edges as you sow.

A Kinder, Gentler Jalapeño

If past experiences with hot peppers have scared you off, try growing a jalapeño with good flavor but less heat, such as Numex Primavera (supposed to pack just one-tenth the wallop), or the intriguingly named Fooled You, an F1 hybrid that looks like culinary dynamite but is devoid of heat.

And here's a tip if you've learned to be cautious around horticultural hotties. Grow truly hot varieties and milder ones in separate areas of the garden. It's all too easy to confuse the two once you have them on the kitchen counter.

Smoking Jalapeños

No, the idea isn't to light them up like ruby red cigars, but to preserve these peppers by drying gradually over a smoky, smoldering fire. The dried result is known as a chipotle. You can use a barbecue with a snugly fitting lid, starting with charcoal briquettes. Then switch to branches or chips of a hardwood such as hickory, ash, oak, or pecan, or a fruit wood such as apple. The wood can be soaked in water to help keep the fire at the moderate temperature necessary to avoid burning the peppers. Also make use of the vents to control the amount of air reaching the fire.

Rake the coals over to one side of the barbecue and place the stemmed peppers on the other side of the grill. Turn the peppers from time to time, and add wood as needed to maintain the fire. It's a slow process, taking at least several hours for the peppers to dry, so you are better off beginning early in the day. Store the cooled peppers in zippered plastic bags.

A Simple Ristra

Ornamental strings of red pepper ristras are a common sight around Southwestern and Mexican households. They're practical as well, allowing the peppers to air dry with little danger of mold forming. You'll need a lot of peppers—5 to 20 pounds of them if you want to make a 3-foot-long ristra, depending on the size of the variety. Possibilities include Anaheim, Cascabel, Cayenne, De Arbol, and Mirasol. The traditional method of stringing peppers involves tying them in bunches and then braiding individual strings along a length of twine. This version is a lot simpler: Just thread sturdy fishing line through the stems, tying the stem of the first pepper so that it will secure those above it. Make a loop at the top of the line

Continued ➔

so that you can hang the ristra. When you want to use a pepper, remove the uppermost one, rinse off any accumulated dust, and reconstitute it by dropping it in simmering water, then turning off the heat and allowing the pepper to sit for 10 minutes or so.

Pumpkins, Big and Fast

You can buy pumpkins for a song when fall comes around. But if you grow your own, the crop will lend a cheerful presence to the garden at a time of year when most plants have given up. When selecting varieties, keep in mind that some are grown primarily for their looks—color, shape, and size. Others are renowned for cooking, with sweet and flavorful flesh.

BUILDING A BIGGER PUMPKIN

Gardeners like to brag about huge tomatoes and moan about huge zucchinis. And there's a particular fascination with pumpkins the size of Cinderella's coach. Here are a few tips for growing the biggest pumpkin on the block.

- Select a variety known for size. A couple of favorites are 'Prizewinner,' a hybrid; and bigger still, Dill's 'Atlantic Giant,' which is a different species from the familiar *Cucurbit pepo*. The largest pumpkin on record is an Atlantic Giant weighing in at 1,469 pounds, but chances are your best effort will be in the range of 200 to 300 pounds. To order seeds right from the developer of Dill's himself, contact him at www.howarddill.com.
- Start early, sowing seed indoors 2 weeks before planting them in the garden.
- Give them plenty of room to roam, at least an area measuring 25 feet square. A jumbo may carpet more than 2,000 square feet with its foliage.
- Anchor them. Growing vines are vulnerable to strong winds. Pile up soil at nodes along the vines; this also has the benefit of encouraging the plant to put down secondary roots. Consider putting up a length of snow fence on the side of the pumpkin patch from which prevailing winds tend to blow.
- Focus the plant's energy by cutting off all but one of the developing fruits.
- To prevent the outer skin of the developing pumpkin from hardening before it reaches full size, put up a board or a section of fence covered with fabric to block the full force of the sun.
- Position them. As a big pumpkin grows, the stem tends to meet it at an increasingly narrow angle. Gently and gradually move the fruit so that the stem remains nearly perpendicular.
- Feed and water them. It stands to reason that a living thing this big has to have a good appetite. Continue to fertilize through the season. Trickle irrigation and soaker hoses are a good approach to watering because they will be less likely than overhead sprinkling to cause mildew problems.

Toward a More Perfect Pumpkin

Pumpkins may become somewhat misshapen if allowed to just park in one place and get huge. To help ensure that they'll develop a pleasing round shape, get into the routine of rotating them about a quarter of a turn every week or so. And if you would like the pumpkins to be really big as well as really round, plan ahead for their need to sprawl by placing the hills 25 feet apart.

PUNKIN' CHUNKIN'?

Fall is that time of year when people feel like picking up a pumpkin and seeing how far they can hurl it. Or, at least some people do. Delaware hosts the annual Punkin' Chunkin' competition in which contestants use all manner of contraptions to all but put that plump orange fruit into orbit. The record now stands at an astounding 4,331 feet, accomplished with an air cannon. According to contest rules, the pumpkins must weigh between 8 and 10 pounds—no Baby Boos allowed. Pumpkins don't always fly straight and true; if it strays in flight, the competitors who fired it have 3 hours to locate it.

Edible Ornamental Winter Squashes

These brilliantly colored squashes make excellent autumn decorations—forget the fake colored leaves and the phony Halloween cobweb effect. Here's a rundown of the prettiest.

- 'Sweet Dumpling' has a brilliant patterning of dark green against warm white. Each squash has enough scrumptious flesh for one serving.
- 'Carnival' is a harlequin among dumpling-type squashes, with a riot of color. A cooler summer will help bring out the schoolbus-yellow coloring. The flavor is considered to be not quite up to the par of 'Sweet Dumpling.'
- 'Cream of the Crop' acorn squash not only is an attractive cream color on the outside but also offers creamy textured flesh within.
- 'Table Gold' acorn is a diverting golden color.
- 'Turk's Cap' is more of a novelty than a culinary favorite, but it works well in soups.
- 'Sunshine' is a Scarlet Kabocha that does seem to bring rays of sunlight into the garden and onto the windowsill.
- 'Orangetti' is a new, brightly colored version of the standard spaghetti squash. As its color suggests, this variety delivers far more beta-carotene. It also has a sweeter flavor and cooks in less time.

You don't need to buy seeds to have an interesting array of winter squashes in the garden. Supermarkets often carry a colorful selection, and you can choose the most attractive, then taste-test them at home before committing the considerable

garden space that they require. Scoop out the seeds, spread them out on a few thicknesses of paper towel to dry, then store in sandwich bags on which you label the variety.

Oven-Dried Tomatoes

Rather than stand over a hot stove stirring tomatoes down into a sauce for canning, you can let the oven do most of the work of preserving them, by drying. Choose a meaty paste tomato, such as the widely grown San Marzano. Slice them in half the long way, remove the seeds, and place the halves on cake racks set on baking sheets. Sprinkle with salt. Place them in the oven, using just the pilot light if you use gas or a setting of about 150°F for an electric oven. The tomatoes will need anywhere from 8 to 24 hours to dry to a pliable state. Pack the dried halves in glass jars, pouring in olive oil to displace the air as you do so. Tuck in garlic cloves, basil, or oregano if you wish.

Fight Anthracnose on Tomatoes

Anthracnose is a soil-borne disease that causes round, sunken spots on tomatoes. These indentations eventually turn black at the center as fungal fruiting bodies are formed. Plants are especially prone to the affliction if you haven't been regularly rotating tomatoes and peppers with other crops.

Although anthracnose can be bothersome to home gardeners, you can stay a step ahead of it with a simple barrier technique. Lay two or three sheets of newspaper on the soil around tomato plants. Lightly moisten the paper, then top with 2 or 3 inches of grass clippings. This traps the disease spores in the soil and prevents them from splashing onto plant leaves during irrigation or rain.

Spaghetti Sauce Shortcuts

Here are a few ideas to take some of the time (and steam) out of the job.

- It's not necessary to have special-purpose sauce or paste tomato varieties to simmer down a great-tasting sauce. But it helps. That's because San Marzano, Roma, and other sauce favorites contain relatively less moisture. That means you spend less time standing over a hot stove at summer's end, waiting for the water in juicier tomatoes to go off as steam.
- You don't have to convert the entire harvest into hot-packed sauce for use months later. Enjoy fresh sauce right now. Begin by getting a start on dinner early enough to allow at least an hour of simmering with the lid off to thicken the sauce. You can speed things up by spooning off clear liquid from the top; reserve this liquid for use in soup stock.
- Why not do your sauce simmering when the weather isn't simmering? Run tomatoes through a strainer as you would normally, then place them in plastic containers and freeze. Label the containers as tomato juice, rather than sauce, so that you'll know they still need to be cooked down before ladling them over pasta. When the weather turns cooler and you won't mind the added heat and humidity, take the containers out of the freezer for further processing.

Tomatoes All through the Winter

A 6-inch pot will be large enough to grow a plant, although a bigger pot will need watering less frequently and you may see more vigorous growth. Varieties to try include 'Healani,' 'Pixie,' 'Small Fry,' and 'Tiny Tim.' Although the plants will be small, they still may need to be staked when fruits appear. Don't forget to rotate the plants so that all sides will benefit from direct sunlight.

You may have to play the role of pollinating insect once the plants develop their yellow blossoms. Just give the branches a gentle tap with your finger to help broadcast the pollen. Look for this dust around blossoms as you jiggle the plant.

Windowsill Tomatoes

You're better off with a small variety such as 'Pixie,' 'Small Fry,' or 'Tiny Tim.' Start seeds, transplant seedlings to pots placed in the window, and fertilize moderately. When watering, make sure the full depth of the pot is moist. As plants develop, support them with sticks poked into the growing medium. A fluorescent light fixture, placed just above the plants, will help to ensure that you get a crop. Rotate the plants so that all sides are treated to a sun bath. Once blossoms appear, tap the plants to help distribute the pollen.

Try These Members of the Tomato Family

Here are a couple of members of the tomato family that are easy to grow, are fun to look at, and have a hint of the flavor of their better-known relative. Their flavor is part vegetable and part fruit, and you can use them in both savory sauces and desserts.

GROUND CHERRIES

For something completely different, experiment with ground cherries, also known as husk tomatoes and Cossack pineapple. Whatever you call them, these old-time treasures offer a novel appearance, with a husk concealing the "cherry," which is in fact a tomato relative. The berry may be yellow, orange, or red, and it's edible, with a distinctive flavor that varies from one variety to another. You might notice a suggestion of pineapple, tangerine, or even vanilla. Start them indoors a week or so before you sow tomatoes. Pick the berries when they develop full color for eating fresh or cooking down into a salsa, jam, pie filling, or ice cream topping.

TOMATILLOS

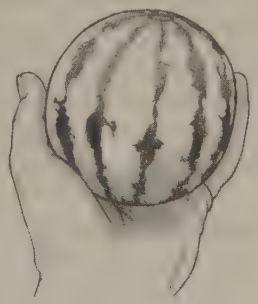
You may associate them with Latin American cooking, but chances are that tomatillos will thrive in your garden. They

Continued →

aren't very demanding, and cook down quickly into delicious homemade salsas that will put supermarket versions to shame. Start them in flats a week or two after you do tomatoes. When the husks turn thin and papery, harvest the fruits. Chop them up and simmer with onions, sauce tomatoes, bell pepper, and cilantro to make a simple sauce for use as salsa or pasta topping. You can grow familiar green varieties, or try purple ones for a special fruitlike flavor.

Personal-Size Watermelons

A big monster of a watermelon is great for a picnic or backyard party, but there may be just too much juicy goodness for a small household. Try growing one of the new modest-size melons, weighing in as low as 2 pounds and closer in size to a softball than a bread box. They not only take up less space in the refrigerator, but also hog less real estate in the garden. Pint-size varieties are available with brilliantly colored flesh in yellow, orange, even a sherbet-colored mix of yellow and pink. The rind is apt to be thinner, meaning a greater percentage of the watermelon is edible.



With tomatoes, it seems bigger is better, but that's not necessarily the case with melons. Plant breeders have come up with mini-melons that are cute, flavorful, and easy to stash in the refrigerator.

Hot Harvest Tip: Cool It!

Snip a head of broccoli or pick a snow pea, and this disconnected plant part continues to live and breathe—but not in a way that improves its quality as something to eat. Enzymes convert sugars to starch. Cells lose moisture, so that crisp becomes flaccid. The plants put off ethylene gas, which hastens the ripening of nearby harvested crops. Flavors and scents depart, too. You can't arrest these natural processes, but you can slow them down by chilling vegetables and fruit as soon as they are picked. That doesn't mean sprinting back to the house to toss your haul into the fridge. But if you'll be in the garden for any length of time, you can place a picnic cooler in a garden cart with a bit of ice, and trail that with you while harvesting. Or harvest early in the morning, before the day heats up and drying winds begin to blow. Here's how cooling helps maintain food quality.

- Slows respiration rate
- Inhibits growth of molds and bacteria responsible for decay
- Slows production of ethylene, and lowers sensitivity to ethylene's ripening effects
- Slows enzyme action
- Reduces wilting from water loss

Freezing further slows the enzyme activity in foods, but it doesn't stop the process. That's why most vegetables will hold up better in the freezer if they are first partially cooked (or blanched) to help inactivate the enzymes. This helps preserve color, texture, and flavor. Generally speaking, frozen food will maintain its quality if the blanching is at a relatively high temperature and of short duration, rather than using low heat over a longer period.

ZUCCHINI FLOWERS FOR THE TABLE

Just about every gardener grows zucchinis, and too many zucchinis at that. For something different, try dipping these big blossoms in a light, eggy batter and frying them in ¼ inch or so of olive oil until they turn golden brown. Just make sure you sacrifice the male blossoms, unless you don't mind reducing the yield. The females will have the telltale bulge of a developing zuke. (The males aren't useless, however; you need a few of them around to pollinate the female blossoms in order to have squash.) You'll have to go out into the garden in the early morning soon after they've opened. Unless you plan on using them right away, you can keep the blossoms perky for a few hours by refrigerating them with the base in a jar of water.

Early Pickings

While it's standard operating procedure to pick tomatoes and peppers only when they've developed their full color and sweetest flavor, you may want to try harvesting part of the crop earlier in the season. Some roadside markets sell green tomatoes well before the end of the season to suit customers who like to fry or pickle them in that immature state. Green cherry tomatoes are great when pickled. And even though peppers will turn a rich red, yellow, or chocolate brown if given the chance, you may want to pick some when green for the color contrast. Jalapeños heading for a pickling jar typically are picked when dark green and crisp in texture, and green serranos are usually the choice for making green salsa.

And of course if a frost is in the offing, you'll want to get out there and pick whatever you can, no matter what the color. Both green tomatoes and green peppers may warm up in color after you've rescued them.

Harvest Time How-To

GREENS FROM UNEXPECTED SOURCES

You don't plant broccoli, Brussels sprouts, and cabbage for their leaves, but they are nutritious and flavorful when cooked up as you would collards or kale. Pick undamaged and relatively young leaves, only when it won't compromise the main crop.

HARVEST BEANS WHEN THEY PASS THE SNAP TEST

If beans are rubbery and won't snap when you bend them, give a little more time before picking. But don't let them go until they show bulges from bean seeds developing within, or you'll be eating fibrous beans.

CATCH CUKES AT THE OPTIMAL TIME

Harvest cucumbers before their seeds become half their full size. Pickling varieties should be dropped into ice water soon after picking to maintain their crispness.

WITH EGGPLANTS, BIGGER MAY BE BITTER, NOT BETTER

Many of us grew up knowing only the big black eggplants of supermarkets. With the bigness often comes a bitter taste that cooks routinely try to remove by treating with salt, but there is no compensating for an eggplant that has become spongy and seedy. To test an eggplant, press it lightly with your thumbnail. If the dent springs back, the fruit is ready to be picked; if not, you've let it go too long. Pick East Asian varieties when much smaller, still brightly colored, and glossy.

HARVESTING LIMAS TWO WAYS

How do you like limas, tender or somewhat meaty? For the most tender beans, wait for the pods to fill out but pick before they are fully mature, when they will take on a more substantial texture.

THE CABBAGE HEAD TWIST

Left to their own devices, certain cabbage varieties may mature and then crack toward the end of the season. To put off the harvest, try the old trick of grasping the head and giving it a gentle root-snapping twist, being careful to avoid uprooting it. With fewer functional roots, the plant may not pick up excess water from the soil.

REFRIGERATE MELONS ONLY AFTER CUTTING

Melons should be kept at room temperature until you cut into them, when they will keep better in the refrigerator.

PINCH BROCCOLI TO GET A BETTER YIELD

Most gardeners begin to harvest broccoli by cutting the main, central head when it is full size, which then stimulates the development of the side shoots. You may be able to get more heads from each plant if you try a different approach: Earlier in the season, when the plants have grown three leaves, pinch off the growing point that would develop into the main head. This causes the broccoli to form larger side shoots than you'd expect to find.

CORN POINTERS

Kernels should be plump and tender, producing milky juice when pierced with your thumbnail. The silks will be dry.

POTATOES DON'T BENEFIT FROM SWEETENING

Once harvested, potatoes don't react well in cold temperatures. Storing them in the refrigerator may cause some of their starch content to be converted to sugars. And while restoring them to a cool room or garage will partially reverse this process, there will be enough residual sugar to cause browning in fried potatoes.

KNOCKING WATERMELONS

It's difficult to know just when a great big watermelon is ready to eat. There are visual cues: The shaded underside will have warmed in color from whitish to a yellow tinge. If the tendril where the fruit stem meets the vine has died, that's a sign the fruit is ready to harvest. And then there's the old thumping test: An immature melon will give a metallic ring, but you'll get a dull thud if the melon is ripe.

Great Flavor from Green Tomatoes

For any number of reasons, you may find yourself at season's end with a bounty of grass-green tomatoes. Rather than toss those green tomatoes of fall into the compost bin, harvest them before the first frost and make good use of them, as gardeners have been doing for generations. Possibly because unripe tomatoes don't have the assertive taste of those that are mature, they can be used in a wider variety of recipes. Here are a few ways to convert your disappointment into good eating.

Chow-chow. Make this old-time pickled salad by chopping up green tomatoes (along with red ones, if you have them), onions, and bell peppers (green ones are just fine), and marinating in a mixture of sweetened vinegar spiced with cloves, dried mustard, allspice, and perhaps ground horseradish. Process in jars in a hot-water bath.

Dilled tomato pickles. Follow a recipe for making pickles from pickling cucumbers. Dilled green cherry tomatoes are an interesting variation on the traditional cocktail olive.

Green tomato pie filling. Combine chopped green tomatoes with chopped apples, and simmer with raisins, sugar, vinegar and lemon juice, cinnamon, nutmeg, and cloves.

Fried green tomatoes. To make this traditional favorite, dip tomato slices in a batter of flour, cornmeal, and egg before frying in oil.

Stewed green tomatoes. Sauté minced onions and sliced green tomatoes in butter, then add curry powder and salt to taste.

Toward Better Tomatoes

Raise the quality of your own homegrown fruits a notch or two with these worthwhile tricks.

COOL (NOT COLD) RIPENING

Tomatoes ripen best when their very last stage of ripening occurs at a moderate temperature. That's because a hot summer day can cause sugars in the fruits to turn starchy. On sweltering days, tomatoes may benefit from being picked a little early, while still somewhat pink, and then brought indoors for ripening. That's assuming your home is cooler than its surroundings. If not, then it's best to allow the fruits to remain on the vine. Whatever you do, keep tomatoes out of the refrigerator: Just 40 minutes of chilling can spoil their texture and flavor, researchers have found.

Continued →

POST-HARVEST TOMATOES DON'T LIKE SUNLIGHT

You probably have heard that tomatoes don't hold up well when refrigerated. Another curious piece of their personality is that once an immature tomato is harvested, you can't speed its ripening by placing it in sunlight, as pretty as the fruits might look on a windowsill. Instead, wrap them in newsprint and place them in unsealed paper bags. Keep the bags in a cool spot where you can check on them frequently.

DECK THE RAFTERS WITH TOMATOES

Determinate varieties are likely to have a not-quite-ripe crop of tomatoes at the end of the growing season. You can pick the green fruit and cook with them. Or pull up the plants and hang them upside down from the rafters in the garage or the joists in the basement. In time, the fruits should redden up. According to the New York State Agricultural Station at Cornell University, you aren't likely to confuse this late crop with your sun-ripened tomatoes, but they'll taste better than the supermarket's off-season fare.

Your Seasonal Vegetable-Care Calendar

Obviously, planting vegetables in Florida isn't the same as planting them in Maine because of the climatic conditions. That's why before you even start planning your vegetable garden, you need to know what hardiness zone you live in.

A plant's ability to withstand a given climate is called its hardiness. The USDA has developed a Plant Hardiness Zone Map that divides North America into ten numbered climatic zones. Zone 1 is the coldest, and Zone 10 is the warmest.

This seasonal care calendar is based on gardening in Zones 5 and 6, which means you'll have to adapt it if you live in a different zone. For example, if you live in a colder zone, such as Zone 3, you'll need to push things off for a month or two (or maybe even three). Instead of starting spring broccoli seedlings at the end of February, start them at the end of March or April. If you live in a warmer zone, such as 9 or 10, you'll need to start things earlier than what's listed here because your garden will probably peter out from the summer heat by July.

January

Although the start of prime gardening season is still a few months away, here are a few things you can do now to prepare:

- Run your Christmas tree through a chipper/shredder to make mulch for your garden paths come spring.
- Look through seed catalogs to dream about what you want to plant. If you plan to start plants from seed, order the seed now!
- Inventory your garden supplies and make sure you have the essentials (such as row covers and plant cages); take a shopping trip or order from a catalog to buy items that are in short supply.

February

Map your garden, and decide when and where you'll plant each vegetable crop you plan to grow. Keep adding kitchen scraps to your compost pile, even though you may have to trudge through the snow to do it. Near the end of the month, start spring broccoli and cabbage seedlings indoors.

March

Start preparing beds by working compost into the soil as soon as the ground has thawed and dried. Start pepper seedlings eight weeks before your last frost date; start tomato and eggplant seedlings six weeks before your last frost date. Plant pea seeds directly in the garden near the middle of the month if the weather cooperates.

April

Now that the weather is warmer, you can do a lot in the garden, such as:

- Plant seed potatoes, and plant lettuce, spinach, and mesclun seed directly in the ground.
- Plant radish, carrot, and beet seeds as well as onion sets and shallots.
- Near the end of the month, plant those broccoli and cabbage seedlings that you started last month in your garden.
- Make sure to mulch your beds, or you'll spend the next five months or so weeding.

May

If you haven't started your own tomato and pepper seedlings, buy some transplants and plant them in the garden after the soil has warmed up. Place collars around the transplants' stems for protection against cutworm pests. Also plant snap beans, corn, squash, and cucumber seeds directly in your beds.

June

It's high season in the garden. Now you can:

- Harvest the peas (try not to eat all of them before you make it out of the garden!).
- Harvest salad greens such as lettuce, spinach, and mesclun before the weather gets too warm and they bolt (go to seed).
- Pull out weeds that crop up through your mulch.
- Give your beds plenty of water so they stay nice and moist, especially if Mother Nature isn't cooperating.

July

Start giving away extra zucchini. Continue watering during dry spells. Harvest onions, snap beans, summer squash, cucumbers,

carrots, beets, and the first tomatoes. Pull out spring crops that are finished producing for the season, such as peas, lettuce, and broccoli. Throw the spent plants on your compost pile.

August
Can tomatoes and continue harvesting corn, peppers, snap beans, and the rest of your garden veggies. Plant a cover crop in any garden beds that are now empty. Sit in the shade and relax with a cold glass of lemonade.

September
Can more tomatoes and make salsa. Harvest pumpkins, carrots, and beets, and plant garlic for next year's crop. Pull more spent plants out of your beds, and continue planting cover crops in empty spaces.

October
Harvest the last of the tomatoes and peppers before the first fall frost. Pull all remaining spent plants out of the beds and plant cover crops. Collect stakes, temporary trellises, and row covers, and scrape off clinging soil. Carve a pumpkin or two for Halloween.

November
Rake up leaves and add them to your compost pile. Organize any notes you took from the gardening season and compile them in a binder, along with a map of what grew where.

December
Relax and enjoy some of those tomatoes you canned back in August and September. Watch the snow fly and dream about next year's garden.

Vegetable Garden Glossary

Beneficials. Helpful creatures, such as birds, bats, toads, snakes, spiders, and predatory insects, that eat pests in the garden.

Bloodmeal. Also known as dried blood, it's a slaughterhouse by-product that contains 13 percent nitrogen. Can be sprinkled on garden beds to repel rabbits.

Bolt. To go to seed. Lettuce, for example, will bolt, or go to seed, when the weather gets too hot.

Bonemeal. Finely ground bones (a by-product of animal slaughterhouses) that contain 10 to 12 percent phosphorus, 24 percent calcium, and a small amount of nitrogen.

Broadcast. To spread fertilizer evenly across an area by hand or with a spreading tool.

BT (*Bacillus thuringiensis*). A spray derived from a naturally occurring bacteria that kills certain insect larvae.

BTK. A BT variety (BT var. kurstaki) that controls cabbage loopers, cabbageworms, tomato hornworms, fruitworms, European corn borers, and pest larvae.

Cloche. Light-permeable plant covers made out of a variety of materials that are primarily used to protect plants from frost. They work much like miniature greenhouses.

Companion planting. Combinations of plants that work well together to repel pests, attract beneficial insects, or make efficient use of garden beds.

Compost. Decomposed and partially decomposed organic matter (such as kitchen scraps, leaves, grass clippings, and dead plants) that is dark in color and crumbly in texture. Used as an amendment, compost increases the water-holding capacity of the soil and is an excellent nutrient source for microorganisms, which later release nutrients to your plants.

Composting. The art and science of combining organic material so that the original raw ingredients are transformed into compost.

Compost tea. A fertilizer made by soaking a cloth bag full of compost in a watering can or barrel for several days.

Crop rotation. Rotating crops from different botanical families to avoid or reduce problems with soilborne disease or soil insects.

Cover crops. Also called green manures. A crop you plant in an empty bed that will grow rapidly and blanket the soil. Cover crops are used to hold soil in place and provide nutrients over the winter, between plantings of vegetables or between growing seasons, or as a way to rejuvenate poor soil. These crops are either harvested or tilled under into the soil. Examples of cover crops include annual ryegrass, buckwheat, and white clover.

Direct seeding. Planting seeds outside directly into the garden.

Double-digging. The process of removing a shovel full of topsoil from a garden bed, loosening the soil below, and then replacing the topsoil layer for a fertile, productive bed.

Fertilizers. A natural or manufactured material added to the soil that supplies one or more of the major nutrients—nitrogen (N), phosphorus (P), and potassium (K)—to growing plants.

Fish emulsion. Made from filtered fish solubles, fish emulsion contains about 5 percent nitrogen. It's useful for spraying as a foliar feeding spray and to fertilize transplants.

Foliar feed. To supply nutrients by spraying liquid fertilizer directly on plant foliage.

Hardening off. Gradually exposing tender seedlings to the outdoors in a protected area for a week prior to transplanting them into the garden.

Herbicide. Substances used to kill unwanted plants. Some types are selective (they kill only a certain type of plant); others are nonselective and will kill any plants they come into contact with.

Humus. A dark-color, stable form of organic matter that remains after most of the plant and animal residues in it have decomposed.

Continued ➔

Mesclun. A mix of salad greens such as endive, arugula, chervil, and lettuce.

NPK ratio. A recognized abbreviation that refers to the ratio of the three major nutrients—nitrogen (N), phosphorus (P), and potassium (K)—in fertilizer, such as 5-5-5 or 10-2-2.

Organic. Materials that are derived directly from plants or animals. Organic gardening uses plant and animal by-products to maintain soil and plant health, and doesn't rely on synthetically made fertilizers, herbicides, or pesticides.

Pesticide. Any substance, synthetic or natural, that is used to kill insects, animals, fungi, bacteria, or weeds.

Raised beds. Three- to five-foot-wide (on average) beds that lie higher than ground level and are separated by paths. Raised beds increase soil aeration and drainage and save space.

Row covers. Sheets of lightweight, permeable material, usually polypropylene or polyester, that can be laid loosely on top of plants to act as a barrier against insect pests or that can give a few degrees of frost protection at the beginning or end of the growing season.

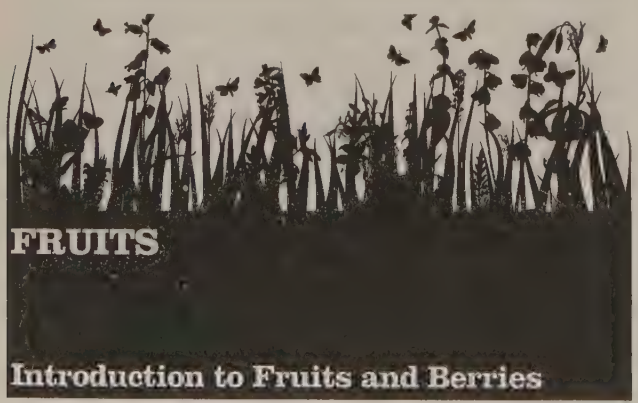
Seed germination. The beginning of the growth of a seed.

Seedling. A young plant grown from seed. Commonly, plants grown from seeds are termed seedlings until they are first transplanted.

Sidedress. To apply solid (as opposed to liquid) fertilizer alongside annual plants during the growing season.

Soil test kit. A set of instructions and a soil bag available through your state's Cooperative Extension Service. Test results indicate soil pH and specify which amendments and nutrients should be added to your soil.

Wallo'Water. A cloche made of upright, narrow plastic tubes filled with water that can protect tomato and other seedlings from frost.



Jeff Cox

Nothing is as delicious as a mouthful of freshly picked fruit—be it a succulent, juicy peach; a tart, crisp apple; or luscious, tangy-sweet raspberries. And when that fruit comes from your own backyard, the taste is even better because you harvest your crop at the peak of perfection—you can say goodbye to the under- or over-ripe fruit found in most grocery stores. And you can grow the best-tasting cultivars, not necessarily the ones that are most attractive or ship best.

To get started, you need to determine what kinds of fruits you'd like to grow. Fruits commonly are subdivided into categories. *Tree fruits* are those that grow on trees, such as apples and peaches. *Small fruits* are either fruits that are small or fruits that are borne on small plants. Strawberries and blueberries are familiar small fruits. Some fruits, though, are difficult to place in a particular category. Mulberries and juneberries are examples of this: Both bear soft, small fruits, but they're produced on full-sized trees. Nuts are actually dry fruits with woody shells.

To develop fruit, most plants need to have their flowers pollinated. When flowers on a plant produce fruit after being dusted with their own pollen, that plant is self-pollinating. Strawberries are self-pollinating, so if you plant only one cultivar, you still get fruit. Flowers that need pollen from a plant of a different cultivar to develop fruit need cross-pollination. Apples, for example, require cross-pollination, so a 'McIntosh' tree needs a 'Golden Delicious' tree (or some other cultivar besides 'McIntosh') nearby to supply pollen. By choosing the right cultivars, gardeners all over the country can enjoy fresh fruit, beginning in spring with strawberries and going through winter with the last of the apples that ripen in cold storage.

Don't overlook the ornamental value of fruit-bearing plants. A peach tree, for example, is transformed into a cloud of pink blossoms in spring. The crimson red color of blueberry leaves in fall rivals that of the sugar maple. And strawberries make an attractive edging.

Growing Fruit Trees

Fruit trees make great landscape plants, blooming abundantly in spring and trimmed with colorful fruit in summer and fall. But unlike strictly ornamental trees, their fruit is not only attractive but also a succulent edible treat. The flavor of tree-ripened apples, peaches, and other fruits is unmatched, and you'll appreciate the savings in your grocery bills. However, to reap good-quality fruit, you must commit to pruning, monitoring, and maintaining your trees.

SELECTING FRUIT TREES

Before you buy, determine which fruit trees can survive and fruit in your climate. Northern gardeners should choose cultivars that will survive winter cold, blossom late enough to escape late-spring frosts, yet still set and mature fruit before the end of the growing season. Southern gardeners need cultivars that will tolerate intense summer heat and humidity. For organic gardeners, choosing disease-resistant trees is especially important. Check with local fruit growers or with your extension service office to see which cultivars have a good track record in your area. You should also do some independent research on your climate and consider your fruit needs.

Fruit trees need a dormant period during which temperatures are below 45°F. Trees that don't get sufficient winter chilling will not fruit properly. Low-chill cultivars flower and fruit with as little as half the usual cold requirement, stretching deciduous fruit production into Texas, northern Florida, and parts of California. Extra-hardy, high-chill cultivars for the far North require longer cold periods and flower a week later than most.

If winter temperatures in your area drop below -25°F, stick with the hardiest apple and pear cultivars; between -20° and 0°F, you can try most apples and pears, sour cherries, European plums, and apricots; if minimum temperatures stay above -5°F, you can consider sweet cherries, Japanese plums, nectarines, and peaches. If minimum temperatures in your area are above 45°F, be sure to select low-chill cultivars.

Freezing temperatures can kill fruit blossoms. If you live in an area with unpredictable spring weather and occasional late frosts, look for late-blooming or frost-tolerant cultivars, especially for apricots and plums.

In humid regions, select disease-resistant cultivars whenever possible. Diseases such as apple scab and brown rot are more troublesome in humid conditions.

If you are fond of baking, top your list with sour cherries and cooking apples, which make excellent pies. For canning, look for suitable cultivars of peaches, nectarines, and pears. For jellies, try apricots, plums, and quinces. If you're interested in fruit for fresh eating, think about how long the fruit will last in storage. Some apples stay good for months if kept cold, but soft fruits must be eaten within about one week or they will spoil.

Fruit trees come in shapes and sizes for every yard. Most home gardeners prefer dwarf or semidwarf trees, which fruit at a younger age and are easier to tend.

Standards. Standard fruit trees can reach 30 feet or taller, becoming small shade trees that can be underplanted with flowers or groundcovers. They are long-lived and hardy but can be more difficult to maintain and harvest.

Grafted Semidwarfs. Apples grafted on size-controlling rootstocks grow well. However, stone fruit trees grafted onto dwarfing rootstocks often are not long-lived. In just a few years, perhaps when the young tree is burdened with a heavy crop of fruit, the graft can unknit and the tree will die.

Genetic Dwarfs. Genetic dwarf or miniature trees are naturally compact trees grafted on standard-sized root systems. They reach about 7 feet and bear about one-fifth as much normal-sized fruit as a standard tree. Genetic dwarfs tend to be shorter-lived than standard trees and are not hardy in northern areas. They can be grown in planters and moved to a protected area where temperatures remain between 30°F and 45°F in winter, such as in an unheated storage room. Genetic dwarfs are ideal for the Pacific Northwest or the southern United States. In fact, in those areas they may be preferable to standard trees because they need less winter cold to flower.

Older genetic dwarf tree cultivars had poor-quality fruit, but modern types approach the flavor of their full-sized counterparts. However, none of the modern genetic dwarfs are disease-resistant. They need diligent thinning because foliage and fruit can become overcrowded.

Pollination requirements are another important factor to consider when selecting trees. Most apples, pears, sweet cherries, and Japanese plums are not self-fruitful. You must plant a second compatible cultivar nearby to ensure good pollination and fruit set. Peaches, nectarines, tart cherries, and some European plums are self-fruitful. Some cultivars of apples, pears, sweet cherries, and European plums are somewhat self-fruitful, but they set better crops when cross-pollinated. Fruit tree entries later in this chapter provide details about pollination requirements.

SITE SELECTION AND PLANTING

Plant fruit trees in a small traditional orchard, or intersperse them in borders, mixed beds, or a vegetable garden. You can even put a dwarf apple at the end of a foundation planting. Some will grow in lawns, but most perform better in a prepared bed.
